"The analysis of stool shows good digestion and absorption of all three types of foods. In addition, the fats show good splitting. In the presence of such good absorption, and the absence of striated muscle in the stool, I feel, in spite of the gross fat present, that pancreatic juice in sufficient quantity to provide normal absorption probably is reaching the intestine. Even if the large amount of fat found on microscopical examination was borne out by the analysis, it would be distinctly unusual to have only the fat-splitting ferment deficient in pancreatic juice."

A roentgen examination on November 20, 1934, (about two weeks prior to patient's discharge), showed, by barium colon enema, that the intestinal tract now presented definite tone and definite haustral markings. The barium at this time was evacuated in 1½ hours, whereas at the first examination there was retention of about 12 hours for the same amount of barium used in the enema.

A roentgenogram of the wrists and hands at this time showed that, while

Right (7737). Note presence of increased intestinal tone and haustral markings after thyroid therapy.

the four carpals present originally were enlarged very slightly, if at all, the distal ulnar epiphyses now were present, though small, in both wrists. Also, the epiphysis of the left ulna noted on the first examination had somewhat increased in size. The period of treatment with thyroid medication, however, had been too brief for one to expect any marked bone advance, but nevertheless, the progress was sufficient to indicate the many varied benefits of the thyroid therapy (Fig. 3).

On December 10, 1934, the patient was discharged. A check up at this time showed that, after eleven weeks of dietetic and thyroid therapy, his ab-

(Elbow). Note absence of epiphysis for the head of the Radius, and for the internal condyle of the humerus. Bone retarded about 2 years.

*Synopsis of Stool Analysis:*

| Diet:                    | Fat   | Carbohydrates | Nitrogen |
|--------------------------|-------|---------------|----------|
| Schmidt's Diet           | 333 G | 573 G         | 48.90 G  |
| Omitted from diet        | 129   | 217           | 10.75    |
| Actually given in 3 days | 204 G | 356 G         | 38.15 G  |

*Analysis of Stool:*

|                      |              |               |          |
|----------------------|--------------|---------------|----------|
| Dry Weight           | 67.0 G       |               |          |
| Fat in dry Stool     | 38.5%        |               |          |
|                      | Fat          | Carbohydrates | Nitrogen |
| Amount in Stool      | 25.80 G      | 3.0 G         | 4.35 G   |
| Therefore % Absorbed | 87.35%       | 99 plus %     | 88.5%    |
|                      | (normal 95%) | (normal)      | (normal) |

*Analysis of the fat unabsorbed:*

|             |         |         |
|-------------|---------|---------|
| Fatty acid  | 11.48 G | (44.5%) |
| Soap        | 3.90 G  | (15.1%) |
| Neutral fat | 10.42 G | (40.3%) |

demen definitely had decreased in size, though it was still quite distended. Yet, the lad was comparatively comfortable, as was attested, and he was much more alert. During this three months' period, he had increased 2 inches in height, and he had gained 5 pounds in weight (in spite of having an upper respiratory infection for one week during the latter part of his hospital stay).

## DISCUSSION AND COMMENT

Hypothyroidism in a mild or masked form differs so greatly and in so many respects from myxedematous cretinism or marked hypothyroidism that it is sufficiently important to warrant careful study and constant alertness for the many and varied manifestations of such symptoms of mild hypothyroidism (1).

In the case here cited, the outstanding and varied symptoms were dwarfism, an apparent malnutrition, anemia and abdominal distension. Such a picture presented a possible case of masked hypothyroidism. Then, subsequent X-ray findings of an atonic intestinal tract, and particularly of osseous delay in the time of appearance of the carpal centers and epiphyseal nuclei affirmed the suspicion of hypothyroidism.

However, various other possible diagnoses presented themselves, as celiac disease, juvenile congenital lues, rickets and Cooley's erythroblastic anemia, all of which might be associated with retarded osseous development. These affections therefore were all individually considered, for the case in hand and eliminated for the following reasons:

**Celiac Disease:** The absence of any acute history, the tolerance to carbohydrates as well as to other foods when on a full diet, the comparatively good absorption of the

three types of food when on a Schmidt test diet, and a normal serum-calcium quantity all ruled out celiac disease.

**"Renal Rickets":** Physical, chemical and roentgen studies excluded the possibility of renal rickets.

**"Cooley's Erythroblastic anemia":** A blood examination, and a roentgen study of the skull and long bones eliminated this possibility.

**Juvenile congenital lues:** The absence of typical physical signs and roentgen findings, of the long bones, and a negative Wassermann reaction excluded this possibility.

**Infantilism** due to organic pancreatic involvement: The comparatively normal stool and the good digestion and absorption of the three types of food, showed good function of the pancreas and therefore eliminated this affection. Furthermore, the writer is not aware of any osseous involvement with organic pancreatic lesions, and in this patient there was osseous retardation.

**"Fermentative" Diarrhea:** (2). Because of the two or three bowel movements per day and because the results obtained by stool examinations after the Schmidt diet approximated Schmidt's figures for fermentative diarrhea, this condition too subsequently had to be considered.

However, fermentative diarrhea was ruled out because the two or three bowel movements were not diarrheal in nature, and because there was no increased intestinal motility—the carmine in the test diet appeared in forty-four hours.

Therefore, in view of the above considerations and in the presence of the dwarfism, the anemia, the abdominal distension, the atonic intestinal tract and the retarded osseous

**TILDEN has Kept Faith  
with Physicians**

## ELIXIR MALTOPEPSINE (Tilden)

Consists of DIOSCOREIN, LACTIC ACID, DIASTASE, PEPSIN with acidic and other ingredients, combined in a manner exclusive with Tilden.

MALTOPEPSINE (Tilden) for many generations has been prescribed as a dietary aid in conditions involving gastric and intestinal upsets. It is a very palatable vehicle for prescriptions carrying such drugs as IODIDES, BROMIDES, SALICYLATES, and NUX VOMICA, and guards against any untoward effect of these substances on the metabolism.

MALTOPEPSINE (Tilden), like all prescription specialties produced by The Tilden Company, is labeled according to law, advertised only to the medical profession, manufactured under strict scientific control, and offered only after years of thorough clinical success.

Literature will be furnished confidentially  
to physicians only on request.

development, a *diagnosis of masked hypothyroidism* was considered most probable; the correctness of this diagnosis apparently was substantiated by the favorable response of the patient to thyroid therapy. Within a period of about eleven weeks of such therapy, he showed marked improvement; a gain of height of two inches, an increase in weight of five pounds, a progressing osseous development, a definite increase in intestinal tone and general feeling of well being.

However, the excretion of excess fat in the patient's stool was per-

| (Schmidt's)                    | 127.4   | 20.90                 | 25.56                              | 11.47                          | 80.0           |

plexing and at present remains unexplained, unless one might consider the excess as a functional, rather than as an organic defect of the pancreas, or as a consequence of a supercaloric diet, which the patient's voracious appetite made quite likely.

What relation, if any, there is between the excess excretion of fat in this patient's stool with the presence of his halisteresis is not certain. However, that an excess of fat may tend to inhibit the absorption of calcium by forming insoluble calcium soaps and thus indirectly causing the halisteresis, is a possibility to be considered. Or, if an excess elimination of calcium in the stool is causing "fixation" of the fat, such also must be considered. As to proof of this phenomenon, a study of the calcium balance may have helped, but unfortunately such could not be made. However, had such a study been made, the findings of a negative calcium balance might have accounted for the halisteresis, but would not have accounted for the delayed appearance of the ossification centers.

SUMMARY

1. An Italian boy, aged six and one-half, dwarfed, and showing a marked abdominal distension was admitted as a case of congenital

\*Allowances, however, must be made for the food omitted from the Schmidt diet because of the patient's dislike for the same and for which other food had to be substituted. Under these conditions higher values would have been obtained had not the diet been modified.

megacolon (Hirschsprung's disease). The patient presented evidences of anemia, malnutrition, an atonic intestinal tract, and marked osseous retardation (equivalent to about two years), as revealed by X-ray appearance of his carpal centers and epiphyseal nuclei. In view of the above findings several diagnoses were considered and eliminated: namely, celiac disease, renal rickets, juvenile congenital lues, Cooley's erythroblastic anemia and pancreatic infantilism.

2. The diagnosis of congenital megacolon was discarded because of the late onset of the intestinal disturbance, the absence of obstinate constipation and incomplete Roentgen findings, and the diagnosis of hypothyroidism was substantiated. This diagnosis was based upon findings of dwarfism, an atonic intestinal tract, anemia, and retarded osseous development. The patient therefore was placed on thyroid medication and a full diet.

3. After a period of eleven weeks of such therapy the patient showed the following:

- (a) A general feeling of well being.
- (b) An increase of two inches in height and an increase of five pounds in weight.
- (c) An increased tone in the intestinal tract.
- (d) An advance in the osseous development—slight yet sufficient for this period.

Constipation's Baffling Complications

with the attendant biliary stagnation are materially relieved with bile salts in combination with phenolphthalein and cascara sagrada as combined in

TAUROCOL Bile Salts Tablets

TAUROCOL is a combination of bile salts, extracts of cascara sagrada, phenolphthalein and aromatics and is an agent recognized by the medical profession and widely prescribed for about a quarter of a century.

Samples of Taurocol on request. We will gladly furnish clinical test record forms if you wish them . . . just tell us how many to send.

The Paul Plessner Co.

Detroit - - - Michigan  
J. D. 7-35

4. Before the patient was discharged, he was given a modified three day Schmidt test diet and his stool then was studied. Good digestion and absorption of all three types of food were found. However, there was present an excess of fat.

5. This presence of excess fat in the stool was perplexing and was finally considered compatible with a functional disorder of the pancreas.

6. The possible significance and the correlation, if any, of this excess fat in the stool with the retarded bone development and particularly the halisteresis in this case, are discussed briefly but not accepted as definite or final.

7. The importance of recognizing seemingly remote symptoms and of considering them as possible clues towards the diagnosis of masked hypothyroidism are emphasized and discussed.

# SECTION I—*Clinical Medicine: Diseases of Digestion*

## On the Etiology of Peptic Ulcer\*

### An Analysis of 70 Ulcer Patients

By

SAMUEL C. ROBINSON, M.D.  
CHICAGO, ILLINOIS

THIS paper deals with the physical builds of seventy "peptic" ulcer patients and their personalities. Some phases of pathology are discussed as well as interesting features of incipient ulcer. Conclusions from this factual information are shown to support the neurogenic theory of "peptic" ulcer. Briefly it claims that fear, anxiety and apprehension stimulate the vegetative system to the stomach and duodenum resulting in hypermotility, hyperchlorhydria and vascular spasm. This spasm in turn leads to thrombosis, ischemia, necrosis and ulceration. Other factors such as hyperacidity, focal infection, diet, etc., are shown to have absolutely nothing to do with the etiology of this disease.

#### RACIAL SELECTIVITY

"Peptic" ulcer has never been found in the lower animals and its production artificially is still debatable. If a portion of the mucosa of the dog's stomach is removed, the defect heals very rapidly without much scarring, new mucous membrane filling in the lesion. This rapid healing process takes place in the presence of natural acidity, or added acidity (1) or any form of diet. The production of chronic peptic ulcer in the lower animals has baffled the experimental physiologist for years and in the opinion of Mann "Chronic peptic ulcers have never been consistently produced experimentally in the gastric mucosa by any method" (11). By means of circuitous anastomoses, some chronic ulcers have been produced but their value is open to question. They are atypical and distort normal anatomy and physiological function to so great an extent as to make any conclusions of doubtful value when applied to the human. Incidentally, incisions in the mucous membranes of human stomachs heal rapidly (2).

"Peptic" ulcer occurs very rarely in the Negro race (3). The New Orleans Board of Health (4), citing mortality statistics for a decade—1919-20 shows an ulcer death rate of .123% among white population and .043% amongst negroes. Even this low percentage would be reduced further if the interbreeding factor could be computed and deducted. The Bellevue Hospital, New York from 1904-1922, gave a total of 120 cases of gastric ulcer of which only two were negroes. Dr. Bergsma (5) reports frequent ulcers in the colored race in Abyssinia. These ulcers are produced on a

chemical basis, the native diet consisting of sour bread and 50% capsicum or cayenne pepper, a mixture which was strong enough to cause blisters on Dr. Bergsma's lips. The ulcers are multiple, occur all over the stomach with formation of fibrotic rings. There is no resemblance to the typical single ulcer in its common location along the lesser curvature of the stomach and the first inch of the duodenum. The present paper is attempting to elucidate only this particular type of ulcer with the classic history of distress after meals, relieved by food, hyperacidity, chronicity with exacerbations and remissions.

"Peptic" ulcer is not found in the lesser pigmented races of the world, either before or after their contact with civilization. The Mexican Indians are free from ulcer although they live under horrible hygienic conditions and their diet is coarse and deficient (6). Dr. McCarrison (7) in nine years of practice, performed 3600 operations on primitive tribes in the Himalaya Mountains and found no ulcers, mucous colitis or appendicitis. The white race living under primitive conditions is less prone to ulcer. Centuries ago, before the advent of the machine age, the disease was very uncommon. Older text books devote very little space to it. But with the turn of the century the disease has been on the increase (8). A highly competitive and more complex civilization has made existence more precarious for most of us; as a result tensions have increased. Those who are on the firing line of this life-struggle, such as salesmen, specialists in all fields particularly medicine, executives, etc., are more prone to this disease.

We have seen that the lower animals do not develop ulcers, the Negro and lesser pigmented races seldom if ever do and the Caucasian race rarely does under primitive conditions.

This is a unique selectivity in the annals of disease. It is obvious that we need the complexities of civilization impinging upon certain types of the white race to produce "peptic" ulcer. It was an attempt at a more careful study of the physical characteristics and personalities of the white man who develops "peptic" ulcer that prompted the analysis of seventy ulcer cases, the data of which are herewith presented.

#### THE ULCER BUILD

Long before anthropometric measurements were extensively used by science, physicians noted that the

\*From the Department of Medicine, Woodlawn Hospital, Chicago.  
Submitted May 29, 1935.

ulcer individual is a long and lanky person. They have likewise associated a vague picture of his personality *viz*—a young man with considerable dynamic energy, with quick reaction-time and of a high tension type. The laboratory has applied its more accurate technique to this "hunch" of the older practitioner, with strengthening verification.

The most exhaustive study of physical types made in this country is that of Dr. George Draper (12) at the Constitution Clinic of the Presbyterian Hospital in New York City. His book "Disease and the Man" might serve as a stepping stone in the elucidation of most of the common disease entities.

Here we find a scientific appraisal and classification of physical types, the basic ingredient of disease itself. Complete anthropometric measurement, as carried out by Dr. Draper, is a very elaborate procedure and re-

series of seventy cases, only three weighed 170 pounds and one 180 pounds. None weighed more.

The ulcer patient's *chest measurement* of this series follows the normal more closely in the smaller brackets than he does in the weight curve (Figure 2). While there are more underweights among the ulcer cases, the number of low chest measurements is about equal to the average run of cases. But there is a sharp dropping off in the larger chest groups so we find no ulcer patient with a chest measurement over thirty-nine inches in this series. In a similar control group of average normal measurements there are seven. This is the measurement that more sharply differentiates the linear from the lateral types and we find the ulcer patient breaking away abruptly from the larger groupings.

The *ponderal index*, or the relationship of height to

Fig. 1

quires much time and special instruments. But the simpler measurements available to the average practitioner can throw much light and classify the ulcer "race," if not so meticulously as Dr. Draper, at least helpful in singling out the striking limitations of measurements into which this group falls.

#### MATERIAL STUDIED

**Weight:** An analysis of the seventy cases of "peptic" ulcer of this series (proved by X-ray, history and physical findings) shows that the type is narrow and linear. There are very few overweights in this group as shown in Figure 1. They are more often underweight altho a definitely large percentage are about normal in weight. It will be seen that they outnumber the average person in the groups up to 150 pounds and fall off rather sharply in the heavier groups. Very few ulcer patients weigh over 180 pounds. The diagnosis of "peptic" ulcer on any person weighing over 190 pounds should be seriously questioned. In this

weight, aims at a more accurate portrayal of human build. This index is arrived at by dividing the weight in pounds by the height in inches. Many advise reducing these measurements to millimeters and grams but the ultimate result seems to be the same. Figure 3 shows the graphic presentation of these calculations and demonstrates more vividly than any of the other diagrams the narrow morphological range of the "peptic" ulcer type.

The *chest circumference-height relationship* is another method of classifying the linear and stocky build and is obtained by dividing the chest circumference by the height. (Figure 4) It correlates the lateral and linear measurements and offsets possible errors inherent in their separate comparisons. We may have two individuals each with a chest circumference of 37 inches yet one may belong to the lateral type being only sixty-two inches tall, the other to the linear type being seventy-three inches tall. Likewise the ponderal index by correlating the height to the weight

Fig. 2

Fig. 3

Fig. 4

Fig. 5

assigns one individual weighing 160 pounds to the short and stocky group and the other of equal weight but eleven inches taller to the long and thin group. These comparative tables show that all the "peptic" ulcer patients belonged to the long and thin morphological type. No lateral build individual was among the 70 ulcer patients studied in this group. These findings are in complete agreement with those of Dr. Draper. In addition a few of his other measurements might be added. The face is broader in its upper half tending to taper sharply to a pointed chin. The upper jaw is frequently somewhat narrow and the upper median incisors project over the two lateral incisors. The angle of the mandible tends towards the acute. The palpebral fissure is consistently wide.

These fixed physical measurements of the ulcer patient direct our attention to the rôle of heredity in the etiology of this disease. The germ plasm alone transmits the potentialities for physical differentiation in the animal and human and plays the deciding part in our neuro-psychological make-up. Evidence of several ulcer patients in one family abounds in the literature and was found in this series.

*Miscellaneous Findings of Seventy Cases.* In this series, there was practically no hypertension. One patient with a blood pressure of 150 was omitted because an ascending urinary infection including pyelonephritis was his immediate complaint, the ulcer having been quiescent for ten years. Dr. Hartman (13) studied hypertension in ulcer patients with and without hemorrhage. He too reports hypotension to be the common finding in ulcer patients but does report six and nine percent of hypertension in his series altho actual blood pressure figures are not cited. Dr. Frank Smithies (14) found 14.7% with hypertension and arteriosclerosis.

In this series the relationship of males to females was 6 to 1. Some of the females showed masculine traits. This is also pointed out by Dr. Draper. One wore a shirt, collar and tailored suit and was in charge of large stenographic department. She was virile, dynamic and aggressive.

*Personality.* This rather definite build houses a personality of almost equal definiteness. It is relatively easy to present the anthropometric measurements of the ulcer patient but a portrayal of his personality is much more difficult. It is true that we have no comparable instruments for measuring personality but a sensitive and observing clinician has available a wealth of material in the statements of his patient especially if properly elicited. His behavior, his facial features and his finer fleeting changes help the intuitive sense in interpreting his story and give deeper meaning to some of the chance or casual remarks. Certain expressed attitudes occur with such frequency as to become characteristic of the group. In the seventy ulcer cases observed, as well as among those described in the literature, there is a striking agreement about the personality of an ulcer patient.

He is keen, intelligent and active rather than lethargic. Dr. Crile refers to him as the hyperkinetic type. His activity is fluctuating rather than sustained chiefly because his endurance is limited and he requires frequent rest-periods. His energy is often divided amongst several enterprises rather than concentrated

in a single channel and yet he is not satisfied with ordinary achievement. He is inclined to be over-precise and holds himself up to a high standard of performance. "My conscience would not permit me to do inferior work, I must give my best to it." Externally he may show a certain aggressiveness but this behavior often covers a real timidity. He is full of bravery in theory but extremely cautious in action. He proceeds with care and travels slowly feeling his way all the time and recoils swiftly when on the wrong trail. This caution is carried into his habits, dietary and otherwise. "I cannot understand why I should have an ulcer. I have been so terribly careful about my food all my life. Never ate spices or very hot foods. I order eggs most of the time when I eat out. Take no chances on cooks' mixtures." He is fearful, apprehensive and easily excited with the result that events which would leave a more stable person untouched, upset and worry him. He takes the world too seriously, himself, relatives and friends. He worries about all of them. Because of his conscientiousness, he soon takes on more responsibility than he is able to carry. He grows more and more weary and an exacerbation of the ulcer syndrome takes place.

Some ulcer patients display a very calm exterior and, at first glance, would seem not to belong to the worrying or tense type. They deny it. But as they unfold their stories they reveal their fears and sensitive make up. In a very few, it is difficult to elicit very much nervous unrest. But it is known that vegetative stimulation may take place on a subconscious level.

#### ULCER BEARING AREA

The site of the lesion is one of the most striking of all the interesting features of "peptic" ulcer. It singles out about four to five inches of the entire length of the twenty odd feet of the gastro-intestinal tract. (15) In the stomach over 95% of the ulcers are bunched together within two inches of the *incisura*. (Figure 9) a few of the remaining

Fig. 9

Fig. 9. Site of Gastro-Duodenal Ulcers (after Holmes and Hampton).

are spread along the lesser curvature for a few inches towards the cardia and some towards the pylorus. In the duodenum practically all ulcers occur on the first inch of the anterior or posterior portion. (19) This predilection of "peptic" ulcers for so limited a region is quite unique for gastro-intestinal ulceration. The lesions in ulcerative colitis extend over the entire length of the colon and circularly in every quadrant of it. In typhoid fever and tuberculosis the ulcers occur throughout the entire length of the jejunum and ileum. The "peptic" ulcer shows a unique selectivity for the lesser curvature of the stomach and the first portion of the duodenum. The remaining 80% or so of the gastric surface is immune to the type of ulcer discussed in this paper. The ulcers that do occur here have a different etiology. They are atypical and have entirely different history, physical findings and response to therapy. (16) This emphasises the urgent need for ulcer classification.\* The *bizarre* picture of the atypical ulcer with its multitudinous and diversified symptomatology clouds the very constant mosaic of a classic "peptic" ulcer.

This lesser curvature of the stomach which is the site of over 98% of all gastric ulcers receives most of the innervation to this viscus. The vagus, coming down from the upper portion of the lesser curvature, sweeps down on this ulcer-bearing area and terminates the bulk of its fibrils into the serosa and together with splanchnics "enter the stomach wall with the arteries, accompany their branches and are distributed to Auerbach's intra-muscular and to Meissner's sub-mucous plexuses. Fibrils from the myenteric plexus extend to the *tunica muscularis* from the submucous plexus to the vascular wall and to the secreting epithelium. They transmit motor, vasomotor, secretory and sensory impulses." (2) This is the portion of the stomach that will receive the blunt of psychic trauma with the resultant hypermotility, hypersecretion, hyperchlorhydria, hypertonicity and vascular spasm.

If we had no information about the pathology of "peptic" ulcer other than this unique site-predilection, we might arrive at the following logical conclusion: The stomach contents can not play a deciding rôle in the etiology of "peptic" ulcer since the organ is a hollow viscus and its churning and contracting action would expose equally all surfaces of the stomach to the erosion of the hydrochloric acid, the digestion of pepsin or the physical trauma of sharp food particles. These are unable to damage over three fourths of the surface of the stomach which includes the greater curvature and most of the cardiac portion. There must be some physiological or structural difference in this small ulcer bearing area, in its musculature or vascular bed or innervation, peripheral or central, that plays the deciding rôle in ulcer formation.

### PATHOLOGY

First we might investigate the macroscopic and microscopic picture of the ulcer itself and see what light it may throw on its origin and development. The destructive process of a gastro-duodenal ulcer is *reversed* from that of the ordinary ulcer found in other body tissue. On cross-section we find that the greatest damage occurs near the serosa, in the muscularis and in the submuscularis, with astonishingly little destruction of the mucous membrane itself considering the chronicity of the lesion. (Figure 6) This

unusual reversal of the destructive process has been variously described by different pathologists. C. B. Morton (11) describes the cross section of many ulcers as the "crater is often cone-shaped with the apex toward mucosal surface" and "the submucosa is definitely, sometimes markedly, thickened having in section the shape of a wedge with the thick part pointing to the crater and the point gradually tapering off and losing itself in the normal submucosa, distal to ulcer" and conversely in the healing process. Bunting (17) says "repair of mucosa is faster than that of submucosa" so that "scars may be present in the serosa with or without adhesions, in the intramural structures with corresponding limitation in blood supply or in the mucosa". W. J. Stewart (11) speaks of the thickening and opacity of serosa as a result of fibrosis and edema". The opening is "often slit like owing to overhanging margins and... undermined edges". This evidence of maximal damage to the stomach wall structures furthest away from the mucous membrane shows that the stomach contents plays no part in initiating the lesion. If it did we would logically expect the greatest damage to be to the mucosa and nearby structures with lessening damage as we approached the serosa. The direct opposite is true. Obviously then, the origin of the destructive process must be sought outside of the stomach. Here again the pathological study helps to show the causative factor.

In nearly every "peptic" ulcer, if careful study is made especially beyond the ulcer bed some evidence of obliterative arterial disease may be found. Dr. Schutz (18) in examining thirty specimens of ulcer found arterial obstructive lesions in every case. Other observers have reported similar findings. (9,19) These thrombi so generally found in "peptic" ulcers serve as a key to its etiology. Such extensive and constant vascular occlusion must be on a basis of spasm. No embolic phenomena could duplicate this picture particularly in view of subsequent proof. Vascular spasm means faulty innervation or vegetative imbalance which takes us back to our personality study of the nervously unstable individual.

Vascular spasm and thrombosis mean a destructive process that is dry and clean, which is precisely what we find in "peptic" ulcers. The first thing about these gastro-duodenal ulcers that strikes the surgeon is their cleanliness. As Deaver (10) puts it they appear as if "punched out by a sharp instrument". (Figure 7.) There is little active inflammatory changes about the ulcer (19). They are clean bacteriologically as well as histopathologically. Smears and cultures are sterile (20).

This is equivalent to the effect of "dry gangrene" in any other part of the body. We are familiar with the sharp demarcation in Raynaud's gangrene. In the early stages when the ulcers occur on tips of dry, opaque and indurated fingers we find clean and sharply cut out defects and if these were exposed to constant washings as is the ulcer of the stomach we would find a replica of its microscopic picture. The pepsin and hydrochloric acid merely perform the physical part of cleaning the ulcer after it is formed but have *absolutely nothing* to do with its primary etiology. After all the gastric mucosa has lived in an acid medium for many millions of years and as might be expected has developed a biological resistance in this long trek of evolutionary development.

\*A paper on the "Classification of Peptic Ulcer" is in preparation.

Fig. 6

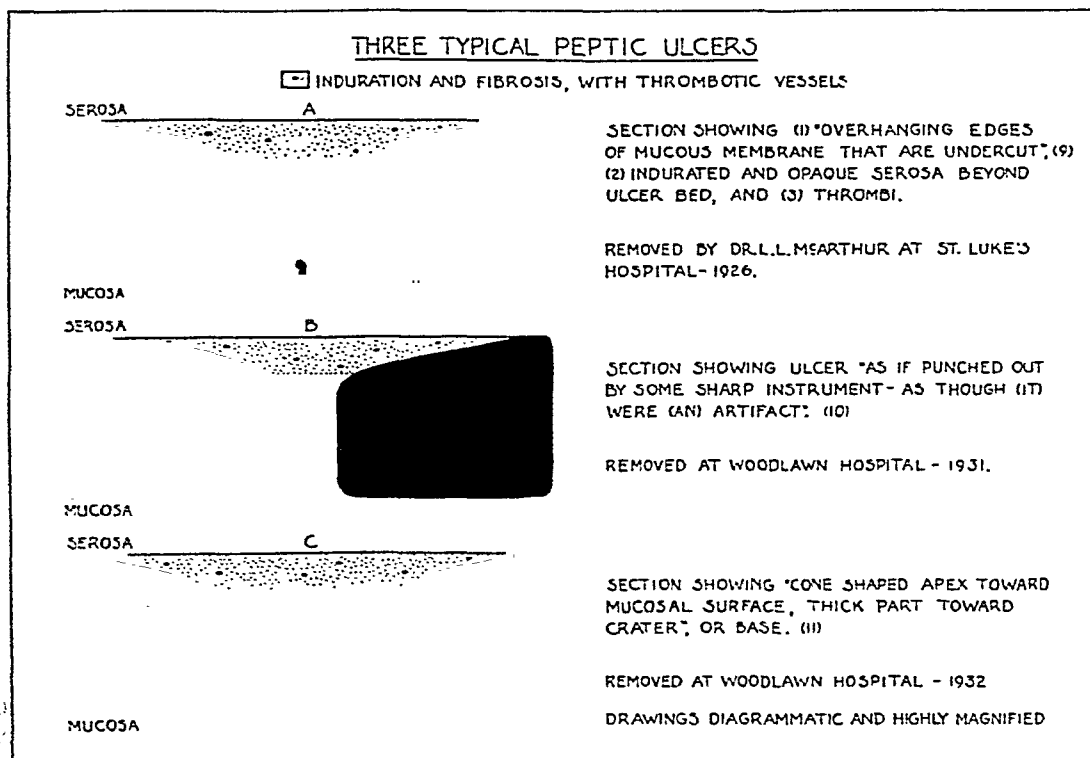

Fig. 7

Thrombosis is responsible for the induration and thickening of the serosa and subserosa. The tissue feels dead to the touch and shows a loss of normal translucency; this is easily visible at the operating table. Often after gastric resection the surgeon is greatly disappointed and surprised not to find any ulcer. The mucous membrane is intact throughout. But the site of trouble may be recognized in the opacity of the serosa with or without scarring which may extend to varying depths showing limited blood supply and thromboses. (17).

with those of "peptic" ulcer excepting for the niche. There is evidence of hypertonicity, hypermotility and hypercontractility of stomach, rapid emptying and deformity of duodenal bulb. The disease has the elements of chronicity together with periods of exacerbations followed by remissions. (22) They cannot be differentiated clinically from the true ulcer patients and to all intents and purposes are the same as far as course and response to therapy are concerned. (23) They differ from the ulcer patient only in the degree of extension of an identical pathological process. (24)

Fig. 8

### REVEALING STORY OF "DUODENITIS" AND INCIPIENT ULCER

We are familiar with the patient who has most of the symptoms of "peptic" ulcer but lacks the final verifying evidence of the niche in the X-ray film. After varying periods of therapy the patient may return for a second or even third X-ray and the niche may become discernible and a diagnosis of ulcer is made. These patients are of the same build discussed above, the male sex predominates 5 to 1, they show similar nervous instability and their distress comes on one or two hours after food and is relieved by alkalis or food. (21) They invariably have hyperchlorhydria and hypersecretion. The X-ray findings are identical

Pathologically we find the serosa thickened and indurated. The muscularis has some round cell infiltration, is edematous and looks pale and ischemic. The mucous membrane in most cases is entirely intact. Later as the process extends pin-point defects may be noticed in a few of the cases. (25) Some surgeons have had the rare opportunity of observing the causative mechanism at work.

"While operating on the stomach I have encountered particularly in the region of the ulcer-bearing area, pale almost white ischemic areas due to local spasm. The area of ischemia persisted for several minutes followed suddenly by a return of circulation. Still no ulcer could be detected. These are the individuals who

so frequently return within a few months after a futile exploratory operation, not only with outspoken symptoms but with definitely demonstrable X-ray signs of ulcer." (26).

They are "ulcer" patients without an ulcer, with an intact mucosa. In other words, the typical ulcer syndrome has been produced by a pathological process in the submucosal layers involving serosa, muscularis and intervening structures up to the mucous membrane. The erosion of the mucous membrane is not a necessary part of the pathology and the classical picture may be obtained without it.

Mental strain and anxiety have produced in these cases of incipient ulcer an imbalance of the vegetative nervous system about the lesser curvature and duodenum. This has led to spasm of the vessels in the serosa and muscularis but the circulatory impairment has not as yet extended to the mucous membrane. (Figure 8) With a temporary release of the individual's tension there is an arrest of this pathological physiology of vascular spasm, therefore it lacks the last stage in the production of a full bloomed "peptic" ulcer. There is enough ischemic pathology in the stomach wall, submucosal structures and "hyper" physiology generally to give the classic syndrome of "peptic" ulcer. (27).

It is clear that hydrochloric acid or pepsin or local trauma could not have initiated the lesion in view of the existence of a normal mucous membrane. Even the most enthusiastic advocates of these theories would not suggest that there possibly could be penetration into the stomach wall through an intact mucosa. The acid of the stomach could not produce the pain since the intact mucous membrane serves as an effective barrier covering the diseased tissue underneath. The rôle of hyperacidity in the ulcer syndrome becomes clear. Here then is a disease of psychogenic origin in which nervous stimuli rain down upon a small portion of the gastro-intestinal tract. The results are enhanced physiological functions mediated by these nerves, *viz.* hypermotility, hypersecretion, hyperchlorhydria and hypertonicity of vascular bed leading to spasm. The increased acidity is an associated finding just as much as leucocytosis is in most infectious diseases. And it would be as idle to focus one's attention on the leucocytosis instead of the invading organism as it is to regard hyperacidity as the *sine qua non* (28) of ulcer and rest content with its neutralization.

#### PSYCHOGENIC FACTORS IN DUODENAL ULCER

Dr. Harvey Cushing describes in his penetrating article (29) how his interest was aroused in the relationship of the brain to "peptic" ulcers. A patient died rather suddenly following an operation for brain tumor and autopsy revealed a perforated "peptic" ulcer. This has had corroborative support from other brain surgeons. Also certain brain tumors are occasionally associated with ulcer of the stomach or duodenum.

Beattie (29) has shown that electrical stimulation of tuberal centers causes increased motility of stomach, hypersecretion and ulceration near the lesser curvature.

Ulcers have been produced by injecting pilocarpine and physostigmine in the experimental animal over a long period of time. These drugs stimulate the parasympathetic system. We know that the interbrain is

the seat of the primitive nervous system and probably of a parasympathetic center.

These are four experiments entirely objective in their scope pointing to the relation of the interbrain to "peptic" ulcer. Let us now turn to the clinical picture which is even more convincing and which embodies the emotional and subjective content of the individual.

#### CASE REPORTS

Case IV. Mr. L. P. A. age thirty-one, who developed a duodenal ulcer under heavy financial responsibility, ill for two months in spite of management, decides to go to the North Woods. Here on irregular meals of a guide's cooking of flapjack and hard tack, with exposure to wet and cold and doing hard work he becomes symptom free in two days. He returns to Chicago and within two weeks suffers an exacerbation of ulcer symptoms.

Case X. Mr. E. C. N. (personal communication Dr. J. A. Hutton) Newspaper reporter with a duodenal ulcer develops symptom when on a specially heavy assignment. Advised to take capsules containing phenobarbital and atropine several days before and during assignments and now is able to complete his work, relatively symptom free.

Case XI. Physician age fifty-two. Gastro-enterostomy in 1915 for duodenal ulcer. Perfect health until June 1932 when he killed a man with his automobile. He bled one month later. X-ray showed deformed duodenal cap. Operation September 22nd showed duodenal ulcer (6).

These case histories show the direct relationship of mental strain and anxiety in the production of "peptic" ulcer (30). They further show that the removal of the mental strain resulted in symptomatic cure. These cures (and numerous others could be cited if space permitted) were accomplished without interfering with acidity, diet or focal infection. Merely a release from mental strain and this alone was necessary to bring about symptomatic cure.

These clinical observations, to which nearly every physician can testify, contain much of the kernel of the ulcer problem with its far flung ramifications into heredity, constitutional and personal selectivity and the emotional and vegetative imbalance.\* These clinical observations of the cause and effect relationship between mental strain and "peptic" ulcer show the need for a shift of emphasis from the ulcer itself and the interior of the stomach to the interior of the cranium.

In the final analysis, the determining factor of the course of this pathological physiology is the individual with his inherited neuro-psychological equipment in interaction with his environment. Whether the disturbing environment stirs up a dyspepsia of hypertonicity and hyperchlorhydria for a few days or a week; or whether it develops an incipient "ulcer" or "duodenitis"; or actually produces ulceration, hemorrhage or perforation; whatever their final result these processes all have this in common:—a direct circuit from the brain to stomach or duodenum. The bombardment of stimuli against the richly innervated lesser curvature and duodenum has as much crushing effect in its bloodlessness as the constant stimulation of the vegetative system has in producing gangrene in the fingers in Raynaud's disease, gangrene in the legs in the thrombo-angiitis-obliterans, and somatic

\*The sympathetic and parasympathetic systems have been omitted deliberately in this paper. Their respective inhibitory and excitatory fibers and their cortical relationship have not been worked out as yet. There is even definite proof of some cerebral control of visceral function. However, the clinical application of their combined interaction can proceed just as well until the whole subject is more fully elucidated. (31)

destruction in trophic ulcer. (30) The identical process stops the heart in coronary spasm and thrombosis and renders the kidney tissue impotent in nephrosclerosis. (32).

We are now on the verge of a fuller comprehension of the extensive damage inflicted on viscera by psychic trauma. It is natural that this source of pathology should be one of the last to be unfolded. We would, of course, in the onward progress of medicine, first study the objective manifestations of disease, *e.g.*, fracture, physical trauma, infectious diseases, tumors, endocrines, etc. Considerable advance has been made in these fields and we now should be prepared to study the effect of "emotional conflicts which are breaking down physical tissues."

### CONCLUSIONS

1. "Peptic" ulcer is shown to possess the following *unique selectivity* which is unusual in the annals of medicine.

#### (a) Racial Selectivity.

The animal kingdom does not develop "peptic" ulcer. The negro and lesser pigmented races are immune to the disease. The white race alone is susceptible.

#### (b) Anthropometric Selectivity.

Only the long thin individual of the white race is susceptible. No lateral build individual was found in this series of 70 cases.

#### (c) Personality Selectivity.

Most ulcer patients show some nervous instability especially undue anxiety, fear and worry.

#### (d) Sex Selectivity.

The male sex is predominantly susceptible, 6 to 1 in this series of 70 ulcer cases. The few females that develop ulcer often show some masculine traits.

#### (e) Site selectivity.

Only about 4 inches of the lesser curvature of the stomach and the first inch of duodenum develop "peptic" ulcer.

2. *Pathological Uniqueness.* It is shown that a cross-section of a "peptic" ulcer shows maximal damage to layers near serosa and minimal damage to mucous membrane. This is a reversal of ulcer destruction elsewhere. Thrombi are present and the erosion is clean histologically and bacteriologically. This must mean vascular spasm due to vegetative nervous imbalance leading to thromboses, ischemia, necrosis and ultimate ulceration.

3. *Incipient Ulcer.* This has further confirmation in the X-ray study and surgical observation of incipient ulcer. The ulcer syndrome is shown to exist

without ulceration of mucosa. The pathology is intramural or in the submucosal tissue. This proves that the destructive process arises from without the stomach, from above downwards and that the stomach contents including hyperacidity have *absolutely nothing* to do with the primary etiology of "peptic" ulcer.

4. Operations on the brain have produced "peptic" ulcers. Electrical stimulation in the region of the basal ganglia and tumors in the interbrain have also caused "peptic" ulcers.

5. Finally case histories are presented showing that mental strain, anxiety and fear are the deciding factors in the exacerbation of symptoms and release from them are shown to result in symptomatic cure.

The psychogenic theory, alone, explains all of these unique features of "peptic" ulcer. The lesion is limited to the lesser curvature of the stomach and duodenum because this region is richest in vegetative nerve supply. The pathological picture of thrombosis and a clean cut out lesion are due to vascular spasm following stimulation of the vegetative system. Only the long thin individual who is given to worry and fears is susceptible. It is common knowledge that the lateral type or short and stocky individual is easy going and less inclined to worry. He is too jovial to upset his gastro-intestinal innervation, so he seldom if ever develops a "peptic" ulcer. The pure blooded negro is practically immune to the disease although he eats the same food and is subjected to the same "focal infection" as the white man. Why does this disease skip an entire race? The answer is an anthropological one based on hereditary differences of psychological structure and function. The negro race in its evolutionary ascent has not, as yet, acquired the habit of worry so peculiar to the white race under pressure of routine civilized living. The negro meets life's frustration with greater calm and equanimity—sometimes even with laughter.

### SUMMARY

This paper advances the psychogenic theory of "peptic" ulcer. It claims that this disease is found only among susceptible individuals of the white race—usually the long thin type who are given to worry and nervous instability. These individuals with their fears and anxieties develop an imbalance of the vegetative nervous system. This results in a bombardment of stimuli to the lesser curvature of the stomach and duodenum producing vascular spasm, thrombosis, induration, ischemia, and finally necrosis and ulceration.

## A Follow-up of Ulcerative Colitis (Non-specific)\*

By

BURRILL B. CROHN, M.D.,

and

BERNARD D. ROSENAK, M.D.

NEW YORK CITY, NEW YORK

THE treatment and care of a case of non-specific ulcerative colitis usually are administered in an atmosphere of pessimism and doubt. The gallery of interested physicians expects the worst, hesitate to believe relief or restitution to health possible and surely expect one or more recurrences should the patient escape an immediate catastrophe. True, not without reason did the earlier clinicians call this disease *colitis gravis*: the severity of the symptoms, the progressive emaciation and anemia, the dehydrating and the exhausting diarrhea, protracted chronic clinical course and its disheartening recurrence might well earn for such a malady this dreaded opprobrium. Should the patient benefit by a therapeutic attempt or by one of nature's surprisingly frequent last-hour reprieves, it is usually held that the "cure" really is only a remission and that the "recurrence" cannot be far ahead.

All of which is unfortunately only too true. Twenty-five years ago, when cases of colitis were few and far between (?) and constituted "rare" cases of unusual difficulty as problems in therapeutics, the gravity of the prognosis was correctly assessed. But today, when through some mechanism which has not yet been explained, cases of colitis are common and familiar, with greater experience, increasing knowledge and a certain modicum of success, the self-confidence of achievement becomes established in the profession. Today, colitis is not a hopeless problem; we feel that we cure a fair, if not a fairly high, percentage of our cases, and what is more, keep them well. This note of optimism is well warranted by the facts; as the years roll on, the individual follow-up of each clinician grows with his maturity. This present generation of clinicians, and particularly gastroenterologists, is the first generation to apply itself intently to the problem of the etiology and therapy of non-specific ulcerative colitis; therefore this generation is the first one, which, having grown up with the problem, is now beginning to approach that stage where follow-up statistics and prognostic generalizations take shape and have real significance.

On this subject, very few statistical reports have been registered in medical literature. The vast experience of the members of the staff of the Mayo Clinic has been ably reported by Bargen (1) and lends a real tone of optimism not sufficiently recognized and appreciated by the profession and the public.

Some years ago we (BBC) reported a careful study

of cases of gastric and duodenal ulcer seen and followed over a course of 5 to 10 years; the cases reported were hospital-ward and clinic cases, culled from the working classes where the best means of treatment and the most conscientious follow-up were not always possible. Shortly after, Friedenwald published identical experiences with private patients under better hygienic and economic conditions. It was felt that the far better results reported by him, and the greater durability of his cures may have been due, in part, to the better social and financial condition of his patients, and to the privilege accorded these patients of being treated and followed over a long period by one man only, and that man one of vast experience.

### MATERIAL STUDIED

The following statistical follow-up of ulcerative colitis is, therefore, based upon 90 cases seen in "private practice". That does not necessarily imply that the patients were drawn from the luxury classes; on the contrary, they represent all strata of society. But they had the advantage of consistent treatment by one person, carried through to a successful or unsuccessful ending, and they had the will and the means to carry out the therapeutic directions and the dietary management which are requisite to the therapy of this disease. From this group of 90 cases, carefully studied and consistently followed from 2 to 14 years, some important facts regarding methods of treatment and the results of prolonged therapy logically may be deduced.

The age and sex distribution in this group differs in no wise from that published by many other authors when such facts have been drawn from far larger series of patients. The disease essentially is one of young adult life, both sexes being approximately evenly affected. The largest group falls in the third decade, the next largest in the fourth decade (Table I);

 Submitted May 31, 1935.

the youngest in this group was 3 years, the oldest 58 years. Nearly always in young persons, (frequently the recent bride or the vigorous youth in his college years, or a young husband and provider) the disease takes toll of youth in its best period.

Of these 90 cases, we have records to date in 75 cases, constituting an 83% follow-up. These cases all have been seen or contacted personally in recent months. Occasionally, we accepted the report of the original physician regarding the present status of the case. Of the 75 cases, we can say with truthful assurance that 33 cases (44.5%) are cured. By "cured" we mean persistent cessation from symptoms and complete restitution to the normal. Again, 23 cases (30%) are regarded as improved. These patients retained their normal weight. Some of them were having at the most two to three soft bowel movements per day, but had no blood or mucus in the stools. They all had returned to their former activities and were in good general health. Others in this group suffered from mild intermittent recurrences of symptoms with intervening periods during which they were absolutely free of diarrhea. Eight cases, (10.9%) were unimproved, which means, to all practical purposes, invalidism. Eleven cases had died (Table II). These statistics will

be discussed in greater detail in the course of the text. Suffice it to say that of the entire group, 75% are cured or improved and restored to efficiency.

Approximately half of the cases had been ill less than a year, thus constituting the treatment of the disease in what practically is a sub-acute or beginning chronic state. (Table III). The other half had been ill for from two to fourteen years, a fact which dem-

TABLE III  
Duration of the Disease When First Seen

| Duration       | Number of cases |
|----------------|-----------------|
| 1 wk. to 3 mo. | 15              |
| 4 mo. to 1 yr. | 29              |
| 1 to 2 yrs.    | 14              |
| 3 to 5 yrs.    | 14              |
| 6 to 10 yrs.   | 9               |
| 10 to 14 yrs.  | 4               |

onstrates the chronicity and the prolonged course characteristic for this malady. One point of interest becomes obvious, and that is that the percentage of cured and improved patients is maintained at a high level, even with the passing of time, providing treatment is begun within the first two years of illness. From this point on, the greater the duration of previous illness, the less likelihood of cure (See Chart A).

CHART A

Showing the Relation of Duration of Symptoms to the Per Cent of Cases Cured or Improved

Because the patient has been semi-invalided and ill for many years does not mean that the possibility of successful cure thereby is excluded. On the contrary, some of the most gratifying results were observed in just this class of long-suffering patient.

That the results are durable is to be seen when one analyzes the percentage of cured and improved cases seen in the course of the gradually increasing period of follow-up observation (Table IV). Over 70% of the cases are cured or improved in the first two and the first four-year periods. If relapses were common, we should expect to find a much smaller percentage of cure at the end of six or ten or fourteen years of follow-up. This is not the case, because, while the numbers followed have been much smaller as the years progressed, in the cases followed between six and fourteen years, the percentage cured is maintained. Table IV is very significant. For example, in a six to ten-year period of follow-up, there are fifteen cases, of which seven cases have been and have remained cured, six to ten years after the initial treatment without relapse. Add to that group, four cases that are so improved as to be regarded as restored to efficiency and ambulatory health and we are much gratified to observe the favorable outcome of therapy, even when observed over so long a period.

Two cases are known to be cured without relapse, and two cases are markedly improved when observed

TABLE IV  
"Cure" and Long Period Follow-Up

| Follow-up period:  | Total Cases | Long Period Results: |          |            |          |
|--------------------|-------------|----------------------|----------|------------|----------|
|                    |             | Cured                | Improved | Unimproved | Deceased |
| 6 mos. to 2 yrs.   | 28          | 11                   | 9        | 6          | 2        |
| 2 yrs. to 4 yrs.   | 21          | 10                   | 6        | 1          | 4        |
| 4 yrs. to 6 yrs.   | 6           | 3                    | 2        |            |          |
| 6 yrs. to 10 yrs.  | 15          | 7                    | 4        | 1          | 3        |
| 10 yrs. to 14 yrs. | 6           | 2                    | 2        |            | 2        |
| Total Cases        | 75          | 33                   | 23       | 8          | 11       |

over a period of from ten to fourteen years. These cures were affected not alone on mild cases, but on some of the most severe cases, most of which had been sick and invalided for from six months to six years before coming under our management, some of them having previously had as many as four or more recurrences.

#### THE EFFICACY OF THE VARIOUS TYPES OF THERAPY

Certain general rules of treatment were followed in all cases. *Retention enemas* of neutral acriflavin, in the strength of 1 to 4000 parts of normal saline solution, were employed as a daily routine. In the earlier years, before the use of intravenous medication, this represented, together with dietary regulations the sole therapeutic procedure. Very good results often were seen with this method when exclusively employed. When retention enemas created more irritation than relief, where a mucoid or catarrhal irritation resulted from their use, they were promptly discontinued. In general however, retention enemas rather than colonic irrigations gave relief and were welcomed by the patient. For several hours after the institution of such an enema the patient usually felt more comfortable and the number of stools was materially reduced. These retention enemas therefore were usually given in the evening in order to assure a better night's rest.

The *diet* in all cases was a liberal one representing all classes of foods, including all classes of vitamins, the main principle being the exclusion of roughage and such articles of diet containing substances likely to irritate the colon. When excessive diarrhea was present, deodorized tincture of opium was employed. The amount of opium was always restricted to the minimal dose which would just reduce the degree of anal irritation from the constant intestinal flux, and which would allow the patient sleep and rest between movements but without inducing constipation. To constipate a colitis case is to make him most uncomfortable. The common use of large doses of opium is deleterious, inducing cramps if continued, borborygmi and the conscious feeling of pent-up or imprisoned gas. A very practical way of administering opium is to give ten minims of deodorized tincture of opium after every alternate stool during the severe stage only. The administration of the drug is thus automatically regulated by the discharges: the more stools, the more opium, the fewer stools, the less medication.

Since 1921, following the suggestion of Arthur Hurst (2), of London, we have employed the *intravenous injection of polyvalent anti-dysentery serum*; this, regardless of whether dysentery organisms or phage or agglutinins were or were not present in the patient's blood. The patient was tested for serum sensitiveness by the intradermal or conjunctival method, (serum diluted ten times in saline) and then received a preliminary dose of 5 c.c. of serum intramuscularly. If no severe reaction followed, the patient received, every other day, an intravenous dose of serum varying from 5, 10 or 15, to 20 c.c., the dose depending on the degree of reaction. A severe febrile reaction was welcomed. A certain degree of anaphylactic shock was regarded as more beneficial than deleterious. The most beneficial results were seen in those patients in whom the intravenous injection of serum resulted in immediate serum shock analogous to a non-specific protein reaction and in those who showed late serum sickness with urticaria and even joint manifestations.

The use of polyvalent anti-dysentery serum seemed to give us best results. (Table V).

In order to determine whether the effect of this serum was a specific or a non-specific one, we attempted, in a number of cases, to duplicate the results by the intravenous injection of typhoid vaccine, such representing a convenient and direct method of non-specific protein therapy. Some fairly good results were seen (Table V). Other miscellaneous methods of treatment were tried at various times in the course of years, these methods including autogenous vaccines of fecal organisms, Bagen's serum and vaccine, transfusions, etc., some with good results, many of them without any noticeable effect. It would seem that among the various types of intravenous therapy, no one item seemed to have a specific effect upon the

\*Autogenous vaccines, Bagen's serum, transfusions, routine diet and medication only.

disease. It soon became obvious that any protein agent which would produce a protein shock and a febrile reaction, could bring about a beneficial change in the chronic course of this disease. The change from the slow, lethargic chronicity into a sudden flare-up induced by the protein therapy of whatever type, frequently seemed to alter the long drawn-out course of the malady. After several severe protein shocks, the temperature would frequently subside, diarrhea gradually and more slowly diminish until constipation was achieved and the general health of the patient, appetite, strength and weight began to show steady improvement. This experience of ours in observing the beneficial effect of protein shock was substantiated by remarks of other observers using still more varied means of therapy. Those using Bagen's serum and Bagen, himself, have observed that the best results were seen where the serum created severe protein shock, indicating that the serum acted as a non-specific protein as well as a specific antitoxic agent. The same may be said of transfusions.

Kantor, (3) using repeated small transfusions, has seen a general gain of hemoglobin and well-being; his

best results (as were ours) were observed when the transfusion was definitely accompanied by a febrile reaction. The experience of Andresen (4), with mercurochrome employed intravenously, was analogous. Here again the best results were seen in those cases exhibiting the greatest reaction to the intravenous therapy.

Our personal experience convinced us of the superiority of the use of polyvalent anti-dysentery serum. Whether the disease is an attenuated dysentery, a mild endemic dysentery or not, whether agglutinins were or were not present in the patient's blood, splendid results followed the specific serum method of treatment. In certain cases, it would appear almost as if the anti-body content of the serum were an important factor, particularly when high agglutinin *titers* were found in the blood of the patient. At other times, when no agglutinins were present, the serum still acted in a most prompt and efficient manner. Not alone does it constitute an excellent non-specific protein, but in its late production of serum-sickness, with urticaria and fever, it seems to act in its very best manner upon the course of the disease. This observation has also been made by Kalk (5), who used simple horse serum for the treatment of ulcerative colitis. His best results were seen in those patients showing the most serious instances of serum sickness.

The mortality of the disease under medical treatment was 11% (8 cases), these cases representing deaths from inanition, gradual exhaustion, anemia complicated by nutritional edema, and an occasional rare case by perforation or by gross hemorrhage; three additional cases died as a result of surgical intervention. Under *surgical treatment*, we regard ileostomy, as do almost all other writers, as the operation of choice, but one which should be restricted only to cases which are regarded as incurable under any form of medical therapy. We realize, that when an ileostomy is performed, the life of the patient may be saved, but that the disease thereby is stamped and

sealed as an incurable illness. In the course of years sigmoidoscopic study of cases of ileostomy shows an unhealed and unhealing mucosa, characterized by deep ulcerations, polypoid transformations, strictures and occasional malignant degenerations of the polys which are present. Only colectomy is indicated, once an ileostomy is performed. Our experience, however, with total colectomy, is insufficient to warrant discussion at this moment. Partial colectomy for localized forms of colitis have been very successful. The mortality of ileostomy, on the other hand, has been very high, not less than 33 1-3%; since however we restrict this operation to the most hopeless cases, one can expect a high mortality. The success of the Lahey Clinic (6) with partial extirpation of the colon and permanent ileostomy is one of the most promising chapters in the surgical treatment of this malign malady.

Our percentage of cured and improved is no better than those of Bergen (7) and his co-workers at the Mayo Clinic. Our follow-up period, for a fair proportion of our cases (6 to 14 years), is longer than those reported in Bergen's latest three-year follow-up. Though we may not accept the *diplostreptococcus* of Bergen as the proven cause of this disease, we have nothing but enthusiasm for his fine therapeutic results. If he, using a streptococcus vaccine and serum, obtains the approximate same percentage of cure as we do, using various means, but mainly anti-dysentery serum, it would all the more appear as if the disease yielded to various agencies, but always best to intravenous protein medication.

*Skillful neglect does not succeed with ulcerative colitis.* An active program and an experienced therapist are essential to terminate and cure those longstanding, chronic, insidious cases. Nature occasionally, unaided, will surprise one with a spontaneous cure. Unfortunately, nature is lax and undependable, but a strict and aggressive therapeutic program will bring to a favorable and permanent outcome a large percentage of supposedly incurable cases.

## The Acutely Ill, Jaundiced Patient: a Report of Twenty-one Instances of Hepatic Icterus, Seven of Whom Had High Blood Nitrogen\*

By

S. G. MEYERS, M.D., OSBORNE A. BRINES, M.D.

and

BENJAMIN JULIAR, M.D.

DETROIT, MICHIGAN

THE patient who is jaundiced but not acutely ill is one frequently met with in clinical medicine. Such a patient might be affected with catarrhal jaundice, carcinoma of the head of the pancreas, stone in the

common duct if complications are absent, or a variety of less common conditions.

The patient who is both jaundiced and acutely ill presents a different picture. The presence of jaundice in a patient who is acutely ill is ominous, death often occurring in a few days. The serious prognosis con-

\*From the Receiving Hospital and the Wayne University College of Medicine, Detroit.  
Submitted May 22, 1935.

sequent on this combination of symptoms makes rapid clinical orientation desirable. Liver damage of a severe degree usually is present; intensive treatment is necessary although in only a small percentage of these patients are the results of such treatment satisfactory.

#### MATERIAL STUDIED

The data in this paper was compiled from the clinical and pathological records of twenty-one cases. These patients, acutely ill and with marked jaundice, were seen at the Detroit Receiving Hospital in the last seven years. The clinical and pathological records of a larger number of patients were studied where the jaundice was a minor sign of an overwhelming but obvious infection, but these cases are not being reported here. This paper is confined to observations where liver damage played an important or dominant rôle in the illness. Each case selected showed evidence of hepatic icterus; all cases of obstruction by malignancy, stone, etc., have been carefully excluded.

#### CLINICAL OBSERVATIONS

The usual *clinical picture* encountered in these twenty-one cases corresponds with the textbook description of acute yellow atrophy. This syndrome also has been named "icterus gravis" and "the cholemic state" by various authors. Table I is a summary of the frequency of symptoms observed. Deep jaundice invariably was present. The icteric index ranged from 37 to 235. In more than half of the cases the icterus index was in excess of 100 at some stage of the disease. The serum bilirubin ranged from 312 to 22.1 mg. per 100 cc. Vomiting was the next most constant symptom occurring in about three-fourths of the group. Abdominal pain was present in 71 per cent and was due to abdominal distention from ascites, distention of the liver capsule or it was a severe, colicky pain resembling gall stone colic ("pseudo-gall stone colic"). Nervous symptoms particularly were common; evidence of mental disturbance was prominent early in twelve of the twenty-one individuals. The mental state was characterized as "markedly lethargic," "irrational," "delirious," "semi-stuporous" or "comatose." Epileptiform convulsions occurred in one patient. Bleeding occurred in five patients, two of whom had hematemesis, one purpurae, one epistaxis and one bleeding from the gums.

The *course* of the entire group was remarkable in that, once the acute symptoms had developed, death occurred in a relatively short time. The following figures illustrate this.

|                                                   |         |
|---------------------------------------------------|---------|
| Lived less than twenty-four hours after admission | 5 cases |
| Lived one to three days after admission           | 3 cases |
| Lived four to seven days after admission          | 7 cases |
| Lived eight to fourteen days after admission      | 2 cases |
| Lived fifteen to twenty-six days after admission  | 4 cases |

|       |          |
|-------|----------|
| Total | 21 cases |
|-------|----------|

The *life expectancy* with this illness fell into two groups: One group in which the entire course of the disease lasted from one day to several weeks; and a second group with a long history of liver disease, which finally terminated in icterus gravis shortly after hospitalization.

#### PATHOLOGICAL DATA

A summary of the hepatic and renal pathology in our twenty-one cases of hepatic jaundice is shown in Table II. It will be seen that only ten of the twenty-one livers showed necrosis, the remaining eleven being

TABLE I

divided among cirrhosis, cloudy swelling and fatty liver. Only three of the twenty-one cases had definite renal pathology, two of whom had chronic focal nephritis and one had chronic glomerulonephritis. All had "bile nephrosis," characterized by pigmentation and cloudy swelling of the tubular epithelium.

#### CLINICAL COMMENT

One case which showed a fatty liver without necrosis of the cells clinically could not be distinguished from the cases of liver necrosis, both having the clinical picture of icterus gravis, marked jaundice, vomiting and confused mentality. The fully developed picture of icterus gravis with vomiting, deep jaundice and delirium also was observed in a case which at autopsy showed merely cloudy swelling of the liver, no other lesions of the liver being found on post mortem examination. A second patient with cloudy swelling of the liver also died with icterus gravis, without a cause for the liver damage being apparent before death. Autopsy revealed an unresolved pneumonia, which definitely fixed this as an infectious hepatitis consequent upon lobar pneumonia. This patient illustrates the difficulty of differentiating idiopathic icterus gravis from icterus secondary to some undiscovered, overwhelming infection.

These patients illustrate that cloudy swelling and fatty liver may cause the clinical picture of icterus gravis indistinguishable in life from the same symptoms caused by actual necrosis of the liver cells. The identical picture of icterus gravis also can be evident when cirrhosis without necrosis of the liver cells is present. This occurred in eight members of this series where a long standing cirrhosis of the liver was present, its termination being with deep jaundice, vomiting, mental symptoms and hemorrhages. In these cases there was present an already seriously damaged liver; the acute hepatic insufficiency was precipitated by some undetermined factor such as an acute infection or alcohol poisoning. In some patients, the cir-

rhosis had given symptoms for months or years by enlargement of the liver and spleen and ascites. In others, the symptoms of cirrhosis of the liver were latent and the patients presented the clinical picture of idiopathic icterus gravis, but at post mortem the previously existing cirrhosis was discovered.

It is interesting that the symptoms and signs of acute yellow atrophy, well known and usually easily recognized, constitute a clinical and not a pathological entity. The identical group of symptoms was associated with such lesions as hepatic necrosis, hepatic cirrhosis without necrosis, cloudy swelling of the liver and fatty liver. The dominating factor in correlating the clinical and pathological data probably lies in the sphere of hepatic function, where the liver has ceased to function the characteristic syndrome appears, at times unassociated with microscopical evidence of hepatic necrosis.

Lepehne (1) gives an excellent summary of the etiological factors involved in icterus gravis. He states that icterus gravis can arise suddenly and without demonstrable cause, or it can arise from a known toxic agent such as chloroform, phosphorus, cinchophen, alcohol, salvarsan; from some infection as syphilis or Weil's disease; from some metabolic change as in pregnancy, or as a terminal event in the presence of previous liver disease, as atrophic cirrhosis, biliary cirrhosis, etc.

The constant presence of icterus in these necrosis cases should not lead one to expect icterus in every case of hepatic necrosis, nor to dismiss the possibility of hepatic necrosis or insufficiency where jaundice is absent. We have encountered definite hepatic necrosis without jaundice in a case of marked thyrotoxicosis. Similar cases have been reported by Kerr and Rusk (2), Barker (3), and Beaver and Pemberton (4). Death, post-operatively, of patients with a cholelithiasis of long standing has been ascribed to "liver insufficiency" by Cave (5), Heyd (6), and Eiss (7). In these cases the jaundice may also be slight or absent, and the liver insufficiency may not be recognized clinically.

### ETIOLOGICAL FACTORS

There are so many possible etiologic factors in hepatic icterus that often it is difficult to choose which is the most likely. In one case, a choice could be made between syphilis, anti-syphilitic therapy and alcohol; in another, between alcohol, pregnancy and drug intoxication. An analysis of the twenty-one cases as to etiological and clinical features is reported in Table III. It is easy to overlook such important etiologic factors as an acute infection with masked or modified symptoms, or the ingestion of a drug the nature or significance of which the patient or doctor does not understand. Quite frequently these patients are mentally confused when first seen and an accurate history is not obtainable.

The differential diagnosis of hepatic icterus from that due to obstruction in one of the larger ducts is extremely important to the patient. An operation undertaken to relieve a wrongly diagnosed obstruction may cause death, the anaesthesia or shock of the operation being sufficient to push the poorly functioning liver over the brink into hepatic insufficiency. Patients with hepatic icterus are notably poor operative risks.

TABLE III  
*Etiological and Clinical Features*

|                                                                                                                                                                                | Cases |
|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------|
| 1. Chloroform Poisoning (Sulcide).                                                                                                                                             | 1     |
| 2. Liver Necrosis during anti-leucic treatment. Probable arspenamine necrosis.                                                                                                 | 1     |
| 3. Idiopathic Acute Yellow Atrophy.                                                                                                                                            | 1     |
| 4. Clinical picture of "Catarrhal Jaundice" of unknown etiology, terminating with icterus gravis; acute yellow atrophy at autopsy.                                             | 2     |
| 5. Clinical picture of "Catarrhal Jaundice" of unknown etiology, then fresh rupture of gastric ulcer. Death 3 hours after operation. Subacute atrophy of liver at post mortem. | 1     |
| 6. Idiopathic acute hepatitis, death with picture of icterus gravis, only cloudy swelling of liver found at autopsy.                                                           | 1     |
| 7. Infectious hepatitis, giving clinical picture of icterus gravis, from a lobar pneumonia not recognized in life.                                                             | 1     |
| 8. Portal Cirrhosis, with previous alcoholic history, death with picture of icterus gravis.                                                                                    | 6     |
| 9. Portal Cirrhosis, no previous alcoholic history, death with picture of icterus gravis.                                                                                      | 2     |
| 10. Portal Cirrhosis, plus terminal infection                                                                                                                                  | 1     |
| (a) Abdominal abscesses                                                                                                                                                        | 1     |
| (b) Pancreatitis                                                                                                                                                               | 1     |
| 11. Hypertrophic Biliary cirrhosis, possibly associated with alcoholism or pregnancy. Death after operation to relieve possible biliary obstruction.                           | 1     |
| 12. Interstitial Hepatitis, death with picture of icterus gravis, possibly alcoholic in origin.                                                                                | 1     |
| 13. Syphilitic Hepatitis, death with picture of icterus gravis.                                                                                                                | 1     |
|                                                                                                                                                                                | 21    |

### ILLUSTRATIVE CASES

Case histories of patients illustrating some of the clinical pictures encountered follow:

1. *Chloroform Poisoning*, Case No. 11: A forty-eight year old attorney was admitted in coma following the drinking of chloroform. He became rational, but, two days after admission, jaundice, delirium, nausea and vomiting appeared, there was decrease in the size of the liver and the patient expired five days after admission. At autopsy necrosis of liver cells, predominantly at the center of the liver lobule, was found.

2. *Idiopathic acute yellow atrophy*, Case No. 1: A twenty-two year old boy was admitted, jaundiced and in coma. Five days before admission he had been taken ill with abdominal pain and had vomited blood. No history of previous illnesses, recent medication, alcoholism or other poisons could be obtained; loss of consciousness developed the day previous to admission. At autopsy acute yellow atrophy of the liver with diffuse necrosis of the liver cells was found.

3. Previous picture of *Catarrhal Jaundice*, termination with *Icterus Gravis*, Case No. 13: A fourteen-year old colored girl was admitted with the clinical picture of catarrhal jaundice of one week's duration. A previous history of pregnancy, operations for two breast abscesses and a right oophorectomy was given. On entrance the patient was well oriented and fairly comfortable altho' the conjunctivae were markedly icteric. Pulse and temperature were normal. The first week of her hospital stay was noted as "improving", "walking about the ward". On the eleventh day after admission, patient was noted as "dull and apathetic; sleeps during day"; on the fourteenth day "frequent vomiting, very toxic", on sixteenth day "temperature and pulse rising; vomiting pronounced, more deeply jaundiced." The patient finally became comatose and died, eighteen days after admission to hospital. Autopsy report showed extensive diffuse necrosis of liver cells.

4. *Portal Cirrhosis*, termination with *Icterus Gravis*, Case No. 8: A forty-two year old, white male, addicted to alcohol but who had discontinued its use eight months previous to final admission because of the development of ascites. He had previously been admitted to hospital, with a diagnosis of portal cirrhosis and had been tapped several times. A week before the final admission, ascites became

marked, jaundice appeared and gradually deepened and he began to vomit frequently. On admission he was very drowsy and intensely jaundiced. Ascites was present and the liver enlarged half way to umbilicus. The liver decreased in size to one finger breadth below costal margin before *exitus*. He vomited bile and later vomited blood. Patient expired five days after admission. *Autopsy* showed portal cirrhosis with recent necrosis of liver cells, apparently a moderately severe acute yellow atrophy.

5. *Infectious Hepatitis, simulating icterus gravis*, Case No. 4: A fifty-three year old white male, a heavy drinker of alcohol for past five years. Two weeks before admission chills and vomiting developed. His physician noted jaundice one week before admission; gradually the jaundice became deeper. On admission, lethargy, hiccup and deep jaundice were marked symptoms; herpes on lips, lungs apparently clear; liver indefinitely felt, three finger breadths below costal margin; temperature from 99° F. to 101° F.; white count 55,200 per cu. m.m., with 98 per cent polynuclear cells. The patient expired four days after admission. At *autopsy* there was an extensive unresolved pneumonia; the liver weighed two kilograms and showed cloudy swelling, and the kidneys showed chronic focal nephritis.

One explanation which suggests itself to account for the high non-protein nitrogen values is that it is due to an increase in the amino acid nitrogen. Thus, Rabinowitch (9) reported a case of acute yellow atrophy with extremely low blood sugar, blood urea of zero and a high amino acid nitrogen (216 mg. per 100 c.c.). Pathologically the liver cells practically were entirely absent, and the kidneys showed an acute degenerative nephritis with marked fatty degeneration of the tubules. The high non-protein nitrogen figures obtained in our seven cases cannot be due to low urea nitrogen and high amino acid nitrogen as can be observed in Table IV which shows that the urea nitrogen figures were also high.

Dehydration also does not explain satisfactorily the rise in the non-protein nitrogen as figures over 60 mg. per 100 c.c. are unusual in dehydration. Certainly the four cases in which the non-protein nitrogen was over 100 mg. per 100 c.c. cannot be explained on this basis.

Alkalosis due to vomiting is a possible explanation for the high blood nitrogen. The mechanism of the rise in non-protein nitrogen would be similar to that of

TABLE IV  
Cases With Blood N.P.N. Above 50 Mg.\*

| Name  | N. P. N. | Urea  | Creatinine | Liver Pathology                                     | Kidney Pathology                                        | Associated Pathology  |

| S. K. | 100      | 145.5 | 4.6        | Cloudy swelling of liver.                           | No pathology except bile nephrosis.                     |                       |

\*All figures in this table refer to mg. per 100 cc.

#### INSTANCES EXHIBITING HIGH NON-PROTEIN NITROGEN

The non-protein nitrogenous constituents of the blood displayed a remarkable and unlooked for behaviour, seven of the twenty-one cases had a blood nitrogen in excess of 50 mg. per 100 c.c. The current belief is that the blood urea is diminished in liver necrosis and insufficiency, since the liver is the sole site for urea formation. Mann (8) and his co-workers have noted that, in the hepatectomized dog, there was a progressive decrease of the urea in the urine and in a few hours scarcely any was present in the blood, urine or tissues. (If the dog's kidneys were removed at the time Mann removed the liver, he noted that the urea content of the blood was stationary; if the kidneys were removed before removal of the liver there was increase in the blood urea, and after hepatectomy this high level was maintained but not accentuated.)

Table IV summarizes the pathology encountered in seven cases of hepatic jaundice having a blood nitrogen over 50 mg.

Renal pathology was demonstrated in only two of the seven cases, one case showing focal nephritis and one chronic glomerulonephritis. In these two cases, there was enough obvious renal pathology to cause a nitrogen retention. In the remaining five cases, the only renal pathology present was bile nephrosis, i.e., pigmentation, and cloudy swelling of the tubular epithelium.

high intestinal obstruction where a depletion of chlorides by vomiting of hydrochloric acid causes the syndrome of high non-protein nitrogen, high carbon dioxide combining power and low blood chlorides. The blood chlorides were determined in one case (333 mg. per 100 c.c.) and the CO<sub>2</sub> combining power was not estimated. Vomiting was a prominent symptom in four of the seven cases with a high non-protein nitrogen.

The renal lesion accompanying liver necrosis undoubtedly explains some of these cases with a high blood non-protein nitrogen. Thus, Helwig and Orr (10) reported a case of injury to the liver with pulpification of the liver tissue and anuria progressing to uremia accompanied by high non-protein nitrogen terminally. Autopsy revealed a pulpified liver and a high grade nephrosis. Helwig and Schutz (11) reported five cases of long standing gall bladder disease, who, before operation, had normal blood and urinary findings, but who after operation developed this liver-kidney syndrome. With its appearance there were abdominal distention, fever, tachycardia, progressive oliguria, and albumin, casts and often blood in the urine. Nausea and vomiting occurred on the fifth to eighth post-operative day; there was bleeding from the mucous surfaces and the patients lapsed into a muttering delirium and finally coma. The blood nitrogen increased and the urinary nitrogen decreased. Autopsy revealed a cloudy swelling, fatty degeneration and, in

some instances, necrosis of the liver cells. The kidneys showed marked tubular damage. Jaundice was present in only two of their six cases. Experimentally, ligation of the hepatic artery of rabbits reproduced the laboratory picture of oliguria, albumin and casts in the urine and a rising non-protein nitrogen.

The authors suggest that a toxin may have been produced by the degeneration of the liver cells which poisoned the kidney parenchyma and caused progressive degeneration and not infrequently complete necrosis of the tubular epithelium of the kidney.

Only two of our seven cases showed definite nephritis; the remaining five showing only bile nephrosis, a lesion not ordinarily accompanied by a nitrogen retention. Another explanation and one which seems to us to be the most logical is that the degenerative products of liver necrosis and insufficiency may inhibit renal function without alteration of renal structure, i. e., we have here a functional renal insufficiency of such short duration that anatomical lesions are not yet definite.

Recapitulating, it would appear that while the rise in the non-protein nitrogen is not clear in all cases, the explanation, where no obvious kidney lesions are present, lies probably in the realm of insufficient renal function.

#### SUMMARY

The etiology and symptoms of twenty-one cases of hepatic icterus are discussed.

Identical clinical symptoms, labelled "icterus gravis" can be caused by liver necrosis, cirrhosis without necrosis, cloudy swelling and fatty degeneration of the liver.

Icterus gravis may result from some known poison, unknown toxin or be a terminal event in a previously damaged liver.

Jaundice does not invariably accompany liver necrosis.

Multiple etiologic factors are often present in icterus gravis.

Infectious hepatitis where the source of the infection is not apparent may simulate icterus gravis.

Seven cases of hepatic icterus associated with blood non-protein nitrogen levels in excess of 50 mg. per 100 c.c. were observed. Only two of these cases had nephritis; the remaining five presented only bile nephrosis, a condition usually not associated with nitrogen retention. Several mechanisms are discussed to explain the dearth of renal findings in these cases, the most probable being that of impaired renal function, due to an acute lesion too short in duration to cause demonstrable structural alterations.

Nitrogen retention occurs frequently in terminal liver disease. It may be, but is not necessarily accompanied by gross renal damage.

## A Clinical Review of Giardiasis

### Twenty-two Cases Observed During Study of 572 Private Patients

By

G. S. de PAULA e SILVA, M.D.  
BELLO-HORIZONTE, BRAZIL

FOR years many authors have published regarding patients harboring giardia (lamblia) in the duodenum. The subject is still a matter of wide discussion and we are very far from a general agreement.

In this paper it will be shown what was observed in a group of patients that had in the bile, drained according to the world-known method of Lyon (1), abundant motile forms of this flagellate.

#### INCIDENCE

Working in Bello-Horizonte, Brazil, in the tropical zone, in a series of 572 patients observed in private practice, from April, 1933, to February, 1935, I found this type of infestation only 22 times (cases Nos. 38, 43,

84, 126, 140, 197A, 283, 286, 292, 358, 372, 394, 409, 419, 439, 456, 514, 518, 533, 554, 557, and 566). There was, therefore, an incidence of only 3.8%. A case was not included that presented diarrhea and giardia in the stools; the drainage, made after the treatment of the diarrhea, showed no parasite in the duodenal contents. Of these 22 patients 15 were males and 7 females. The age varied between 18 to 61 years.

This study concerned only private patient material; neither the cases seen in the ward nor these examined in other services were included. Recently, Prof. Alfredo Balena (2) has published a series of papers concerning cases observed in his ward services, where I am an

assistant. It has been his observation, and also mine, that giardiasis occurs with much greater frequency among the poor than among the well-to-do, because of greater contamination of water supply, vegetable and fruits.

### DIAGNOSIS

In all my patients the diagnosis was made after drainage of the gall tract, as referred to above. In this series 112 drainages were performed for diagnostic and control purposes on different occasions. In every case several samples of the draining bile were collected in large centrifuge tubes and centrifuged for 10 minutes (3,500 revolutions a minute). With the material thus collected in the bottom of the tubes several slides were prepared promptly and carefully examined, while warm, by the microscope.

In only one stool examination, in this series, cysts of giardia were found 12 times (54%); even with repeated examinations some patients gave persistently negative results (one with 15 repeated examinations).

### SYMPTOMS

So frequently the coincidence of symptoms was observed in the bearers of these flagellates, symptoms that decreased and vanished with the elimination of the parasites, that a relation of cause and effect had to be considered. It is never possible to assume that what the patient complains of actually represents symptoms solely due to the infestation he harbors. It is necessary to seek other correlated factors and to estimate to what extent the giardia can be responsible for the clinical picture. In this series 3 cases showed symptoms that later could not be explained as being caused by the infestation: two with digestive complaints, and one patient with vertigo and diarrhea in whom the treatment failed and, with it, the therapeutic test.

The time of onset of the symptoms varied in this series between 5 months and 49 years. The symptoms presented by the patients can be arranged in 3 groups:

A. Symptoms attributed to the infestation of the duodenum and gall tract.

B. Symptoms attributed to a wider infestation of the intestines other than the duodenum.

C. Systemic symptoms.

#### A-I

A. The symptoms attributed to the infestation of the duodenum and gall tract consisted mainly of painful manifestations, frequently associated with dyspeptic symptoms, as follows: 1. Severe pain, like biliary colic—seven patients complained of severe pain in the epigastrium and right hypochondrium, radiating to the back (3 cases) and to the right shoulder (1 case), with all the features of colics due to stones; one patient showed evidence of co-existing stones. Unhappily, the existence of stone in this case and the non-existence in the others could not be proved since their gall-bladders were not surgically removed to examine the contents.

Well performed radiologic examinations, only possible in 3 patients, were not of help: one showed good visualization with a normal gall-bladder shadow, and in the others there was no visualization of the gall-bladder by the contrast dye.

Only one patient presented in the sediment of the bile, cholesterol crystals (abundant) and calcium bilirubinate. This case continued to present colics after the removal of the parasites whereas 4 improved in which the treatment also brought disappearance of

the giardia. This coincidence of being the only patient that showed cholesterol crystals and calcium bilirubinate in the sediment of the bile and the only one of the group in which the long treatment directed against the giardia did succeed without disappearance of the symptoms, suggests the possibility of lithiasis; in this case the X-ray examination revealed no visualization of the gall-bladder.

If a patient complains of attacks of colics like these which occur with the finding of abundant giardia in the biles, and if these colics then disappear after the parasites are eliminated then the most logical standpoint is to infer this may be cause and effect. Of the seven patients two are still under treatment at this time.

Only further observation of such patients will show that this diagnostic inference is correct in as much as the history of these patients indicates that, in the large majority, there is a long interval between the painful crises. Therefore, there must be a long follow-up period of observation. For instance, female patient 394, until 2 years before the examination had had annual crises and, since then, had entered a quiet period; also case 557, a male, had had crises in 1912, 1920 and 1929; and female patient 439 had had, 6 years ago, a period of 12 days with colics and none since. Two other patients suffered crises recently and no conclusion, therefore, can be drawn. Only one patient, a male, had severe colics within an interval of 4 months, after driving through bad roads; this man was benefited by the treatment. No patient developed jaundice during the colics; only the female patient 394 observed herself moderate scleral jaundice.

With this frequently long interval between the colics we are prone to judge the results of treatment based upon the disappearance of collateral symptoms that annoyed the patient. These were mainly dyspeptic in nature. After meals they were apt to feel a sense of weight in the epigastrium (2 cases), fullness (4 cases), distress (3 cases); in two instances nausea and vomitus with relief of symptoms (in one the vomitus was induced); pyrosis and eructations (2 cases).

The radiologic examination of stomach and duodenum, performed according to Berg's technique in 5 of these 7 patients, gave normal results in 4 instances; in one—patient 292—was found a duodenal ulcer.

The physical examination in these cases was possible to be made during the colics in only two instances: the patients presented pronounced soreness in the upper abdomen and resistance of the parietes. Between the crises as made in the other 4 cases (not including the one suspicious of lithiasis) the examination revealed tenderness over the right upper quadrant in all cases and over the epigastric region in 3 cases; there was no evidence of enlargement of the liver. As advised by Crohn (3), we performed the Libman test (pain on pressure over the styloid process) to detect the sensitiveness to pain of most of these cases. Of these 6 patients, 4 had +++ and 1 had ++; one not performed. So, there is marked predominance of the hypersensitive type.

II. Upper abdominal pains, without the character of colics (6 patients) or during the interval of the colics (3 cases) were also found. The following distributions could be made:

a. Pain soon after meals, in two patients, localized in the epigastrium (radiating to the back in one

of them), accompanied by nausea, sense of fullness, pyrosis, vomiting with relief. Careful X-ray examination showed nothing abnormal in one of the cases in the stomach and duodenum. Physical examination revealed in both cases the epigastric and the gall-bladder regions painful on pressure. The Libman test, in one case + + +. Both are under treatment.

b. Late pains, in two cases, in these patients the pain appeared from 2 to 3 hours after meals, accompanied by distress, a sense of weight and fullness in the epigastrium. There was no relief with food. Sometimes the pain was continuous or appeared during the night. The X-ray revealed in one case a duodenal ulcer, and nothing abnormal in the stomach and duodenum of the other. The physical examination showed in both, the right upper quadrant painful on pressure; in one the epigastric region was also painful; there was no evidence of enlargement of the liver.

c. Irregular or continuous pains in the upper abdomen were found in 5 patients. In 3 instances there was radiation to the back. Two felt the pains also during the night. Only one had no digestive complaints. Of the other 4, 3 had sense of weight in the epigastrium after meals; 3 had a sense of fullness; one had eructations; one had pyrosis; and one vomited.

The physical examination during the pain crises was possible only in two patients. One had more severe pain in the left hypochondrium, radiating to the back; the other seen some hours after the onset of the pain, still had upper abdominal tenderness on pressure in the epigastric region and two, also, in the upper abdominal tenderness. Of the remaining 3 patients, all presented tenderness on pressure in the epigastric region and two, also, in the upper right quadrant. Of these patients but one presented evidence of slight enlargement of the liver (during the painful crisis). The radiologic examination of the digestive tract revealed in this group, intermittent duodenal stasis and appendicitis, one instance; "duodenitis descendens," 1 instance; organic duodenal stasis, 1 case; the fourth was normal.

III. Dyspeptic complaints, not associated with pain were presented by only one patient. These complaints (certain sense of weight after meals, fullness and distress) were very infrequent and slight; physical examination gave normal results. As shown above, the dyspeptic complaints were always associated with painful manifestations. This fact is to be emphasized.

#### B

Symptoms attributed to a wider infestation of the intestines were neither constant nor uniform. Of this series of 22 patients, 9 had regular bowel movements; 4 had alternation of constipation and diarrhea; 6 had attacks of diarrhea; 2 had moderate constipation.

During diarrhea attacks 3 had tenesmas. Frequency of evacuations was, during these attacks, variable (up to 20 times a day); the feces were watery or mushy, without blood (only once a patient noted some red streaking); the stool examination revealed some mucus in 6 cases.

The physical examination revealed a certain degree of spasticity of descending colon and sigmoid in 7 patients.

#### C

Systemic symptoms are rather polymorphous. Five patients had loss of weight; 3 complained of insomnia; 6 had nervousness and irritability; 5 had

headaches during the morning or associated with digestive troubles; 3 had hemicranial attacks coincident with digestive troubles.

Special attention must be directed to two cases in which the most striking feature was fever. The fever was irregular, appearing either during the morning or during the afternoon, oscillating up to 106° Fahrenheit; it lasted a variable number of days and disappeared without following any particular type. In one patient the fever lasted one month without interruption. Besides the fever, the patient presented pronounced weakness, uneasiness, vomiting, great loss of weight and diarrhea. A maximum of 20 movements a day was reached; stools were watery, with some mucus, but without blood. This puzzling picture challenged the most refined judgment, and plenty of tests were performed until the finding of the flagellates and proper treatment cleared the situation. One of the patients was seen during an afebrile period, but numerous giardias were found in his watery stools during the febrile period. The other case received, without benefit, quinine and arsenic, for the suspicion of malaria had arisen, although the examination of the blood for plasmodia was negative. There was no jaundice in either case. Reviewing the records of the other cases, in 4 instances it was found the incidence of fever not quite surely explained.

Of the series only a female patient presented jaundice, but not attributable to giardia. She was the third member of a family of two brothers I examined who had hemolytic jaundice. In her case all the features suggested a hemolytic origin of the jaundice.

Summarizing, the complaints that obliged the patient to consult the physician were: Painful manifestations in the upper abdomen, frequently associated with digestive troubles, in 13 cases; fever and diarrhea, 2 cases; diarrhea, 1; loss of weight, 2; slight and inconstant digestive troubles, 1. Three cases in which giardia could not be considered as being the cause were excluded (two with digestive symptoms and one with vertigo and diarrhea).

#### TREATMENT

While some authors either do not treat or give but slight treatment for giardiasis, considering it of no pathogenic importance, I insist upon using medicines, and in repeated intensive courses. After many trials and failures, I adopted the combination of neosalvarsan by vein, after a good drainage of the gall tract, and stovarsol and yatren 105 by mouth, intensively.

Neosalvarsan was used to combat giardiasis in 1917 by Yakimoff (4) in white mice. Hollander (5), in 1923, used it in 3 patients. Lyon and Sevalen (6) used drainage of the gall-tract and intraduodenal injection of neosalvarsan and other medicines.

Either etovarsol or yatren were used by Castex and Greenway, but in smaller doses than those used by me. Also attention should be directed to certain publications by Smithies (8) who first called attention to giardiasis of the gall-bladder and first suggested the use of arsenic and mercury (calomel) in therapy.

During the first period of the treatment (20 to 25 days,) when biliary drainage are performed at intervals of 5 days, followed by intravenous injections of neosalvarsan, I use stovarsol and yatren without the intervals that are advised by the authors. The biliary drainages, well done, help to detoxify the patients.

During the second period, when the drainages are done at longer intervals, for control purposes, the doses of stovarsol and yatren are much smaller and, as a rule, well tolerated by the patients.

Before beginning the treatment and during its administration it is necessary to take some precautions. Beside the accurate clinical general examination to detect some sign of intoxication (erythema, skin eruptions, suborbital edema etc.) some laboratory tests are indicated. In the blood, icterus index or Van den Bergh. In the urine, careful examination of the sediment of a fresh specimen for albumin, blood, urobilinogen, biliary salts and biliary pigments. At least these precautions have to be taken before each injection of neosalvarsan and, later, at monthly intervals, during the treatment by mouth.

#### TECHNIQUE OF THE TREATMENT

**First Period (20 to 25 days):** During the morning the duodenal tube is passed and, when in place, 30 c.c. of a 30% mg.  $\text{SO}_4$  solution are slowly introduced. The bile is allowed to drain, and instillations of 20 c.c. of the mg.  $\text{SO}_4$  solution are given in repeated doses, until no more concentrated bile is obtained. After this good drainage the tube is removed. An intravenous injection of 0.30 to 0.45 gm. of neosalvarsan is given. Two tablets of 0.25 gr. of stovarsol are diluted in half-a-glass of water and taken by the patient, who is sent home, being advised to have a certain rest and "light" diet. In this same day at 3 P.M. and before retiring he takes 3 pills of 0.25 gm. of yatren, each time.

This whole procedure is repeated every 5 days, although the flagellates usually disappear after the second or third drainage. It is advisable to administer 4 to 5 injections (always preceded by the drainage, well done) of neosalvarsan (0.45 gm.). This is important.

Between these seances of drainage—neosalvarsan the patient takes, daily: before breakfast 2 tablets of stovarsol; at 12 M. three pills of yatren; at 5 P. M. one tablet of stovarsol; being retiring, 3 pills of yatren. The appearance of diarrhea is not uncommon due to the use of yatren.

**Second Period:** After the last drainage—neo-

salvarsan seance the patient begins to decrease the doses of stovarsol and yatren. During the following 5 days he only uses 2 tablets of stovarsol on rising and 3 pills of yatren on retiring. After these five days he then uses 1 tablet of stovarsol while fasting and 2 pills of yatren before going to bed. The use of stovarsol and yatren in the last manner is carried on for 6 months. Control examinations of duodenal contents are made after 1, 2 6 and 12 months, at least.

#### RESULTS

It is too early to speak surely about the end-results of the treatment. The longest period of control we have is now only 7 months. But the patients, in the majority, feel well, the annoying symptoms disappear, and only upon repeated requests will they return for control examinations. Thus they appear to be clinically cured.

Of this series of 22 patients, 16 had followed the treatment in such a way as to authorize us to speak about results.

One patient continues to harbor the parasites; another also continues to be infested (in this case the initial dose of neosalvarsan was 0.15 gm., too little), these two patients did not use yatren.

In 14 patients it was possible to get the bile free from the parasites over a period now (February 1935) of seven months. Further examinations will show the possibilities of relapse, if such occurs.

**Accidents:** As a rule all this intensive treatment runs without accident. The beneficial effects of the well done drainages is to be recalled.

One patient developed jaundice during the treatment; the outline of the treatment was made by me but executed in a distant town by a local doctor. I had not sufficient data to judge this accident. It may have been an arsenical jaundice.

The subject of giardiasis is still open to discussion until further well conducted studies bring a better understanding of the clinical picture and the necessary treatment.

**NOTE:** I wish to express my thanks to Dr. B. B. Vincent Lyon, of Philadelphia, for his criticism and advice in the writing and arrangement of this paper.

## A Consideration of the Patient with Gastrointestinal Complaints but Who is Without Evidences of Organic Pathology\*

By

G. ALEXANDER YOUNG, M.D.

and

RICHARD H. YOUNG, M.D.

OMAHA, NEBRASKA

**T**HE intake of food, the processes of digestion and elimination play such important rôles in our existence as individuals that any disorder of these functions

\*From the Department of Neurology and Psychiatry, Univ. of Nebraska School of Medicine.  
Submitted, March 12, 1935.

assumes considerable importance. The complaints produced by dysfunction of the gastrointestinal tract are among the most common symptoms for which a patient seeks relief. So frequently are gastrointestinal complaints encountered, that it seems worth while to re-

formulate a plan for study of these cases and to consider particularly those cases who have complaints without evidence of organic disease.

In any medical case, the physician starts with certain facts, *i.e.*, the complaints as given by the patient. A scientific approach next leads us to consider the conditions under which the complaint developed, then the course, and finally the picture at the time of examination. These facts are further embellished by the data that are obtained from a past and family history. When the facts are assembled conclusions are drawn as to whether this is a case of a local disturbance or whether the symptoms are secondary to a more sweeping systemic disorder.

The above is a usual procedure which paves the way to a diagnosis. The final interpretation usually is in terms of some organ pathology or disease process which affects the function of the gastrointestinal system. The differential diagnosis in cases of abdominal distress is too long to consider here but our whole training as physicians (which has become more and more scientific) has developed the questionable habit of expecting to find something organically wrong in all of these patients. This attitude or habit of thought has, in turn, led to the subjection of countless patients to abdominal operative procedures which besides being unwarranted have been entirely devoid of any benefit, and at times harmful. These patients have been operated upon in good faith with the hope of finding the organic disease that was not discernible by the usual diagnostic methods.

Medicine tends to reduce disease to organ pathology with the interpretation of distress in relation to nearby referable somatic or visceral structures. We study "part" or organ functions but learn little about how they serve the individual in their reciprocal relations as integrated parts of the "he" or "she" we administer to as patients. A symptom such as vomiting or diarrhea is considered as a "non-mental" fact, a symptom produced by the disorder of an organ or system of organs. However, our knowledge of individuals, a knowledge usually not obtained in a medical amphitheatre, tells us that an anxious, fearful individual may have a diarrhea and that an individual who has experienced a sharp reaction of disgust may vomit. These facts we might call "mental" facts, or better "personality reactions", the reactions of the personality of an emotional nature to a situation of strain. It is with such facts that the physician must interest himself. Our present day mores, totems and taboos, the economic depression, the competition in work, and attempts to make a satisfactory marital adjustment are productive of situations of stress and strain and at times color our lives with rather unpleasant personality reactions. About one person in every seventy reacts in such a way to these strains that a period of care in a psychiatric institution is necessary at some time in his life.

As individuals we are so integrated that, in situations of strain, our bodies protest. Cannon and other physiologists have shown the sweeping physiological changes that accompany emotional states. Alvarez at the Mayo Clinic has done gastroenterology a great service by repeatedly emphasizing the fact that the emotional states affect the gastrointestinal tract and are productive of symptoms.

The question arises as to how the physician can utilize the fact that personality disorders play a role

in the production of gastrointestinal complaints. In the first place, there must be the realization that we are dealing with an individual who has certain complaints. These complaints must not be classified on the "either—or" principle, due either to organic or to functional cause. A patient may be anxious, tense, fearful of the future with an ulcer in his duodenum. It is important to consider all the facts both organic and functional.

In order to evaluate the rôle that the personality functions play it is necessary to quiz each case as to the personality reactions. This can be done simply without resorting to a formal mental status. Alvarez has found it very useful to ask his patients with gastrointestinal complaints if they have any trouble reading. This simple question usually reveals any thinking disorder. Thinking disorders are present in the schizophrenic disorders, the depressions and with many of the psychoneurotic difficulties. Lewellys Barker and others inquire as to the patient's mood or spirits. This usually allows some evaluation of the affective state; whether the patient is depressed, anxious, fearful or tense. Simple questions about worries or concerns, whether the patient feels the world treats him well and about sleep may be very informative. These very few interrogations may allow a formulation of the personality reaction and a classification of the reaction type which is responsible for a part or all of the gastrointestinal distress. Some of the more usual reaction types which furnish the basis for gastrointestinal complaints may be mentioned.

#### ANXIETY AND TENSION STATES

The anxious individual usually appears tense and concerned. He may be tremulous with perspiring hands. While the majority of the body complaints associated with this reaction type are above the diaphragm there may be certain symptoms referable to the gastrointestinal tract. A very frequent complaint is a tightness or constriction in the throat (*globus*) which at times is said to interfere with swallowing. Occasionally there are vague abdominal complaints of "gas" and epigastric discomfort. This may be in part due to an increased gastric acidity that at times is associated with an anxiety state. Diarrhea is another occasional accompaniment of anxiety and tension. Medical students each year develop gastro-intestinal complaints and even flares-up of ulcer under the stress of the examination period.

The production of gastrointestinal complaints in a situation of anxiety and tension is well illustrated by the following briefly reported instance:

L. B. A 25 yr. old farmer complained of gas and digestive distress. About a year ago he developed a vague mid-abdominal distress for which no adequate cause could be determined. This failed to yield to usual forms of treatment and during the winter an appendectomy was done with the thought that this organ might be at fault. The distress continued and in July of this year he sought out another physician who questioned him as to masturbation. The man admitted it and was then told that his prostate was about twice normal size, that he probably would have to experience a serious operation in years to come, that he should give up his plans for marriage and stop masturbating. The patient became rapidly worse and sank into a depression which allowed him little sleep, with more body complaints including a fullness in the rectum, thought of a self-condemnatory nature and a serious consideration of suicide. In going into the history we find that this man's initial gastrointestinal complaints came on in a situation of anxiety and tension. A year ago he was anx-

ious to marry a young woman in his neighborhood. The marriage had not been consummated because of financial difficulties and because of his own vague fears about his potency as a result of masturbation. He was haunted by some of the folklore which he had heard as a youth to the effect that he wasted a "seed" each time he masturbated and he was fearful that the supply had been exhausted. This anxiety plus the increased sex tension which developed as the result of the frustraneous sex excitement of the engagement undoubtedly were the main factors in the production of his complaints. In this situation appendectomy could offer little help. His interview in July only served to confirm his worst fears and the man slid into a depression which complicated his treatment immeasurably.

#### INVALID STATES

A second reaction type in which one finds gastrointestinal complaints is the invalid state. This is the so-called hypochondriasis of a simple type, invalidism without any depression or evidence of a more sweeping disorder. The invalid is one who is greatly preoccupied with his or her body complaints. The complaints are almost delusional in type and attributed to effects of exaggerated disorders of the gastrointestinal tract. The patient is not infrequently the victim of infection with an organic diagnosis, is bound down by "adhesions" to habits of invalidism, is very inactive, excessively particular about the diet, imposes upon himself long periods of bed rest and enjoys the satisfying attention of friends, neighbors and family.

#### DEPRESSIVE STATES

A third personality reaction type productive of gastrointestinal symptoms is the depressive state. The person depressed is slowed down, feels "low," "sad," "unhappy," or "blue." There are usually the physiological accompaniments of constipation, poor sleep, appetite and weight loss. Henry and others have shown the physiological changes in the gastrointestinal tracts of depressed patients that cause the abdominal distress that is frequently present. It is surprising how frequently the depressed patient complains of poor appetite, constipation and "gas on the stomach." Occasionally cases are seen where the gastrointestinal complaints are present before the mood disturbance is noticeable. Such cases are spoken of as having gastrointestinal "equivalents" of depression. The abdominal distress is a visceral expression of the mood disorder. A case under observation this past year illustrates this point.

H. R. is a 47 year old business executive who a year ago began to complain of digestive distress of the so-called ulcer type; the distress came on several hours after meals and was relieved by eating or soda. He did not respond to the usual Sippy *regime* and some months later because of poor sleep and weight loss he sought psychiatric consultation. When examined he was found to be tense, anxious, depressed and fearful that he was going through a depression such as he had experienced fifteen years before. He became more depressed and as the mood disturbance came to the foreground the digestive distress disappeared. The gastric analysis showed a rather marked hyperacidity at the onset. A gastro-intestinal Roentgen series showed no evidence of an active ulcer and a cholecystogram was normal. The depressed period lasted a matter of six months and gradually disappeared. However, after the mood became normal, the gastrointestinal complaints reappeared. After a difficult period these in turn faded. Here we find digestive distress ushering in the depression as an "equivalent" and reappearing at the end of the illness to disappear with complete recovery.

Other personality reaction types may feature gastrointestinal complaints. One should mention the schizophrenic reactions, those queer, twisted types, and where there are complaints of a *bizarre* nature or those which have an odd ring, e.g., "feel as though there is something firey that runs from one side of my abdomen to the other and then shoots out my rectum," one should be suspicious of an underlying schizophrenia. The same would be true where one encounters an empty, flat, abdomen with hypochondriacal harping on certain digestive complaints.

#### TREATMENT

Physicians everywhere have a tendency to rationalize their own lack of interest in the so-called "functional" cases by the thought that little can be done for them. Too often the symptoms are passed off as "imagination" or there is a careless reduction of the difficulty to some organ pathology even though none is found. The majority of these cases can be handled by the general practitioner if he will but interest himself in their care.

Treatment cannot be based solely upon management of the alimentary tract or treatment directed to any given organ. It is necessary to treat the individual and the personality reaction. In doing this perhaps the best help is to provide the patient with an opportunity to talk. In our present day handling of the behavior disorders there is too often a tendency to disturb the patient by an aggressive search for sexual difficulties. This may be harmful particularly in the major mental illnesses and cause the patient to erect a defensive wall to further questioning. This tendency has developed as the result of attempt to obtain rapidly a finished dynamic picture which satisfies the etiological needs of the physician but which is of no consolation to the patient.

Once *rappport* has been established and examination has shown there is no evidence of a disease process then the diagnosis should be stated in unequivocal form. The interpretation of the illness must of necessity depend upon the intellectual assets of the patient. His difficulty should be explained to him as a personality reaction to a situational strain causing emotional features and nervousness that so affects the body physiology as to cause symptoms of distress. The digestive distress may be termed the body's protest to a situation of strain. Reassurance should be given and if the dynamic factors are forthcoming, a common-sense discussion of these factors will be of benefit. The simplest methods of treatment are sometimes the best and simple types of regulation with removal of the patient from the situation of strain may afford great help.

In the case of the invalid one should attempt to break up the "adhesions" which bind the patient down. The patient should be given a regime of activity that fills the day. This requires careful thought and imagination on the part of the physician.

Where the symptoms appear in a depressive setting the problem is more difficult. A depressive reaction always is charged with the danger of self-destruction and every depressed patient should be considered a suicidal risk. For this reason such cases are best cared for in specially equipped hospitals. Medical treatment in the form of broken doses of barbitol or its derivatives is indicated. Mineral oil usually corrects the constipation. A high caloric diet should be

forced when there is weight loss. Hydrotherapy in the form of tubs or packs is indicated to relieve tension. A probing into psychogenic factors had best be avoided early in the treatment for fear of stirring up material that cannot be digested in a depressed state.

In cases where the gastrointestinal complaints are features of a schizophrenic reaction type the patient will need care in a psychiatric hospital.

Medicine should be used sparingly and when given the reason clearly stated. Bromides must be used carefully because of the danger of a bromide intoxication with delirium. This is particularly true in cases where there is any cerebral vascular pathology because bromides have a depressive effect upon the vascular system and these individuals show signs of intoxication with rather small amounts of bromides.

## SUMMARY

In summary, it is urged that in consideration of any case with digestive complaints the attempt be not made to reduce the condition to an "either—or" basis. Cases are not either organic or functional. In any diagnostic problem one must consider all the facts, non-mental and mental; facts dealing with organ functions and personality functions. To do this one must make inquiry as to the mood, as to whether there is thinking difficulty and as to the thought trend. If there is some personality difficulty it can best be reached by studying the conditions and situations in which it developed. The care of the milder forms of disorders can be best handled by an acute interest in the difficulty, by providing the patient opportunity for discussion and by the use of common sense and a certain imagination in management.

## Non-tuberculous Mesenteric Lymphadenitis in Childhood\*

By

LOUIS H. SEGAR, M.D.

and

B. D. ROSENAK, M.D.

INDIANAPOLIS, INDIANA

**M**OST physicians have seen children who complain of abdominal pain and other gastro-intestinal symptoms which are due apparently to intra-abdominal disease and yet defy satisfactory diagnosis. These cases may suggest the presence of any of several disorders, but most often they simulate appendicitis. We believe these gastro-intestinal disturbances to be more often associated with mesenteric lymphadenitis than is commonly supposed.

Tuberculosis of the mesenteric lymph nodes, known for many years as *tuberculosis mesenterica*, is a commonly acknowledged cause of acute abdominal symptoms. Less has been written of non-tuberculous mesenteric lymphadenitis. This condition was known to physicians of the past as "strumous abdomen" and was given credit for its ability to mimic most intra-abdominal diseases. However, Braithwaite and others deny that non-tuberculous mesenteric lymphadenitis exists as a cause of abdominal symptoms.

Heusser has reported 40 cases of mesenteric lymphadenitis in which tuberculosis was carefully ruled out by negative guinea pig inoculations, negative cultures and negative anti-formin examinations. Speese has seen 57 cases in which the glands removed at operation were non-tuberculous. In 281 routine autopsies at the James Whitcomb Riley Hospital for Children there were 32 cases or 11% which showed non-tuberculous hyperplasia of the mesenteric lymph nodes. In this group there was a high incidence of previously existing entero-colitis. Irwin found enlarged mesenteric lymph nodes in 53 of 375 patients operated on for various abdominal conditions. Clute states that only 18—

22%—of the mesenteric nodes examined from the autopsy material at the Lahey clinic were tuberculous.

Non-tuberculous mesenteric lymphadenitis is seen most often in childhood. The ages in the group here reported were from 2 months to 12 years. Of Heusser's 40 cases, 29 were in children under 15. More than 50% of Speese's patients were under 12. Alvarez has, however, seen several cases in adults.

## PATHOLOGIC ANATOMY

The lymph nodes of the terminal ileum, cecum and appendix lie along the mesenteric attachment of the viscera and drain into the regional nodes between the leaves of the mesentery. These are the nodes most frequently involved in both tuberculous and non-tuberculous mesenteric adenitis. The direction of lymph flow is upward into the *cysterna chyli*. These glands constitute a part of the lymphatic system of the bowel which consists of the lacteals of the villi, Peyer's patches and the lymph vessels which drain into the mesenteric nodes. A striking analogy between the gross relationship of the units of the lymphatic system of the intestine and mesentery to those of the pharynx has been observed by Wilensky and Hahn. Alvarez quotes Adami as showing that bacteria and other material can be transmitted through the wall of the intestine by this lymphatic system in the absence of any lesion of the mucous membrane. Short and Speese have also pointed out that the normal bowel wall is permeable to bacteria. They state that the function of the mesenteric nodes is to deter bacteria and other foreign material which come from the intestines in the afferent lymph vessels. As in the cervical region, these nodes will remain normal as

\*From the Indiana University School of Medicine and Hospitals, Indianapolis.  
Submitted, March 16, 1935.

long as they are not overburdened with infectious material.

For many years physicians have regarded infections of the mesenteric lymph nodes as always being of tuberculous origin. It has been the general belief that this disease was due to bovine tubercle bacilli which gained entry to the alimentary tract in contaminated milk or food, or to human tubercle bacilli swallowed in the sputum from pulmonary lesions. Braithwaite maintains that all mesenteric lymphadenitis is tuberculous. He explains the simple inflammatory changes which are frequently encountered as being due to very early tuberculosis. Speese quotes Symmers as saying that the simple hyperplastic changes are due to the toxins of the tubercle bacilli. There is no doubt that tuberculous mesenteric lymphadenitis exists, and that the mode of infection might well be as described. But glands which are readily susceptible to this type of infection could hardly escape occasional infection by other pathogens which are even more abundant in the gastro-intestinal tract than the tubercle bacillus. The frequent association of abdominal symptoms in children having upper respiratory tract infections suggests strongly that the source of infectious material is the swallowed secretions from the nose and throat. Histologic examinations of large numbers of glands removed at operation consistently have shown simple hyperplastic changes with no evidence of caseation or tubercle formation. Bacteriologic studies likewise have been negative for acid fast bacilli in most cases. However, bacteriologic examinations in definitely non-tuberculous glands have not been very illuminating. In most instances no organisms have been recovered. Brown has mentioned cases in which streptococci have been found and he advises against the removal of glands for examination in these cases because of the danger of producing a peritonitis.

The favorable therapeutic results in many mesenteric adenopathies by laparotomy and general medical after care argue emphatically that the glanular involvement was not due to tuberculosis. Another consistent observation in these cases is the concomitant absence of a pulmonary tuberculosis; although Carson maintains that mesenteric lymphadenitis may constitute an independent focus of tuberculosis in the body. The undoubted occurrence of inflammatory processes involving mesenteric lymph nodes in very young children who have no history of tuberculous contacts and having negative intra-cutaneous tuberculin tests is conclusive evidence that infection of the mesenteric nodes is not always tuberculous.

The most frequent site of hyperplasia of the mesenteric glands is at the ileo-cecal angle. The reasons advanced by Clute, Speese, McFadden and others for this localization of the infection is that there is a greater concentration of bacteria in the bowel contents at this point and that the fecal flow is at low ebb. Others have speculated as to the part that the appendix might play in making this the site of predilection. Wilensky and Hahn regard the appendix as insignificant in the etiology of non-tuberculous mesenteric lymphadenitis. The majority of the cases reported in the literature had no significant pathologic changes in the appendix. Of the cases reported in this paper only one showed any inflammation in the appendix and that was an old inactive lesion. Most surgeons of experience have confirmed this observation. Nevertheless, Higgins quotes reports of 4 cases of suppuration of

the mesenteric lymph glands secondary to appendicitis, and Lamson has seen a case of acute mesenteric adenitis complicating an acute appendicitis. It is probably safe to conclude that mesenteric lymphadenitis does not often complicate appendicitis, and that this organ has nothing to do with the usual site of mesenteric lymphadenitis in the ileo-cecal region. Turberville has seen 2 cases of suppurative lymphadenitis in the mesentery of the left side of the abdomen. In the group of cases seen personally the glandular involvement was widespread throughout the abdomen in all of the younger children and was definitely localized in the right iliac fossa in the older ones.

The exceeding rarity of inflammation of the mesenteric lymph nodes in appendicitis has been pointed out. The occurrence of this type of lymphadenopathy in the absence of demonstrable lesions in the wall of the intestine itself is seen in this series of cases and has also been noted frequently by other writers. There remains for discussion the relationship of hypertrophy of the mesenteric lymph nodes to diseases involving the small intestine. Sporadic reports of cases of hypertrophic enteritis of the small intestine of a non-tuberculous nature dot the literature for many years. In 1932 Crohn and his associates reported a group of cases in which the pathological and clinical unity of a certain type of non-specific inflammation of the small intestine was clearly demonstrated. This disease has been termed "regional ileitis". In this group there was a constant thickening of the mesentery of the ileum and a simple inflammatory hypertrophy of the ileo-cecal lymph nodes. Most of the cases which we are reporting had no evidence of ileitis at operation or at autopsy. The last case cited falls into the group in which a definite inflammation and thickening of the terminal ileum was found. This case must be regarded as one of "regional ileitis" with secondary lymphadenitis leading to suppuration and mesenteric thrombosis. Since the description of this disease the diagnosis is being made with increasing frequency due to the greater care that surgeons are taking in exploration of the small intestine.

A. Rendle Short has specified that a normal mesenteric lymph node should be soft, discreet and no larger than a pea. It is impossible to make this description fit all normal mesenteric nodes. They may be considerably larger than Short specified and yet show no gross or microscopic pathologic anomalies. The gross pathologic abnormalities that may be encountered vary greatly. The glands may be markedly enlarged and reddened and yet be discrete. Such glands are usually the seat of an acute non-tuberculous infection; probably in most instances due to one or more of the pyogenic cocci. Others, of a more chronic type, are firm and matted together. These glands do not show caseation or tubercle formation. Frank suppuration of the nodes though rare has been reported by Turberville and by Higgins and was seen in one case of the present group. Calcification is regarded by Wilensky and Hahn as the terminal stage of all mesenteric adenitis whether tuberculous or not.

#### CLINICAL MANIFESTATIONS

*Pain* is the most constant and characteristic symptom of mesenteric lymphadenitis. Leonard Freeman in 1923 stressed the surgical significance of the condition and emphasized that abdominal colics were the most important and distinguishing feature of

the syndrome. He mentions that violent spasms of the bowel may be seen upon handling them during operations, and considers that the adenitis produces an irritability of the mesenteric nerves. Kiss, in a study of the relationship between nerve plexuses and lymph nodes of the abdomen, found that the mesenteric nodes follow the course of the superior and inferior mesenteric arteries and are found close to and often among the nerve fibers. He states that because of this anatomic association inflammation of these nodes may cause pain as well as functional disorders of the associated viscera. In addition to pain produced by intestinal colics the mesentery itself is able to cause abdominal pain. It is easily demonstrated that the abdominal viscera may under ordinary conditions be very roughly handled without producing pain, whereas the least pull or stretch of the mesentery is extremely painful. Thus, an infant with an intussusception is comfortable with a swollen engorged loop of bowel until a peristaltic wave attempts to pass and produces a strain on the mesentery. The mode of production of pain in mesenteric adenitis is by irritation of the Pacinian bodies which are the sensory nerve endings in the mesentery.

### CASE REPORTS

*Case 1.*—The first patient to be reported is a case in point. A boy 7 years old was brought for examination with the following history: Since infancy he had had many recurrent gastro-intestinal upsets with more or less abdominal discomfort of an indefinite sort, with vomiting and moderate rise of temperature. He had been a difficult feeding problem, had gained poorly and had had abdominal colic. He never had anything, however, that could be construed to be an acute enterocolitis. Of late his attacks had changed in character, and the father described them as follows: "Two or three times a week after taking a few mouthfuls of food he would double up with pain, become deathly pale, and have to lie down for a short while to gradually recover."

On physical examination the patient was pale and undernourished; the oral temperature was 100.2; his abdomen distended but without localized tenderness or palpable masses. The Mantoux test was negative and his leucocyte count was moderately elevated. A *gastro-intestinal X-ray study* was non-informing; repeated examinations of the urine made renal colic improbable.

After several weeks of observation and treatment by rest, a careful dietetic regimen, and good elimination, which failed to alter the condition of affairs, an exploratory laparotomy was done based upon a tentative diagnosis of chronic mesenteric lymphadenitis. Large masses of glands, matted together by adhesions, were found. One of them was removed for biopsy and a normal looking appendix was removed. There was no caseation or tubercle formation in the gland and the pathologist reported "a non-tuberculous inflammatory process." The boy made a good post-operative and subsequent clinical recovery.

*Case 2.*—In many ways this was similar to the first; a girl, age four, whose mother, prior to marriage, had been operated upon for tuberculous peritonitis. This child ran a slight fever, had mild attacks of colic, but nothing comparable with the agonizing pain of the boy just described. Her chief symptom was vomiting; this had occurred of late associated with anorexia, considerable loss of weight, extreme abdominal distension and increasing pallor. The intra-cutaneous tuberculin tests in increasing concentration uniformly were negative, which did not convince her mother that the child's condition was in any wise different from what she herself, had experienced during her girlhood. It was chiefly through the mother's insistence that a laparotomy was performed. A non-tuberculous mesen-

teric lymphadenitis was found, a normal appendix removed and this child, like Case 1, made an uneventful post-operative and clinical recovery.

Hyperirritability of the mesenteric nerves as a result of mesenteric adenitis is known to be capable of producing spasm of certain loops of the intestine. Freeman likens this condition to pylorospasm and speculates on the part that such intestinal spasm may play in the mechanism whereby intussusception is produced. Also, he regarded this condition as a potential cause of spastic ileus. Symptoms of obstruction may occur in cases of mesenteric lymphadenitis. Clute and also Wilensky mention the possibility of obstruction of the bowel by adhesions, or by compression due to enlarged mesenteric nodes. Appelmans, in a study of 29 cases of duodenal obstruction, found one case in which the obstruction was caused by the compression of an enlarged lymph node. Danis has reported three cases of compression of the duodenum from lymph nodes in the mesentery. In all three of these cases duodeno-jejunosomy was necessary to relieve the obstruction.

The next two of our cases demonstrate upper intestinal obstruction due to spasm secondary to mesenteric lymphadenitis.

*Case 3.*—A child when two month's old was first seen because of vomiting. He had been breast fed for 6 weeks and then had been put on a nutrient formula. The vomiting began during the breast feeding period and had grown worse on artificial feeding. The boy's rectal temperature consistently was a somewhat over 100° F. His abdomen exhibited visible peristalsis, but no tumor could be felt and at no time, during the period of medical treatment for what was diagnosed as pylorospasm, did the patient pass "starvation stools". He retained food with the aid of atropine, lavage and refeedings sufficiently adequate to enable him to gain slightly in weight. By the time the lad was 5 months old however, all concerned were so discouraged with his lack of progress that they were willing to attempt relief by surgical intervention. A marked mesenteric adenitis was found. Associated with it, however and with no demonstrable lesion at the pylorus, the surgeon described a moderate dilatation of the duodenum and a spasticity of the jejunum and upper ileum. The post-operative course was uneventful, but his clinical condition was in no way improved. Vomiting continued and within a few weeks after operation became "bilious". Huge amounts of bile stained fluid were vomited every few days. At the age of 8 months a gastro-enterostomy was done with a view to side-tracking the dilated duodenum. At the second operation the mesenteric adenitis had not changed from the condition found previously. During the following months the patient's abdomen was daily exposed to ultra-violet radiation and several X-ray exposures in an endeavor to influence the mesenteric adenitis. He gradually improved, but it is difficult to decide whether or no the therapy he received influenced his recovery.

*Case 4.*—A 5 months' old baby who had never done well. This infant vomited both when on breast and artificial feeding. The baby cried a lot and had a slight fever most of the time. The abdomen exhibited marked visible peristalsis; as was Case 3, this patient likewise was diagnosed, pylorospasm. The child was put on thick cereal feedings and luminal but without improvement of its condition. In an effort more accurately to make a diagnosis, barium meal was given; this showed that there was no pyloric obstruction, but actually a very marked gastric hyperperistalsis which rushed the meal through the stomach and duodenum only to have it meet what seemed to be a real obstruction in the upper ileum. Immediate operation was advised. The family procrastinated but was willing to leave

the baby in the hospital for the administration of fluids, parenterally. This was done for 24 hours when the baby's abdomen became tremendously distended and the patient passed into collapse. When seen within a quarter of an hour of this occurrence it was obvious that the infant had suffered an acute gastric dilatation. A tube was inserted and an enormous amount of fluid was aspirated from its stomach. The subject's condition improved, but the dire catastrophe just averted served to bring about the family's ready acquiescence to surgery. Under local anesthesia the abdomen was opened. A spastic ileum, associated with a very marked and widespread mesenteric adenitis, was found but no other lesion. There were no congenital peritoneal bands or adhesions, or any pathology other than that described to account for the condition. Post-operatively, the baby was transfused and parenteral fluids were administered. Its stomach however, never regained normal motor function. Food introduced by gavage could be removed hours later supplemented by great amounts of fluid which had collected in the stomach. At autopsy no pathology other than that found at operation could be demonstrated. The adenitis was of the non-tuberculous type; gross and microscopic examination of the intestinal wall showed nothing pathological.

Most writers on the subject of mesenteric lymphadenitis call attention to the readiness with which the condition can be confused with acute appendicitis. McFadden attempts to point out a distinguishing characteristic in the localization of tenderness. He says that in mesenteric adenitis the point of maximal tenderness is not at McBurney's point, but is higher and more medial. Also he states that the lateral, sacral glands often are involved and may be felt along the lateral wall of the pelvis on rectal examination. Recently Karger has described a method of deep "gliding palpation" in which the abdominal contents are palpated against the spinal column. This, he claims, enables one to determine the presence or absence of enlarged abdominal lymph nodes. None of these suggestions has proven of particular helpfulness in the personal experience of the Authors. The two instances which follow are recent ones in which the diagnosis of acute appendicitis definitely was made and at operation acute lymphadenitis was found.

*Case 5.*—A girl of 12 was seen in the evening of a day that illness had been ushered in by chilliness and nausea; these symptoms followed by vomiting and acute abdominal pain. Her oral temperature was 102° F. She was definitely tender in her right lower quadrant and her right rectus muscle was rigid. A moderate leucocytosis was recorded. There was no preoperative doubt of a diagnosis of acute appendicitis and no hesitation in recommending surgery. At operation however, the appendix proved to be long but otherwise normal but about the ileo-cecal junction was a mass of swollen, reddened, discrete and soft mesenteric glands. The child recovered without incident. The glands histologically were negative for tuberculosis.

*Case 6.*—A girl of 12, gave a history of recurrent attacks of abdominal pain for several months; these were associated with anorexia, fever and vomiting. The attack in which she was seen had had its onset a few hours before and was more severe than had been any previous experience. Her physical signs were sufficiently typical to warrant concurrence with the attending physician's diagnosis of appendicitis. The appendix undoubtedly was the scene of previous conflict. It was bound to the cecum by dense adhesions but was not acutely inflamed and it is doubtful if it played any part in the production of the symptomatology which led to laparotomy. There was a group of acutely inflamed mesenteric nodes in the ileo-

cecal angle which probably were the cause of the acute abdominal upset. These glands showed only simple inflammatory changes on microscopic examination.

*Case 7.*—Demonstrates a different type of mesenteric adenitis in which there were unusual complications. The patient, a boy age 6, was admitted to the hospital for a study of his asthma. Almost a month after admission he, as were six other children on the ward, was seized with a febrile illness associated with abdominal pain and leucocytosis. The other children never presented definite physical signs other than fever and all recovered after three or four days. All were diagnosed as influenza with abdominal symptoms due to mesenteric lymphadenitis. This particular patient, however, continued to have symptoms. His abdomen was distended and generally tender, but at first without localization of pain or tenderness. Vomiting was frequent. The temperature was at first remittent in type and the rises were occasionally associated with chills. After the first few days the temperature became more constant and reached 105.6° F. On the tenth day, the abdominal pain became more severe and the patient looked considerably worse; a firm, tender mass was palpable in the right lower quadrant. He was operated upon with a tentative diagnosis of appendiceal abscess. At first a McBurney incision was made but the cecum could not be found. A small loop of inflamed intestine was delivered. A large mass then was palpable toward the mid-line. A right rectus incision next was made and after considerable difficulty the small bowel was freed from a mass of adhesions. It was markedly inflamed and was very thick and leathery in consistency. A large mesenteric node was found; evidently this had suppurated and had become surrounded by a thick exudate. All of the mesenteric vessels examined were thrombosed. No gangrenous bowel was noted. The abdomen was closed with ample drainage; the child recovered after a stormy convalescence. Since that time he has been free from marked abdominal symptoms although he has occasional abdominal cramps. Otherwise he is well and in good nutritional condition.

This case demonstrates several important features of the clinical and pathological picture of mesenteric lymphadenitis. It is an extremely variable syndrome and may be a serious one. Case 7 illustrates, first, that mesenteric lymphadenopathy may complicate an inflammatory disease of the intestinal wall itself, in this instance regional ileitis. The lymph nodes may, but fortunately do not often, suppurate. Peritonitis may result in those cases in which the nodes break down. Whether mesenteric adenitis may be one of the underlying factors in the etiology of so called idiopathic peritonitis is a question which cannot be answered. Another possible pathologic complication of mesenteric lymphadenitis, which was demonstrated by Case 7, was mesenteric thrombosis.

#### COMMENT

The surgical importance of mesenteric lymphadenitis has been stressed by almost all writers whose work has been quoted in this report. The advisability of surgical intervention in any instance of intra-abdominal disease which suggests the probability of appendicitis cannot be doubted. Dr. Holt has said, "in appendicitis in children all signs fail". The impossibility of diagnostically eliminating appendicitis in most cases of mesenteric lymphadenitis without a laparotomy would appear to make operation imperative in practically every instance. The responsibility of not operating upon a case of appendicitis because of confusion in this difficult differential diagnosis is too great to be assumed by any physician. A large num-

ber of cases of simple mesenteric adenitis seem to have been cured by simply opening the abdomen. Explanation for the efficacy of this procedure is lacking, but there is much evidence that relief from symptoms occurs following post-operative recovery in definitely non-tuberculous patients.

After-treatment, consisting of general hygienic management, rest and proper diet, and of ultra violet

and X-ray exposures of the abdomen, has been carried out by most physicians who have reported cases of non-tuberculous mesenteric lymphadenitis. Whether the medical care or the surgery has been the beneficial agent in these children may not be stated on the basis of proof. Hence until the diagnosis of non-tuberculous mesenteric lymphadenitis can be made with more certainty than now, surgery must not be withheld.

## ABSTRACTS

E. S. EMERY, JR., AND R. T. MONROE.

*Peptic Ulcer. A Study of 1435 Cases. Arch. Int. Med.*, 1935, Vol. 55, p. 271.

This study of a large group over a long period shows that the disease tends to persist through life when once established. The cause of ulcer remains unknown. The disease is rarely fatal, and does not generally shorten life, and in the average case does not tend to get worse as time goes on.

None of the present medical or surgical methods of treatment, no matter how strict, do more than help to induce remissions. Surgery produces longer intermissions, but has a definite mortality and mechanical and chemical complications. A plan of treatment is offered to produce the best result at the least cost. Its chief aspect is prevention of a relapse by lessening fatigue, worry and infection. Surgery is used only to close a perforation, to relieve permanent obstruction (with over 40% 6 hour barium residue) to overcome a tendency to bleed, and in cases of suspected malignant degeneration. The patient should have complete medical treatment and follow up after operation. Periods of hypersecretion call for special medical care. Operation at this time is disastrous.

Franklin W. White, Boston.

OTTENBERG, REUBEN.

*Painless Jaundice. J. A. M. A.*, 194:1681, May 11, 1935.

In the majority of cases of jaundice the diagnosis is not difficult. In the remaining 20 to 30 per cent of the cases, however, there is no laboratory or clinical method of distinguishing whether we are dealing with an obstructive or a toxic type of jaundice.

The history is generally more helpful than the physical examination. The determination of whether bile is enter-

ing the intestinal tract is useful. The author has found the icterus index more accurate than the van den Bergh test in the estimation of the bilirubin of the blood. Extremely high levels of blood bilirubin most commonly occur in hepatic degeneration.

In obstructive jaundice the blood cholesterol is usually high. In hepatic degeneration the blood cholesterol is generally low.

The positive galactose test indicates hepatic degeneration.

The differentiation as to whether the case is a medical or a surgical one is important. Surgery should be done early.

In the medical treatment the high carbohydrate diet seems protective. Reduction of protein in the diet seems to have experimental backing. Drugs are apparently of no importance. Cathartic treatment should not be pushed too vigorously. The use of bile salts and other cholagogues is not advocated.

Francis D. Murphy, Milwaukee.

GARDNER, JR., CLARENCE E., AND HART, DERYL.

*Enterogenous Cysts of the Duodenum. J. A. M. A.*, 104:1809, May 18, 1935.

The authors report a case of a cyst of the duodenum which was successfully treated surgically by anastomosis between the cyst and the duodenal lumen. The authors review six cases of cysts of the duodenum from the literature. The mortality in these six cases was 100 per cent. No case has been diagnosed before operation or autopsy. Three of the collected cases were treated surgically.

The probable origin of the cyst is from an embryonic diverticulum.

Francis D. Murphy, Milwaukee.

## SECTION II—*Experimental Physiology*

### The Effect of Oxygen Inhalation on Gaseous Distention of the Stomach and the Small Intestine\*

By

JACOB FINE, M.D., JOHN B. SEARS, M.D.

and

BENJAMIN M. BANKS, M.D.

BOSTON, MASSACHUSETTS

IN a previous communication (1) it was demonstrated that nitrogen and hydrogen constitute the major portion of the gases responsible for gaseous distention of the stomach and small intestine. There is urgent need for a more effective method of eliminating these gases than is now available. A possible answer to this problem is suggested in the work of McIver, Redfield and Benedict (2) who found that a loop of small intestine distended with nitrogen can be deflated more rapidly if the animal is allowed to breathe pure oxygen instead of air.\*\* This is attributable to the resulting elimination from the blood of the nitrogen dissolved in it, thus permitting diffusion of this gas from the intestine into the blood in accordance with the law that, other things being equal, the rate of diffusion of a gas across a semi-permeable membrane is proportional to the difference in the partial pressure of the gas on the two sides of the membrane.

The present study comprises an extended series of observations along similar lines for the purpose of establishing a broader basis for the application of this principle to the clinical condition of intractable distention.

#### METHOD

Cats were starved for a minimum of 24 hours so that the stomachs and the small intestines were found free of gas and fluids when the experiments were started. Through an abdominal incision under nembutal anesthesia a ligature was placed around the cardia, pylorus and ileocecal valve without disturbing the circulation. The entire stomach or small intestine or both, if empty and collapsed, were then inflated by means of a gas-filled leak-proof syringe and needle with a carefully measured volume of gas sufficient to produce moderate or severe distention. The hole made by the needle was effectively sealed by squeezing the gut between the fingers. The abdomen was closed. "Commercially pure" oxygen was then supplied under atmospheric pressure through a tracheal cannula connected with one way Tissot valves for inspiration and expiration. After periods varying from six to twenty-four hours the

animals were sacrificed and the residual gases removed, measured and, in some instances, analyzed by means of the Van Slyke manometric apparatus with an attached combustion chamber for hydrogen determinations. The results were compared with controls treated in the same way but breathing air instead of oxygen.

When the empty gastro-intestinal tract is inflated with a pure gas, diffusion of other gases ( $\text{CO}_2$ ,  $\text{O}_2$  and  $\text{N}_2$ ) from the blood into the intestine immediately takes place, so that the residual gas removed at the end of any given period is a mixture of gases. In the subsequent text it will therefore be necessary to distinguish between the change in *total gas volume* and that of the pure gas originally injected.

#### RESULTS

1. *A comparison of the effect of breathing pure oxygen with that of air on the change in total gas and nitrogen volume in the small intestine distended with nitrogen and ligated at the pylorus and ileocecal valve—Table I, Figure I.*

The small intestines of four cats were inflated with volumes of nitrogen varying from 75 to 130 c.c. The cats then breathed 100% oxygen for approximately six hours. The residual gas volumes were 67, 74, 81, and 88 percent respectively. For corresponding control animals of equal weight and approximately equal volume of injected gas, but breathing room air, the results were 82, 106, 112, and 109 percent respectively. Oxygen inhalation for six hours, therefore, caused an average *decrease* in total gas volume of 18% as compared with an average *increase* of 2% when the animal breathed air.\* From analyses of intestinal gases made by other observers (2) and from several listed in Table I it appears that about 90% of the residual gas is nitrogen, the remainder being nearly entirely oxygen and carbon dioxide. The residual volume of nitrogen is therefore some 10% less than these figures for total gas volume. In terms of nitrogen the average decrease equalled 26.2% in the "oxygen cats", as compared with 8.2% in the "air cats", or an acceleration in the rate of nitrogen absorption of 320% as a result of the use of oxygen.

\*From the Surgical Laboratory of the Beth Israel Hospital and the Harvard Medical School, Boston, Massachusetts. The expenses of this investigation were provided by the DeLamar Mobile Research Fund, Harvard Medical School.  
Submitted April 3, 1935.

\*\*Thus in a 30 cm. loop of small intestine containing 20 c.c. of nitrogen, 7.5 c.c. were absorbed in 6 hours if the animal breathed air as compared with 10.2 c.c. if the animal breathed pure oxygen.

\*This increase is due to the diffusion of oxygen and carbon dioxide from the blood into the gut in greater volume than of nitrogen out of the gut into the blood.

\*Approximately same weight for both cats in each experiment.

\*\*Calculated on basis of gas analyses in Exp. 9, 11 and 14 and from data in literature showing that residual volume of nitrogen constitutes approximately 80% of the total gas volume.

\*\*\*2% increase due to diffusion of O<sub>2</sub>, CO<sub>2</sub>, and N<sub>2</sub> from the blood into the intestine. See gas analyses in column labelled remarks.

When the same experiments were repeated for periods of 12, 18, and 24 hours the percentage absorption of total gas and nitrogen volume increased with the time.

In summary the results show that:

(a) In cats breathing air the *total gas volume* in the small intestine is reduced 13.1% within 12 hours. During the subsequent twelve hours however diffusion of gases from the blood into the intestine apparently exceeds absorption of gases from the intestine into the blood because the reduction in total gas volume equals only 3.4% after 24 hours.

(b) On the other hand, in cats breathing oxygen a progressive decline in *total gas volume* in the small intestine occurs until a maximum reduction averaging 59.2% is reached in 24 hours.

(c) When air is breathed, the average decrease in volume of nitrogen in the small intestine after 12 hours equals 21.1%. After 24 hours this decrease equals only 12.9%.

(d) When oxygen is breathed, an average of 44.9% of the nitrogen in the small intestine is absorbed dur-

ing the first twelve hours. An additional 17.4% disappears in the succeeding twelve hours.

The advantage of breathing pure oxygen over air for the reduction of total gas and nitrogen volume in the small intestine is therefore obvious.

2. *A comparison of the effect of breathing pure oxygen with that of air on the change in total gas and nitrogen volume in the stomach distended with nitrogen and ligated at the cardia and pylorus—Table II, Figure II.*

The observations under this heading were made simultaneously with those on the small intestine described in section I. The duration of the experiments and the amounts of nitrogen used were as a rule the same. In Table II it will be observed that the *total gas volume* in the stomach was (excluding two notable exceptions\*) approximately the same after periods vary-

\*In experiments 5 and 9 a huge increase in volume occurred (237.4% and 173.3%, respectively). The ligatures at the cardia and pylorus were intact. Analysis of the gases showed the usual percentages of O<sub>2</sub>, CO<sub>2</sub>, and N<sub>2</sub>. Whether these results constitute examples of the phenomenon of acute dilatation of the stomach is uncertain. A deliberate effort to produce this condition by over-distention of the stomach failed on two occasions in average sized cats, once with the use of 175 c.c. of nitrogen and again with 320 c.c.

TABLE II

*The Effect of Breathing Oxygen vs. Air on the Change in Gas Volume in the Stomach Distended With Nitrogen*

\*Approximately same weight for both cats in each experiment.

\*\*Anomalous results not included in average figures in next column—see footnote in subsequent text.

\*\*\*Calculated on basis of gas analysis in Exp. 9, 11, and 14 and from data in literature showing that residual volume of nitrogen constitute approximately 20% of the total gas volume.

ing from 6-24 hours as at the beginning and that this was the case whether air or oxygen was used. Indeed, in many instances a little more gas was recovered than was injected. Cats breathing oxygen however usually had a somewhat smaller residual volume than those breathing air. Except for Experiments 5 and 9 the absorption of nitrogen averaged about 10.3% in the "oxygen cats" and 3.9% in the "air cats". Oxygen accelerates the rate of absorption of nitrogen from the stomach 260%, but the decrease in nitrogen volume is negligible even when oxygen is used as the respiratory gas. The stomach is therefore of no consequence as an organ for the absorption of nitrogen.

The relative capacity of the stomach and small intestine for the absorption of nitrogen and the reduction of total gas volume is however very considerable, particularly when oxygen is used as the respiratory gas. Thus when air is breathed, the absorption of nitrogen from the small intestine at the end of 24 hours is 6% and from the stomach 2.1%, a ratio of 2.85. When oxygen is breathed the corresponding figures are 62.3% and 6%, a ratio of 10.4.

3. *A comparison of the effect of breathing pure oxygen with that of air on the gaseous exchange in the stomach and small intestine separately distended with pure hydrogen.*

An examination of the data in Tables III and IV permits the following conclusions:

(a) When the small intestine of an air-breathing cat is inflated with hydrogen, the percentage reduction

of total gas volume after a given period is very much greater than is the case when the intestine is inflated with nitrogen. This is due to the fact that hydrogen has a much higher diffusibility coefficient than nitrogen, as already observed by others.

(b) The inhalation of oxygen in place of air considerably increases the percentage reduction of total gas volume in the small intestine (Figure III).

(c) When the stomach of an air-breathing cat is inflated with hydrogen the total gas volume is reduced to a very much smaller extent than in the small intestine. In the stomach no material change in the total gas volume is effected by oxygen (Figure IV).

(d) These findings are similar to those obtained when nitrogen is used as the distending gas, but upon consideration of the data in the gas analyses in Tables III and IV it will be seen that the mechanism involved is not the same. In experiment 21, for example, in the cat breathing oxygen, 68.3% of the initial volume of hydrogen was absorbed from the small intestine while 80.7% was absorbed in the cat breathing air. On the other hand in the "oxygen cat" only 4.5 c.c. of nitrogen diffused into the intestine from the blood as compared with 43 c.c. in the "air cat". In the stomach of the "oxygen cat" the percentage absorption of hydrogen was 19.4% and in the "air cat" 45.2%. Only 3.4 c.c. of nitrogen entered the stomach from the blood in the former while 25.9 c.c. entered in the latter. Accordingly it appears that the absorption of hydrogen from the stomach and small intestine is at

Fig. 1

least as efficient in the cat breathing air as in the cat breathing oxygen\*. Nevertheless, by preventing the diffusion of nitrogen into the gastro-intestinal tract from the blood, oxygen accomplishes, as already stated, a greater eventual decrease in *total gas volume* in the small intestine.

### DISCUSSION

According to the foregoing data, oxygen must be used for at least 12 hours to secure a substantial reduction in the total gas volume in the small intestine originally distended with nitrogen. Shaw and Behnke (3), in experiments on man, have found that about sixty percent of the nitrogen in the blood and tissues is exhaled within the first hour of inhalation of pure

\*Indeed, it would seem from the data in Experiments 21, 60, and 61, in which the analyses are complete, that the inhalation of oxygen actually retards the diffusion of hydrogen from the stomach.

Fig. 2

Fig. 3

oxygen. But such a rapid removal of nitrogen from the intestine cannot be expected owing to the fact that the nitrogen in the blood and tissues is in physical solution, while in the intestine nitrogen exists as a gas bubble only the periphery of which is exposed to an absorbing surface.

The absorption of nitrogen from the stomach is so poor, even when oxygen is breathed, that its disposal for the most part can only be accomplished by regurgitation into the oesophagus, or by evacuation into the small intestine.

The striking difference between the stomach and small intestine in the absorption of nitrogen can be explained on the basis of the following considerations. The rate of diffusion of a gas across a semi-permeable membrane is governed by (a) the nature of the mem-

\*Approximately same weight for both cats in each experiment.

brane, (b) its thickness, (c) the pressure of the gas on the two sides of the membrane and (d) the surface area available for absorption.

If the mucosa of the stomach and intestine is regarded as a physical barrier to the passage of gases rather than as a chemically secreting and absorbing membrane, it is probably safe, on the basis of anatomical structure, to consider the first two factors the same for both.

The third factor is not likely to be exactly the same for both since a given gas volume may produce different intraluminal tensions in the stomach and small intestine. We did not measure the gas pressure following injection because we felt that the variability of muscle tonus from time to time in the same animal and from one animal to another would make a single determination meaningless. We were however impressed by the greater resistance to the injection of the last fraction of the same gas volume in the small intestine than in the stomach. The initial pressure in the small intestine was therefore probably greater than in the stomach. That this might account to some extent for the greater speed of absorption from the small intestine cannot be denied. Nevertheless the data of Tables I and II demonstrate beyond reasonable doubt that the tension created by the injected gas cannot be responsible for more than a fraction of the difference actually observed. For example, in Experiments 4 and 14 of Table II the stomachs of two cats of nearly equal weight and breathing oxygen were injected with a nitrogen volume of 150 c.c. and 100 c.c. respectively. The residual total gas volumes remained unaltered after 22 and 24 hours respectively and the percentage absorption of nitrogen was 10% in both instances. Similarly in Experiments 33 (cat wt. 2.5 kilos) and 20 (cat wt. 2.9 kilos) with injected volumes of 100 c.c. and 75 c.c. respectively the absorption of nitrogen from the stomach after twelve hours equalled 8.2% in the former and 9.1% in the latter. In experiments 20 and 45 of Table I the small intestine of two oxygen-breathing cats weighing 2.9 and 3.4 kilos respectively was injected with nitrogen volumes of 75

c.c. and 140 c.c. respectively. In proportion to weight the latter probably had a much greater initial intraluminal tension, but after twelve hours the absorption of nitrogen was about the same in both instances (52 and 53 percent respectively). A comparison of the data of two six-hour oxygen experiments (Exp. 19 and 31) illustrates the same point. Hence the initial difference in intraluminal tensions between the stomach and small intestine cannot be regarded as an adequate explanation for the marked difference in the absorption of nitrogen from these two organs.

Reliable data on the relative surface areas of the stomach and small intestine is meagre. Custor (4) and Sappey (5) have reported figures which fail to take adequate account of the valvulae conniventes. Dargein's (6) direct measurements of the internal surface of the moderately distended adult human duodenum and stomach (110 c.c. water in the duodenum, 1200 c.c. in the stomach) were 432 and 700 square centimeters respectively. If, on the basis of length, the duodenum is estimated to represent 1-18 of the total internal surface of the small intestine, the latter may then be considered to have a surface area fourteen times ( $\frac{432 \text{ cm}^2 \times 18}{700 \text{ cm}^2}$ ) that of the stomach. But calculated on a basis of surface area per unit volume of fluid the ratio is  $6.72 \left( \frac{700}{1200} \right)$  or  $0.583 \text{ cm}^2$  of surface area per cubic centimeter for the stomach,  $\frac{432}{110}$  or  $3.92 \text{ cm}^2$  per cubic centimeter for the duodenum;  $\frac{3.92}{0.583} = 6.72$ . If these ratios apply to the cat as well, their average is sufficiently large to account for the observed differences (Table I and II) in nitrogen absorption between the stomach and small intestine on a surface area basis.

When pure hydrogen is utilized as the distending agent the inhalation of pure oxygen effects a substantially greater decrease in *total gas volume* in the small intestine than occurs when air is breathed. This is not due to an increase in the rate of diffusion of hydrogen from the gastro-intestinal tract as a result of the use of oxygen. The gas analysis data in Tables V and VI show that in an animal breathing air hydrogen

TABLE IV

The Effect of Breathing Pure Oxygen vs. Air on the Change in Gas Volume in the Stomach Distended With Hydrogen

\*Approximately same weight for both cats in each experiment.

diffuses out of the intestine and stomach even more rapidly than when oxygen is breathed. It has been shown repeatedly (1), (2), and again in these experiments that once the intestine becomes inflated by any gas, nitrogen will diffuse into the intestine from the blood until the partial pressure in the blood and intestine is equalized at 4-5 of an atmosphere. In an animal breathing air the decrease in volume resulting from the escape of hydrogen into the blood is to a considerable extent nullified by the concomitant entrance of nitrogen from the blood into the gut in very considerable volume. The decompressing action of oxygen inhalations is not to be credited to any properties inherent in oxygen but to the fact that by shutting nitrogen out of the inspired air the direction of flow of nitrogen must be away from the intestine and toward the lung, thus preventing diffusion into the intestine. Pure oxygen may thus serve not only to facilitate the absorption of nitrogen already present in the gut but as a prophylactic against its accumulation secondary to the generation of other gases within the intestine.

From what has been said, it follows that the decrease in the total gas volume of the distended intestine will be directly dependent on the concentration of oxygen in the inspired air. The closer it is to 100% the better the effect. A few experiments with 70% oxygen failed to yield results comparable to those with higher percentages.

If the use of 100% oxygen for a period of not less than 12 hours is to be considered for clinical application for the relief of gaseous distention it is essential to inquire whether interruptions to continuous administration which feeding and nursing may demand would, by temporarily admitting nitrogen into the blood, substantially reduce the beneficial effects of the oxygen already inhaled. In six experiments (Table I) pure oxygen was given for four three-hour periods with intervals of air breathing varying from one-half to one hour. The residual gas volumes compared favorably with those obtained by continuous oxygen inhalation. The volume of nitrogen which may diffuse into the intestine during the air breathing interval is apparently insuf-

ficient to vitiate the decrease in volume effected by the oxygen already inhaled. Intermittent oxygen, allowing reasonable periods for rest, feeding or nursing, may therefore be expected to accomplish about the same results as continuous oxygen.

We have limited this study to the factors governing the diffusion of hydrogen and nitrogen because, as already stated, these are the gases of consequence in distention. Methane is the only other relatively non-absorbable gas which might occasionally become a factor in distention, i.e., when the gastro-intestinal tract happens to be loaded with foods rich in cellulose. Since this is an unlikely occurrence in distention as ordinarily encountered in post-operative patients or in most other types of distention in the sick, methane can for practical purposes be ignored.

In the treatment of distention the stomach, like the colon, can be readily decompressed because the gases are accessible by a rubber tube. Since the absorption of nitrogen and hydrogen from the stomach is not substantially improved by the inhalation of pure oxygen it follows that the use of this agent will not obviate the need of removing these gases from the stomach by the Levin tube or the Wangenstein gravity suction apparatus.

During the administration of pure oxygen\* nitrogen can no longer enter the gastro-intestinal tract from the blood or by mouth except when feeding or nursing is done during a respite in room air. As far as possible therefore these procedures would best be carried out while the patient is in the oxygen tent. The selection of foods should take account of the gas producing properties of the various types ordinarily given such patients (1). Certain carbohydrates and milk especially should be avoided.

Where it is of vital importance to keep the gastro-intestinal tract as collapsed as possible, e.g., in peritonitis, or in cases suspected of organic obstruction in whom surgery is being withheld, or in order to avoid tension on suture lines following gastro-intestinal

\*A tent suitable for this purpose has been devised for clinical use and will be described shortly elsewhere.

surgery, oxygen may prove to be a valuable adjunct to the usual measures.

### SUMMARY AND CONCLUSIONS

1. When the empty small intestine of the air breathing cat, ligated at the pylorus and ileocecal valve, is inflated with pure nitrogen, there is a slight increase in total gas volume at the end of six hours. During the succeeding 18 hours a decrease of about 16% in total gas volume occurs.

2. When oxygen is substituted for air as the respiratory gas in such animals there is a decrease of 26% in the total gas volume of the small intestine after six hours. The reduction in distending volume continues progressively until about 61% of the total gas volume has been absorbed within 18 to 24 hours.

3. Pure oxygen given intermittently for 12 hours is approximately as effective as when given continuously. The free intervals may last one hour, possibly longer, without destroying the effect obtained by the oxygen already inhaled.

4. When the stomach of a cat breathing oxygen is distended with nitrogen, the total gas volume is, as a rule about as great after periods varying from 6-24

hours as at the beginning of the experiment. When the stomach of a cat breathing oxygen is distended with hydrogen, the total gas volume is reduced some 10% after 12-24 hours. The inhalation of pure oxygen therefore cannot be expected to deflate a stomach distended by nitrogen or hydrogen.

5. The difference in the effect of oxygen on the total gas volume between the stomach and small intestine inflated with nitrogen is probably due to the difference in the surface area available for gaseous exchange.

6. Hydrogen is much more readily absorbed from the gastro-intestinal tract than nitrogen. Pure oxygen inhalation does not increase the rate of absorption of hydrogen. Nevertheless by preventing the access of nitrogen to the intestine oxygen causes a greater decrease in the total gas volume than occurs when air is breathed.

7. The efficacy of oxygen for the absorption of gases from the small intestine is directly proportional to the concentration of oxygen.

8. The clinical implications of the foregoing observations are discussed.

## ABSTRACTS

SAMUEL MORRISON, M.D., AND MAURICE FELDMAN, M.D.

*The Effect of Bacteria on the Normal Stomach and on Acute Experimental Gastric Ulcer in Dogs. Am. Jour. Med. Sciences, May, 1935, p. 696.*

In a previous study it was determined that ulcers could be produced by the injection of 1% hydrochloric acid solution into the gastric tissue and that such ulcers have a tendency to heal usually within a period of three weeks. Chronic ulcers did not occur from this procedure alone, so the question of infection was studied by bringing the gastric mucosa and the acute ulcer into intimate contact with potent cultures of the common organisms.

Regarding the effect of gastric secretion upon bacteria, Bartle and Hawkins found no germicidal effect was demonstrable with free HCl concentrations below 0.04%; but gastric juice containing 0.08% and upward was bactericidal.

In their experiments the authors administered the bacteria mixed with food so as to dilute and neutralize the gastric contents and insure the retention of the bacteria in the stomach for longer periods and protect them from "acid" attack by their admixture with the food. Bacteria alone were given in one group of dogs, and in another group large amounts of sodium bicarbonate were administered to neutralize the gastric acidity while the bacteria were in the stomach.

In other experiments ulcerations were produced by injection of hydrochloric acid into the gastric wall and the animals fed bacteria alone and with the addition of sodium bicarbonate.

The bacteria exhibited were: *Streptococcus* 1.5 billion per cc.; *B. Coli* and *staphylococcus* 5 billion per cc.; the site of injection being marked with a bead. In Table 1 it is shown that in all the dogs injected variously with *staph. aureus*, *S. Viridans* and *B. Coli*, the mucosa at

autopsy was found normal. In these dogs no gastric ulcers had first been produced by injecting the gastric wall first with 1% hydrochloric acid.

In Table 2, is portrayed the effect of daily feeding of the above bacteria after HCl injection. Eight dogs were fed *staph. aureus*, 4 dogs were fed *S. Viridans* and 7 dogs were fed *B. Coli*. To three dogs no sodium bicarbonate was fed and at autopsy definitely healed ulcers were found. In 5 dogs one ounce of sodium bicarbonate was fed and at autopsy, one deep ulcer, one perforating ulcer, one definite ulcer and one completely healed ulcer were found. In the *S. Viridans* dogs no sodium bicarbonate was given and at autopsy no ulcer was found. Two dogs were given an ounce of sodium bicarbonate daily and in these definite healing ulcers were found. Of the *B. Coli* dogs no sodium bicarbonate was fed in three and at autopsy 2 showed healed ulcers and one a normal mucosa. In 4 *B. Coli* dogs one ounce of sodium bicarbonate was fed daily for from 3 to 27 days and two perforated ulcers were found at autopsy; one dog showed a small ulcer and one had no ulcer. Time in days in all these experiments for both tables were variously from 3 to 57.

As a separate study 3 dogs were injected with 0.5 cc. of 1% hydrochloric acid into the muscular walls of the stomach. Necrotic ulcers were produced in three days and then 1 cc. of *S. Viridans* (24 hour broth culture) was injected through the serosa into the muscular and sub-mucosal areas surrounding the ulcers.

Soda Controls. In 2 dogs in which ulcers were produced soda alone was given for 88 days; both revealed healed ulcers.

In the summary it is stated that "chronic gastric ulceration cannot be produced by bacteria acting on acute hydrochloric acid ulcers, at least not in the dog. It seems that another factor must play an important role in its chronicity."

Allen Jones, Buffalo.

## SECTION III—Nutrition

### The Role of Serum-Calcium Fractions in the Effect of Viosterol on the Bleeding Tendency in Jaundice\*

By

J. S. GRAY, M.S.

and

A. C. IVY, Ph.D., M.D.

CHICAGO, ILLINOIS

McNEALY, Shapiro and Melnick (1) have reported that viosterol in therapeutic doses is useful in controlling the hemorrhagic diathesis which frequently complicates jaundice. Since calcium therapy has been widely used in the treatment of this bleeding tendency, and since viosterol is known to play an important rôle in calcium metabolism, it was thought desirable to determine the effect of the viosterol administered to these patients on both total and diffusible serum calcium.

#### METHODS

Fifty-six of the jaundiced patients studied by McNealy, Shapiro and Melnick (1) at Cook County Hospital, Chicago, constituted the subjects for this work. Viosterol 250 D was administered, 30 gtts. t.i.d. *In those cases with acholic stools, bile salts were given to insure proper absorption of the vitamin.* An initial blood sample was taken and then viosterol therapy was instituted, blood samples being taken each week thereafter until the case was concluded, usually within two to three weeks. A control group consisted of patients given no viosterol, but in all other respects receiving identical treatment. In no case was calcium administered.

Twenty c.c. blood samples were taken, (usually in the early morning), with a clean, dry syringe and without hemolysis. At the same time the bleeding-time was obtained by the venostasis method (2). The blood samples were brought to the laboratory and the calcium analyses begun the same day. All icteric indices were determined at the hospital. Diffusible calcium analyses were not begun until the work had been some time in progress. The data presented are from completed patient-records only.

For the determination of the ultrafiltrable calcium, the high pressure ultrafiltration method described by Nicholas (3) was employed. Ultrafiltration was carried out at 150 lbs. pressure of nitrogen gas. Nicholas (3) showed that variations in pressure from 50 to 200 lbs. had no effect on the concentration of calcium in the ultrafiltrate. Hertz (4) denies that pressure influences the diffusible calcium and Cox and Hyde (5) present evidence that variations in pressure are without effect when the membrane, as in this apparatus, is well supported, rather than suspended as a sac. Table I shows that methods employing higher pres-

ures\* do not necessarily give higher yields of diffusible calcium.

The Nicholas method has the advantages of speed of filtration and of uniformity of the membrane employed. Du Pont cellophane No. 300 is used as an ultrafiltration membrane.

Nicholas (3) reported that cellophane is impermeable to serum proteins, uniform in permeability to calcium, and that successive sample of ultrafiltrate from the same process of ultrafiltration contain the same concentration of calcium. Similar tests were made in this laboratory, confirming these results. Further, the membrane is impermeable to bilirubin.

From 4 to 5 c.c.'s of serum were ultrafiltered, the calcium being determined in 2 c.c. quantities of ultrafiltrate by the Clark-Collip method (6). Ordinarily about 4 hrs. were required to obtain 2 c.c. of ultrafiltrate. During this time evaporation was prevented by maintaining the receiving tube snugly against the ultrafilter. The non-diffusible calcium was obtained by difference (total serum Ca minus Ca in ultrafiltrate), no correction being made for the absence of protein in the ultrafiltrate. This method for the determination of diffusible calcium is much superior to previous collodion membrane methods in regard to simplicity of operation, and probably also in consistency of results obtained in the hands of persons not skilled in making collodion membranes.

#### RESULTS

*Normal Students:* The diffusible serum calcium of 13 healthy medical students was determined. These normal values ranged from 1.5 mg. to 6.5 mg., averaging 5.8 mg. Expressed as the percent of total calcium the range is from 46% to 58%, averaging 54%. This is in contrast to the 64% average reported by Nicholas (3). The procedure and apparatus used in this work were identical with those employed by Nicholas. A possible explanation of the difference lies in the fact that Nicholas subjects were Texans, presumably exposed the year round to the sun's rays, whereas our subjects were laboratory workers in Chicago, who were exposed very little to the sun's rays. Ultraviolet irradiation *in vitro* has been reported by Clark (7) to increase the diffusible calcium of serum, although Moritz (8) was unsuccessful in his attempts to in-

\*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago, Illinois. This work was aided in part by a grant in aid from the Mead-Johnson Company.

\*Corrected for Obviously low total calciums averaging 8 mg./100 cc.

crease the diffusible calcium of rabbits by irradiating the animals.

That this high pressure ultrafiltration method gives a true value for diffusible serum calcium is suggested by an analysis of previous reports of normal values in man. The literature contains 21 reports (Table I) of the diffusible calcium of normal human subjects. They vary widely from 46% to 66%, depending upon the method used. The average of all the reported values is 54.0% which compares favorably with the 54% average which we have obtained. Additional support is found in the calcium content of the cerebrospinal fluid, which has been considered a dialysate of the blood, at least under normal conditions (9) (10) (11) (12) (13) (4) (37) (38). The average of 13 reports on the cerebrospinal fluid calcium in normal humans is 50.7% (Table II). It is significant that the averages of many analyses by different investigators employing different methods give results which compare with those obtained by us using the Nicholas method.

*Jaundiced Patients:* In jaundice the total serum calcium was found to be within normal limits, although the average is slightly lower than that of the normal group (Table III). Similar data have been reported by a number of other observers (14) (15) (16) (17) (18) (19) (20) (21) (40). The average ultrafilterable calcium was also normal in the jaundice cases, although a greater range of variation was noted when compared with those in the normal series. There was no correlation between the factors of bleeding-time, icteric index, and diffusible calcium, thus confirming the work of other investigators (14) (19) (16) (4) (40) (53). Emerson (22) and Kirk and King (23), however, report a decrease in diffusible calcium in jaundice.

Viosterol administered to the patients with a prolonged "venostasis-bleeding time" uniformly reduced it to within normal limits (240 secs.). The effect of viosterol on the total serum calcium (Table V) was limited to a prevention of the slight fall that would have occurred had they received no viosterol, as evi-

\*Less than 240 seconds.

denced by the fall in total serum calcium in the control group (Tables III, IV and V).

Reports in the literature are conflicting as to the ability of *therapeutic doses* of irradiated ergosterol to raise the serum calcium level (24) (25) (26) (27) (28) (29). Therapeutic doses of viosterol did not raise the total serum calcium in our jaundiced patients. Jaundiced patients also show a resistance to the hypercalcemic effect of intravenous calcium, according to Walters and Bowler (30).

Neither is the literature in agreement as to the effect of viosterol on the diffusible calcium (31) (32) (33) (34) (35) (36). The diffusible serum calcium values showed a slight decrease under the influence of viosterol. Unfortunately, just those subjects who showed a fall in total calcium happened to have the diffusible fraction determined, so that no particular significance is attached to the fall in percentage of diffusible calcium. *However, these results suggest that jaundiced patients should receive calcium in addition to viosterol.*

*From our results the explanation of the effect of viosterol in reducing the bleeding time in jaundice is not to be found in its effect on blood calcium, or its ultrafilterable fraction.*

### DISCUSSION

Although a "calcium deficiency" undoubtedly exists in jaundice, (30) (61) (62) (63) (64) (65) (66), the chemical evidence indicates *either* that it is not of sufficient degree to be reflected in the serum calcium, either total or diffusible (14) (19) (16) (4) (40) (53) (15) (17) (18) (20) (21), or our present methods are not sufficiently adequate to demonstrate the change in the blood. The chemical evidence, however, is corroborated by the physiological, for the absence of neuromuscular hyperirritability in jaundice indicates a physiologically adequate calcium content of the blood. Furthermore, a calcium deficiency would be expected to hasten the appearance and increase the severity of tetany in a parathyroid-ectomized jaundiced animal,

whereas in reality it has the reverse effect (64) (67). Of course, it may be argued that the state of jaundice has a depressing action which counteracts a chemically "masked" calcium deficiency. Nevertheless, the facts afford definite proof that *bilirubin does not combine with the calcium ion of the blood to produce a functional deficiency* of the latter sufficient to decrease the coagulability of the blood, as has been the suggested explanation for the bleeding encountered in icteric patients (65) (18) (68) (76). If more proof be necessary, it might be pointed out that the bleeding tendency bears no relation to the intensity of the icterus (14) (69) (70) (16) (88), nor is bleeding found in *icterus neonatorum* (164). A search of the literature failed to reveal such a tendency in congenital hemolytic jaundice.

Granted a "masked", functional, serum calcium deficiency, it must still be shown how such a condition could be responsible for a hemorrhagic tendency. Tetany, the example of serum calcium deficiency, *par excellence*, is unassociated with a tendency to bleed (71) (72) (73). Furthermore, it has been reported (74) (75) that citrates and oxalates delay coagulation, not so much by removing calcium as by combining with fibrinogen to render the latter incoagulable.

It has even been proposed that it is the non-diffusible calcium which figures in blood coagulation (77) (78) (79), but this fraction, also, remains unaltered in jaundice. This fraction is low in nephrosis (33) and in parathyroid deficiency (4) (12) (33) (157) (158) (159) (160) (161) (162), but neither the former (165) nor the latter disease (71) (72) (73) is associated with a bleeding tendency. Furthermore, the nondiffusible calcium is bound to serum proteins (33) (52) (80) (81) (82) (83) (84) (85) (86) (87), and probably to the albumin fraction only (53).

Finally, it must be borne in mind that the calcium deficiency explanation of icteric bleeding is based on the fact that agents which precipitate calcium delay or prevent coagulation, a mechanism which cannot be

reconciled with the fact that a delayed coagulation-time is not a uniformly characteristic finding even in the bleeding jaundiced patient (69) (70) (89) (90) (2) (100) (105) (19). *In the light of our present knowledge, therefore, a disturbance of calcium metabolism per se offers no explanation for the hemorrhagic diathesis of jaundice.*

Bile salts *in vitro* are known to prolong the clotting-time of blood (150), and *in vivo* to delay the formation of experimental thrombi (91). In jaundice undoubtedly they are present in abnormal amounts (142) (99) (97) (98), consequently bile salts have not been overlooked in the search for the etiological agents of this bleeding tendency. However, they reach their highest level in the blood and urine early in the course of the disease, (92) (93) (94) (95) (96), for the "back pressure" of the bile in obstructive jaundice damages the liver (109) (110) (111) (112) (101) (21) (94) (102) sufficiently to inhibit the formation of bile salts (97) (98) (95) (94) (169) (170) (171) (172) (173) (174) (175), and hence they are at their lowest concentration late in jaundice when hemorrhage is most frequently encountered (103) (89) (104) (88). No correlation has been found between the "Pettenkoffer substances" of the blood and the bleeding tendency (99). Since bile salts are rapidly eliminated from the blood stream, after removal of the obstruction, probably they are absent during the bleeding which complicates post-operative recovery (94).

The concentration of bile necessary to prolong the coagulation-time of the blood *in vitro* is far in excess of the amounts found in the blood in jaundice (106) (104), although this may not be true of the intravenous injection of bile salts (91). Attempts to reproduce the hemorrhagic tendency experimentally by a successful anastomosis of the common bile duct to the *vena cava* have been fruitless (107). The effect on the capillary walls of abnormal amounts of bile in the blood over a long period of time has never been investigated. However, as far as it is known at present, the hemorrhagic tendency in jaundice is not attributable to the presence of bile salts in the blood.

Frequently it has been observed that the bleeding tendency parallels the extent of liver damage (100) (103) (107) (108) (89) (1) (70). Obstruction of the bile passages is known to produce liver damage. The greater the duration of the obstruction, the more extensive becomes the hepatic involvement, and it is in just such long-standing cases that hemorrhage is most to be feared. Frequently it has been observed clinically that hemorrhage is most serious in cases of malignant obstruction (114) (115) (116), and in such cases the liver is usually markedly affected (107). Bleeding often manifests itself shortly after operation at a time when anesthesia and operative trauma have contributed to the hepatic injury. Since recovery of the damaged liver after obstruction requires time (166) (167) (168), it may be still incomplete a week after obstruction, when the danger of hemorrhage still is present (89) (104) (117).

The liver, undoubtedly, plays an important rôle in blood coagulation. It is believed to be the site of formation of fibrinogen (113 and antiprothrombin (118). All types of injury, such as phosphorus carbon tetrachloride (121) (119), and chloroform (120) poisoning, interference with hepatic circulation (122), acute yellow atrophy (123) and hepatectomy itself (124) produce alterations in blood coagulability. At present

## 5-b

TABLE V

*Effect of Treatment on Total Calcium in Jaundice*

| Treatment              | No. of Cases | Before        |                   | After         |                   |
|------------------------|--------------|---------------|-------------------|---------------|-------------------|
|                        |              | Total Calcium | Ivy Bleeding Time | Total Calcium | Ivy Bleeding Time |
| None (Controls)        | 9            | 9.9           | 400               | 9.5           | 490               |
| Viosterol              | 16           | 9.7           | 410               | 9.7           | 220               |
| Operation No Viosterol | 5            | 10.2          | 290               | 9.4           | 140               |

one can only speculate as to the exact mechanism by which liver damage in jaundice might lead to a hemorrhagic diathesis. It is certainly not through alteration in blood fibrinogen (105) (88) (19) (125). Some investigators believe that the liver injury results in an excess of antiprothrombin in the blood which is responsible for the hemorrhage (108) (100) (126) (127) (128). Antiprothrombin, or "heparin", increases the sedimentation rate of erythrocytes (129), which has been used empirically with some success as an indication of a bleeding tendency in jaundice (90) (69) (130) (131). But, there is as yet no direct, quantitative proof or agreement in regard to the presence of excessive amounts of "heparin" in jaundiced blood.

Some recent work indicates that in jaundice the bleeding tendency and the fragile clot are due to the presence of abnormal amounts of cysteine in the blood (19). Practically nothing is known about the amount of cysteine in the blood under normal or pathological conditions, and very little concerning its metabolism, so that more investigation is necessary for a proper evaluation of this factor.

If it be admitted that liver involvement fundamentally is related to the bleeding tendency, then a possible explanation is provided for the beneficial effects reported with the use of calcium (132) and glucose (133) (149) in the control of hemorrhage in jaundice. Glucose has long been known to exert a "protective" action on the liver (133) (134) (135) (136) (137) (138) (139) (140) (141). Calcium has been shown to counteract certain poisons which, selectively, affect the liver (121) (143) (144) (145) (156). It has been used clinically in eclampsia and acute liver injury (146) (147) and to prevent complications resulting from arsenic therapy (148) with reported excellent success. There is very little evidence for such action on the part of viosterol, although it has been reported to reverse the frequently positive hemoclastic crises observed in dementia praecox (133). Viosterol has been shown, however, to decrease the coagulation-time in normal rats through increasing the thrombocyte count (154) (155).

The venostasis method of obtaining the bleeding-time involves the production of a condition of venostasis in the area where the bleeding is experimentally induced. It is significant that a latent tendency to hemorrhage can be revealed frequently only by subjecting the incised vessels to this additional stress (2). Contractility and retractility of the capillaries, and thrombus formation in the vessels and tissues constitute the chief mechanism for accomplishing hemostasis (151) (152). Since the coagulation-time may be normal in icteric bleeding, an exaggerated venostasis bleeding-time must reveal either a fragility of the clot or a deficiency in capillary contractility, or both, which, on the basis of the available evidence, is sec-

ondarily due to hepatic injury rather than to serum calcium changes or circulating bile salts.

## CONCLUSIONS

1. Total serum calcium and ultrafilterable serum calcium were found to lie within normal limits in jaundice.
2. No correlation was found between the ultrafil-

terable calcium, the "venostasis bleeding time", or the icteric index.

3. Viosterol, which restores the normal bleeding time in jaundice, unless the liver damage be extreme, does not do so by altering the serum calcium, either total or ultrafilterable.

4. The etiology of the hemorrhagic diathesis in jaundice is discussed.

## SECTION IV—*Roentgenology*

### Appendiceal Abscess: A Roentgenologic Consideration, with Especial Reference to the Diagnostic Difficulties and Its Differential Diagnosis \*

By

MAURICE FELDMAN, M.D.  
BALTIMORE, MARYLAND

**A**CUTE suppurative appendicitis is quite a common affection, occurring frequently in most busy clinics. The acute type of appendiceal disease is rarely roentgenographed, not only because the clinical diagnosis as a rule is made with ease, but also due to the fact that the roentgen examination offers but little aid in the diagnosis. The acute form of this disease will therefore not be considered here. In this presentation we are primarily concerned with the chronic type, as a result of a suppurative infection, which has perforated the appendix and has become walled off, producing a localized abscess with tumor formation.

While chronic abscess of appendiceal origin with formation of a mass is not a common complication, it may present a major problem in differential diagnosis, requiring a painstaking roentgenologic investigation. The incidence of this complication varies considerably in different clinics. Adams (1) records a series of 25,000 operations for appendicitis in which there were only 45 localized appendiceal abscesses. Robinson (2) on the other hand found 46 cases of abscess in 979 operations for appendicitis, while Campbell (3) records an incidence of 16.7 per cent in his study of appendiceal abscess. Our roentgenologic experience indicates that chronic abscess of appendiceal origin is not commonly observed in the roentgen laboratory. Appendiceal abscess may often be mimicked by a rather large group of affections occurring in the right lower quadrant, presenting similar roentgenologic findings, which may produce a picture often difficult to interpret. Similarly, the clinical picture of this type of case likewise is difficult to differentiate from other tumefactions but with a more accurate appraisal of the roentgen signs, together with the clinical manifestations, the diagnosis of appendiceal abscess is far more easily facilitated. This subject therefore is of sufficient interest to warrant a brief communication, emphasizing anew its roentgenologic characteristics.

In the extensive literature on appendicitis, the scarcity of information regarding the peculiar roentgenologic characteristics of appendiceal abscess is striking. A survey of the more recent literature likewise reveals but few roentgenologic studies of this complication. The roentgen findings have been described by

a number of observers, notably by Pohl (4), Westernborn (5), Ritvo (6), Lundberg and Lilja (7), Arnell (8), Schwartz (9) and Avellan (10).

The origin of a mass in the right iliac fossa presents many difficulties in interpretation. Its close relation to the terminal ileum, cecum and ascending colon, to which it is often attached, frequently gives rise to the impression of a malignant tumor. While tumors arising from the pelvis may frequently produce similar roentgenologic findings that are confusing, the clinical, roentgenologic and pelvic examinations aid in establishing its origin. In most instances, however, a tumor in the right iliac fossa is most difficult to diagnose from a clinical and physical examination alone, but the true nature of the mass may be frequently disclosed by a thorough roentgenologic investigation. At times, even this examination may not reveal the classical roentgen picture of appendiceal abscess. The exact nature of the mass and its origin in some instances is therefore not always possible to determine until surgical investigation and pathologic studies are made. It is interesting to note that inflammatory masses in the right iliac fossa may be other than appendiceal in origin. Hypertrophic ulcerative stenosis of the ileum (12) and pericecal abscess due to a foreign body and retroperitoneal abscess often produce inflammatory masses not infrequently simulating appendiceal abscess.

The roentgen investigation, on the other hand, often will definitely establish the origin of the mass as being either an intrinsic or extrinsic colonic tumor, pointing directly to its situation and relation to the gastrointestinal tract. It will, in most instances, reveal its location better than any other procedure with the exception of surgery. The roentgen examination produces a definite group of signs in many instances, especially when the mass is of large size. Of the smaller masses and those situated in the retrocecal, retrocolic and retroperitoneal areas, in the pelvis, or distant from the right iliac fossa, the roentgen signs are very often of an indefinite nature, or may be frequently absent.

The following roentgen signs are most commonly encountered in the classical picture of appendiceal abscess. (a) Tumor mass, (b) pressure defects, (c) elevation and displacement of the ileum and cecum, (d) fixation of the ileum and cecum, (e) hyperirritability, hypermotility, (f) cecal spasm, (g) sensitiveness and tenderness, (h) inflammatory changes with

\*From the Department of Roentgenology, Sinai Hospital, Baltimore, Md.  
Submitted June 1, 1935.

alteration in contour of the cecum, (i) ileocecal patency and changes in the ileum and (j) non-visualization of the appendix.

A palpable tumor mass may be noted in many instances, but the absence of a palpable mass does not however exclude the presence of this complication. In most cases, the examination of the colon by means of the progress meal, barium enema and air insufflation of the bowel are usually sufficient to establish all the necessary data for an accurate diagnosis of tumors in the right iliac fossa. The mass and its effect upon the ileum and cecum may be more completely depicted by utilizing all of the roentgen procedures. The abscess completely may be encapsulated or it may communicate with the cecum or neighboring organs. The determination of the presence of an abscess mass, its size, shape, mobility, position and its relation to the contiguous organs are disclosed in a most striking manner by means of a thorough roentgen examination. The mass varies in size, is frequently small, but may attain huge proportions, ordinarily easily palpable, rounded, circumscribed, often spherical and frequently sensitive or tender on pressure. The tumor mass is usually fixed, but may be movable in some instances; it is homogeneous but not always dense enough to cast a shadow on the roentgenogram. Appendiceal abscesses are usually single, but multiple types have been reported by some observers (7). The position of the abscess is most commonly observed at the tip or apex

of the cecum, it may however, be noted on either side of the cecum, retrocecal or be retrocolic. A tumor mass with its origin outside the colonic tract often produces some deformity and displacement of the adjacent organs. The mass must attain sufficient size in order to produce displacement, but in most instances where a mass is palpated the displacement is quite marked. The mass frequently involves the contiguous viscera together with the peritoneum and omentum. There may be dense adhesions and also coils of small intestines involved in the mass. It may occupy any part of the abdomen; when large it may extend to the bladder, sigmoid or even the rectum. It may also be found in the pelvis, to the left side of the abdomen and in the hepatic area. The abscess may float freely in the abdomen (19). Homans and Powers (11) observed that, when an abscess appears to be in an unusual position, it is the appendix which is ordinarily displaced and not the cecum. The tumor mass and the inflammatory thickened omentum may obliterate the shadow of the psoas muscle and in rare instances a scoliosis of the lumbar vertebra may be observed.

In all instances where a mass is palpated, a "scout" film of the abdomen should be taken. This will occasionally reveal the mass, the presence of a fluid and air level and increased amount of gas in the small and large bowel. Arnell (8) points out that post-appendiceal abscess may be diagnosed without contrast filling by visualizing a large diffuse shadow surrounded by gas filled loops of intestine. Occasionally it may become necessary to take a roentgenogram in the upright posture in order to visualize a fluid level within the abscess. Frequently, however, in the chronic abscess following resolution, only a small amount and, at times, no pus may be found and therefore no fluid level may be observed. The importance of obtaining many views in different positions during the roentgenologic studies must be emphasized.

In chronic appendiceal abscess with tumor formation, a pressure defect is nearly always produced on the contiguous organs. The size of the defect varies considerably, depending largely upon the size and mobility of the mass. The defect most frequently involves the tip of the cecum and terminal ileum. The ascending colon and other segments of the bowel also may occasionally reveal the presence of a displacing defect. The defect is usually smooth, rounded, evenly distributed, frequently producing an elliptical pressure sign. The defect, however, in many instances may be very small and irregular often producing the roentgen picture of an intrinsic lesion. Pressure defects may not always be observed in the cecum. The defect depends in a large measure upon the close proximity of the mass to the cecum. Defects due to fecal material, insufficient amount of opaque medium and those from organic diseases carefully must be eliminated.

The tumor mass frequently produces a displacement and elevation of the ileum, cecum and ascending colon. A large mass in the right iliac fossa has a tendency to elevate the mobile portion of the bowel. Elevation and displacement not always may be observed as this depends in a large measure upon the position and size

Fig. 1

Fig. 1. Drawing, demonstrating the characteristic roentgenologic picture of appendiceal abscess. a. Cecum elevated, tip narrowed and compressed. b. Tumor mass, compressing cecum and ileum. c. Ileum narrowed and compressed by the mass.

of the mass. Displacement of other segments of the bowel as well as other structures may be occasionally disclosed.

An inflammatory mass in the right iliac fossa usually is found to be fixed. Dense adhesions with involvement of the peritoneum and omentum frequently produce marked fixation. The terminal ileum and cecum are often attached to the mass, resulting in fixation of these segments of the bowel.

In most inflammatory lesions that occur in the right iliac fossa, hyperirritability and hypermotility are prominent roentgen signs. In the progress meal examination, the barium often flows through the right colon with great rapidity. The barium is observed to fill the ileum, the cecum most often is poorly filled on account of its rapid emptying, while the remaining large bowel may be well filled. Occasionally Stierlin's phenomenon may be observed: this shows a lack of filling of the cecum, and gives the impression that the barium passes directly from the ileum into the ascending colon. Hyperirritability and mass hypermotility, producing rapid emptying of the cecum, may be frequently observed following the expulsion of the barium enema.

As a result of a low-grade inflammatory process of the right colon, which is not uncommonly associated with appendiceal abscess, spasm of the cecum and ascending colon frequently may be observed. Spastic contractions of the cecum and ceco-colon may be persistent or intermittent. Considerable significance must be attached to localized spasm occurring in the right colon and according to Gershon-Cohen (17) it is probably one of the earliest manifestations resulting from inflammatory conditions. This phenomenon likewise may be produced as a reflex condition from the inflamed area. Cecal spasm is well illustrated in many instances following the barium enema and air insufflation examinations. This sign is not always observed in appendiceal abscess and it may be reproduced by any inflammatory lesion in the right bowel.

Hypersensitiveness and tenderness may be elicited in the right iliac fossa. The tumor mass is most often sensitive or tender on pressure.

In the encapsulated abscess, changes in form of the cecum is the most constant sign. This is due to the mass pressing upon the cecal wall. The cecum usually remains regular, which, according to Pohl (4), is a very important sign in the differentiation from primary lesions of this portion of the bowel. However, notwithstanding the ordinary regularity of the cecum in this condition, irregularities associated with appendiceal abscess frequently are encountered. In some instances, the tip or apex of the cecum may reveal a distinct irregularity; it may become narrowed as a result of a hyperplasia, presenting a roentgenologic picture of a narrowed tube. Although marked inflammatory changes in the cecum are unusual they may occur associated with appendiceal abscess. The ascending colon and rarely the proximal transverse colon may be occasionally involved. The inflammatory reaction may produce extensive changes in the right bowel; this is roentgenologically portrayed by narrowing of the lumen, loss of haustration and rigidity of the colonic wall, signs not unlike those observed in ulcerative colitis.

Patency of the ileocecal opening is a common roentgen finding in affections of the right bowel. This is especially observed in inflammatory lesions and is therefore not an uncommon finding in appendiceal ab-

scess. However, patency is of little significance since it occurs in the normal. Changes in the terminal portion of the ileum are frequently found, such as widening of the ileocecal opening, fixation, and also constrictions, signs resulting from an inflammatory process. Hyperplasia surrounding the ileocecal area frequently produces a deformity of this segment. The terminal ileum is often infiltrated, and thickened, frequently forming part of the abscess.

The appendix is not as a rule visualized. The relation of the abscess to the appendix is variable as the perforation may occur at any point. The whole appendix may be gangrenous and form part of the abscess, the appendix lying within it. The appendix usually forms part of the inflammatory mass. Frequently it is buried in the cecal wall. If the abscess communicates with the appendix or cecum, the abscess cavity may become filled with barium. This finding, however, is of rare occurrence.

The routine examination by means of the gastrointestinal progress meal reveals certain roentgenologic findings which are often quite essential in the study of appendiceal abscess. Information not only is given by this method as to the functional state of the bowel, but also the anatomic relationship of the mass to the adjacent organs. The abnormal motility of the right bowel especially is depicted. Evidence of increased irritability is also clearly portrayed by this procedure. This examination likewise may aid in the differential diagnosis of the many obscure conditions which occur in the right lower quadrant. In some instances the progress meal examination may fail to reveal the presence of an abscess and the case may go undiagnosed, until perhaps a barium enema investigation is undertaken.

The barium enema examination often discloses extremely valuable information in appendiceal abscess which information cannot be determined by other means. The barium is observed to flow up the bowel readily until it reaches the cecum, where distinct roentgen changes are often depicted. The cecum may or may not become completely filled, often shows evidence of pressure, irregularities, increased irritability, rapid emptying and ileocecal patency; these produces a filling of the terminal portion of the ileum. Evidence of an inflammatory process of the cecum may be likewise observed. The mass usually is palpated during this examination and its relation to the cecum and ileum can be determined. The fluoroscopic examination of the right iliac area is especially important to determine the relation of the distorted portions of the ileum and cecum. This procedure is one of the most essential steps in the investigation of the appendix area in order precisely to disclose the exact location of the mass as well as to determine whether or not it is within or outside the intestinal tract. The ileum and ileocecal opening is also best studied by this procedure.

The barium enema frequently produces a typical, classical, characteristic roentgen picture of appendiceal abscess. The barium is allowed to flow into the bowel slowly and a meticulous study is made of the area surrounding the mass. The cecum may show but little evidence of inflammation. Appendiceal abscess may or may not produce inflammatory changes in the adjacent organs. When the ileum, cecum, ascending and transverse colon are affected by inflammatory changes, the diagnosis becomes increasingly more difficult, inasmuch as other infections produce similar roent-

Fig. 2a

Fig. 2a. Roentgenogram (barium enema), illustrates a case of appendiceal abscess. Cecum elevated; narrowing of cecal tip and fixation of wall of ileum is shown at arrows. (case proven at operation).

Fig. 2b

Fig. 2b. Shows marked irritability of the bowel, with rapid emptying of the cecum. Note large amount of barium retained in the ileum.

Fig. 3a

Fig. 3a. Ragged appearance of the tip of the cecum is shown at arrows. Cecum is elevated; the extreme cecal tip is narrowed; the terminal ileum is narrowed and fixed. (appendiceal abscess found at operation).

Fig. 3b

Fig. 3b. Illustrates marked hyper-irritability of the cecum, with rapid emptying, a frequent sign of an inflammatory process.

manifestations. It must be borne in mind that the roentgen examination of the colon may not always disclose any sign in the cecum which might indicate the presence of an appendiceal abscess, especially when it is very small, or in instances where it is situated distant from the cecum. When a mass is palpated, it is of paramount importance to determine its relation to the ileum and cecum. Frequently a pressure defect is observed producing an upward displacement of these segments of the bowel. The resulting pressure usually produces a smooth regular defect, but does not as a rule reveal roentgen evidence of an infiltrating affection.

A small persistent irregularity, or filling defect, or incomplete filling of the tip of the cecum is strongly suggestive of an appendiceal abscess, but great caution should be taken in interpreting this finding. When the cecal tip is poorly filled following a barium enema. Even in the absence of a palpable mass, the possibility of this complication should be considered. Filling defects occurring in the cecum are often confused, because of the marked similarity of the roentgen findings produced by other affection occurring in this area. It should again be emphasized that when a mass is palpated in the right iliac fossa, it may not always be due to an appendiceal abscess inasmuch as other lesions are frequently encountered in this area which mimic those of an abscess.

After studying the bowel by the usual roentgen methods, it may occasionally become necessary to make further investigations in order to study the origin of the mass. The introduction of air into the bowel may be quite helpful in some instances in delineating the mass and adjacent organs. Spasm and irritability of the cecum also may be observed in this examination as well as displacement due to the tumor.

Pneumoperitoneum has been mentioned as a procedure for visualizing abdominal tumors. In our opinion this method of examination is dangerous in the presence of inflammatory masses.

There are many diagnostic difficulties encountered in the study of this complication. This is no doubt due in a large measure to the varying roentgen picture, so commonly observed in appendiceal abscess. As mentioned before, this affection may not reveal any sign whatever which might indicate its presence, or on the other hand there may be minimal roentgen signs that are too indefinite to point to the exact nature of the condition; then again a large pressure defect may be depicted in the cecum indicating the presence of an extrinsic mass. These variable roentgenologic findings observed in appendiceal abscess make this condition at times one of the most difficult to interpret. However, it is often possible to make a correct diagnosis together with the clinical findings, but, even here, the exact diagnosis of the true nature of the mass cannot always be made with certainty.

In the appraisal of the roentgen signs of appendiceal abscess consideration of a group of other lesions occur-

ring in the right iliac fossa must be considered in the differential diagnosis. The key to this diagnostic study is first to determine whether the lesion is localized, second, whether or not it is within or outside the bowel and third, whether or not it is an infiltrating tumor. The most common conditions which must be considered in the differential diagnosis are: benign and malignant tumors of the appendix, carcinoma of the cecum, hyperplastic (13) and hypertrophic (18) tuberculosis, retroperitoneal tumors, abscess, enlarged or abscessed glands, non-specific granulomata involving the ileum and cecum (12), ileitis (20) and other inflammatory conditions, psoas abscess, psoas tumors, pelvic tumors, peri-nephritic abscess, ectopic kidney (16), kidney tumors, hydrops of gall bladder (14), mesenteric tumor or abscess, abscess due to a foreign body, inflamed omentum with adhesions (16), amebic infection, ileocecolic invaginations, fungus infections (4), and right sided diverticulitis.

Of the above conditions which may closely mimic appendiceal abscess, the most commonly encountered which often require special consideration are, carcinoma of the cecum, ileo-cecal tuberculosis, retroperitoneal masses and tumors arising from the pelvis.

#### SUMMARY

Appendiceal abscess produces a mass in the right iliac fossa which often creates a great deal of discussion in the interpretation and differential diagnosis. The extreme variation in the roentgen picture from little or no roentgen signs to a large group of signs is the most important factor, which accounts for many of the difficulties and errors in diagnosis. It is likewise mimicked by a large group of conditions which require painstaking study in the differential diagnosis. On the other hand, appendiceal abscess frequently produces a roentgenologic picture of an extrinsic mass which is closely attached to the ileum and cecum, often producing changes in these segments of the bowel suggestive of an inflammatory process. Since it involves the contiguous organs one may often interpret these findings as due to an appendiceal abscess. The roentgen examination is quite important in determining whether or not the mass is intrinsic or extrinsic. This however, is not always possible, especially when there are minimal changes in the cecum.

The roentgen signs of appendiceal abscess are at times quite characteristic, revealing a pressure defect, inflammatory changes in the ileum and cecum, hypermotility and hyperirritability of the right bowel and the presence of a tender mass in the right iliac fossa. One must on the other hand, be aware of the many conditions which simulate this complication and make the differential diagnosis with some caution, inasmuch as it is often difficult to state the exact nature of the mass. The roentgen examination offers the best means for investigation of appendiceal abscess and its differential diagnosis. When considered with the clinical findings, the diagnosis may be made in a large percentage of cases.

## A B S T R A C T S

JULIAN M. RUFFIN AND DAVID T. SMITH, DURHAM, N. C.

*The Treatment of Pellagra with Certain Preparations of Liver.* Vol. 187, pp. 512-521, April, 1934.

On the basis of thirty-seven cases of pellagra, fourteen of which were used as controls, certain interesting conclusions are reached as to the effectiveness of liver therapy. The fourteen control cases were treated by a diet containing known and adequate anti-pellagra factors which had previously proven to be effective in the cure of the disease. The cases in which liver therapy was instituted were placed on a diet similar to that which they had been taking prior to the development of symptoms. This diet contained adequate amounts of fats, proteins and carbohydrates, minerals and all the known vitamins, except Vitamin G (B<sub>7</sub>). Patients with pellagra reported in this series did not improve on this diet. However, when this group was put on an aqueous extract of liver in doses of 90 c.c. daily by mouth; or given a powdered extract of liver in doses of 3 vials daily; or given an insoluble residue derived from the alcoholic extraction of an aqueous extract of liver, prompt abatement of symptoms ensued with eventual cure. Five cases on this same diet lacking only in vitamin G (B<sub>7</sub>) failed to improve when treated with liver extract No. 343 intramuscularly in doses of 5 c.c. daily.

When the oral aqueous extract of liver was substituted for the intramuscular extract in this same group of five, a dramatic clinical improvement began between the third and fifth day, and continued until the patients were apparently well.

Evidence is presented indicating that the bilateral symmetry of the skin lesion is due to bilateral exposure to sunlight, as in this series it was shown that unilateral lesions can be produced by unilateral exposures.

MILLER, D. K., AND RHODDS, C. P.

*"The Vitamin B, and B2G Content of Liver Extracts and Brewers' Yeast Concentrate."* *J. Exper. Med.*, 59:315-330, March, 1934.

A series of growth experiments on rats, using liver extract powder or vegex as a source for B1 and Brewers' yeast for B2G. The results in rats indicate that growth is not adequate with B1 alone, especially when the liver extract is given by intraperitoneal injections. The addition of B2G in these experiments results in a return to and maintenance of normal growth. The authors conclude that the extrinsic antianemic factor described by Castle is not identical with the thermostable growth producing vitamin B2G.

## SECTION V—*Therapeutics*

### A Symposium on Management of Oesophagitis

#### Article I

**M**Y general plan in the therapy of oesophagitis is as follows:

1. The first thing in the morning, to cleanse out collected mucus, sodium bicarbonate, 2 Gm. (30 grains), in a glass of water, to be sipped down in five or ten minutes. This either softens the mucus and carries it into the stomach or the solution is regurgitated with the mucus. In either event the subsequent swallowing of food is facilitated.

2. About twenty minutes before each feeding the patient sucks an unsweetened lozenge containing 0.13 Gm. (2 grains) of aethyl aminobenzoate. This promises sufficient anesthetic effect to allay pain and spasm when food is swallowed.

3. One hour after each feeding the patient swallows bismuth subcarbonate, 1.3 Gm. (20 grains), in a very small amount of water; this acts to coat the inflamed area.

4. The diet at the outset is of the bland, highly vitaminized peptic ulcer type, but when the stomach is not involved the feedings are much larger in quantity and are spaced further apart than they are when ulcer is present.

Walter A. Bastedo, New York City.

#### Article II

##### A. ACUTE OESOPHAGITIS

Application of ice bag to sternum and neck. Allow bits of ice to be dissolved in the mouth. Administer olive oil containing bismuth subcarbonate by mouth. (Two teaspoonsful of olive oil with a suspension of ten grains of subcarbonate of bismuth every three or four hours). In severe types, intravenous glucose feedings and water by bowel or subcutaneously and nothing by mouth. When the patient is better, allow ice cold milk by mouth in teaspoonful doses and gradually increase; then soft food after a time. When pain on swallowing is extreme, dissolving othoform or anesthesin lozenges in the mouth and swallowing the saliva is beneficial.

When the lesion is acute (as following the swallowing of poisons) a duodenal tube may be kept in situ (or a Levin tube) and all feeding and medication given through the tube, except protective medicines as oils, suspensions of bismuth or local anaesthetics as orthoform.

##### B. CHRONIC OESOPHAGITIS

When due to the abuse of alcohol, alcoholic drinks should be prohibited. In other forms, when due to disease of the lungs and heart, the main treatment should be directed to the primary lesion. Tobacco and hot fluids should be avoided; bland, cold diets may be

given, especially ice cold milk taken in small amounts at frequent intervals. A smooth diet is permissible.

A one per cent solution of nitrate of silver or tannic acid may be applied through a catheter. Olive oil in tablespoonful doses and bismuth in small amounts taken three or four times daily are valuable.

The following prescriptions will be of service:

| 1.                        |          | 2.                        |          |
|---------------------------|----------|---------------------------|----------|
| Acidi Tannicae            | grs. V   | Argent. Nitrate           | grs. V   |
| Ol. Olivae                | oz. II   | Ol. Olivae                | oz. II   |
| Shake label.              | Sig.: 30 | Shake label.              | Sig.: 30 |
| drops in little cool milk |          | drops in a dessert spoon- |          |
| 4 times daily.            |          | ful each of cool milk and |          |
|                           |          | glycerine 4 times a day.  |          |

These are to be taken only for a short time.

Julius Friedenwald, Baltimore.

#### Article III

##### MANAGEMENT OF OESOPHAGITIS

Consideration of the etiology of oesophagitis forms the basis for rational therapeutic procedures. The chief subjective symptom is "heart burn."

Normally the acid gastric juice does not come in contact with the lower end of the oesophagus. Frequent regurgitation of stomach contents and vomiting irritate this sensitive area and a chronic inflammatory process results. In severe cases, as emphasized by Chevalier Jackson and his co-workers, peptic ulcer is formed.

The dietetic treatment is quite similar to that of gastric and duodenal ulcer. The food must be soft and fiber-free and should be served cool. All hot drinks and condiments must be avoided. Petrolagar (plain) is useful in doses sufficient to prevent constipation; it also acts as a protectant to the irritated, engorged oesophageal mucosa.

The patient must be instructed to "control belching." Immediately after eating and whenever an uncomfortable feeling of fulness or distention is experienced, he must take a series of deep breaths with special emphasis upon exhalation. The vigorous action of the diaphragm tends to force the stomach "gas" out of the pylorus instead of permitting it to escape at the cardia.

Alkalies are rarely indicated, sodium bicarbonate especially is prone to favor eructations of gas which may draw acid contents into the inflamed area.

The Author often gives small doses of atropine sulphate (grain 1 500) in tablet form, every six hours with the idea of assisting the cardia in regaining its functional tonus.

Ambulant treatment is preferable to bed rest. Eructations are more likely to occur when the patient is in the recumbent posture.

Horace W. Soper, St. Louis.

## SECTION VIII—*Editorial*

*NOTE: The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Gastroenterological Association is in no way responsible for editorial expressions.*

In January, 1935, *The Spanish Journal of Diseases of the Digestive Apparatus and of Nutrition (Revista Espanola de las Enfermedades del Aparato Digestivo y de la Nutricion)* began publication in Madrid, Spain, by the house of Espaso-Calpe, S.A., Rios Rosas, 26—Apartado 547. The Editorial Committee comprises over 20 well known Spanish gastro-enterologists and the directing committee is composed of S. Carro, T. Hernando, E. Oliver, and H. G. Mogen. The foreign subscription rate is 40 pesetas (\$5.10 at present). The material printed each month consists of original articles, Editorials, abstracts and Book Reviews. The journal is well-printed and well-illustrated. All Editorials and abstracts are signed by the authors. Conservative advertising and an attractive format, as well as the obviously high-grade editorial material used, promise a long future for this publication.

The American Journal of Digestive Diseases and Nutrition extend congratulations and best wishes for long-continued success to its sister Journal.

The Editorial Council.

### AMERICAN BOARD OF GASTROENTEROLOGY

**I**NQUIRIES are constantly being received regarding the activities of the American Board of Gastroenterology. Many are openly critical of the inactivity of the Board, the correspondents feeling that, with the large influx of incompetent practitioners calling themselves "stomach specialists," a method of "dividing the sheep from the goats" is urgently needed. These individuals feel that issuing certificates to qualified gastroenterologists is all that is required to accomplish this end.

The problem, however, is not so simple as it seems. Some of the already functioning qualifying boards have found themselves in difficulties. No board can compel a practitioner to take its examinations and no patient can be coerced into consulting only the experts approved by a board. To have each board or even a co-ordinating board advertise to the public would not only involve a prohibitive expense but would probably be considered unethical. It has been realized for some time that the American Medical Association is the only organization that could control the whole situation adequately, and, in the past few years, definite steps have been taken to insure its controlling or actually taking over the activities of the existing boards as well as the organization of new boards.

The American Board of Gastroenterology, organized over a year ago by the two recognized national gastroenterological organizations—The American Gastro-Enterological Association and the Section on Gastro-

enterology and Proctology of the American Medical Association—and composed of members from different parts of the country, had its annual meeting in Atlantic City on June 12, 1935, during the week of the American Medical Association meeting. The report of its president is published below. It expresses the belief of all the members of the Board that it would be well not to attempt to force the issue with the American Medical Association, but to await the approval, co-operation or even actual control of the certification of gastroenterologists by the American Medical Association. The By-Laws of the Board, conforming to the standards set up last year by the Council on Medical Education and Hospitals of the American Medical Association, absolutely require that candidates for examination shall have had training in schools, hospitals, clinics and laboratories approved by the American Medical Association Council as being competent in gastro-enterological work; also its fundamental requirement is that all candidates first must be qualified internists. Qualification of internists has not yet been accomplished, but the Section on Internal Medicine of the American Medical Association has just appointed a Committee to meet with a similar committee of the American College of Physicians to form a Board of Internal Medicine. Prominent internists who have hitherto opposed the recognition of gastroenterology as a specialty have expressed approval of this requirement of our Board and in the future we can expect an increasing interest in and support of our stand namely, that a qualified internist has the right to limit his (or her) practice to gastroenterology as a specialty, that such a person has the right to be considered a specialist and that the standards of the specialty must be maintained by the application of the principles expressed in the By-Laws of the American Board of Gastroenterology.

A. F. R. Andresen, Brooklyn.

### REPORT OF THE PRESIDENT

Following the organization of our Board on June 14th, 1934, with the adoption of By-Laws and the election of officers, the seven members then present went before a notary and signed original and duplicate copies of the Articles of Incorporation. Your President then wrote to the secretary of the Advisory Board for Medical Specialties calling his attention to the fact that the House of Delegates of the American Medical Association had instructed the Council on Medical Education and Hospitals to add Gastroenterology to the list of specialties approved for the certification of specialists and informing him that we would soon make application for approval by the Advisory Board. Some lively correspondence ensued, the Advisory Board contending that our Board had used crooked politics in

having the resolution passed by the House of Delegates and your President pointing out that the resolution had been passed in the regular way, following an open hearing at which the Council on Medical Education and Hospitals had had numerous representatives, and that the real purpose had been to enable the Advisory Board to confirm its previous approval of our Board.

In July, 1934, a meeting of the Board of Regents was held at the office of B. B. Vincent Lyon in Philadelphia, the three members necessary for a quorum to transact business being present (Doctors Gaither, Bockus and Andresen). At this time it was decided that the Board should not make any further efforts to gain the cooperation of the Advisory Board, but should confine its efforts to recognition by the Council on Medical Education and Hospitals of the American Medical Association. It was also decided that incorporation should not be completed until our Board had the complete approval and cooperation of the Council. At subsequent meetings in October, 1934, and January, 1935, this stand was further approved by our Board of Regents and by the Council of the American Gastroenterological Association.

Meanwhile, the Council on Medical Education and Hospitals has been studying the whole subject of certification of specialists, with a view to supervising or perhaps taking over this work. In a personal interview with Doctor W. D. Cutter, Secretary of the Council, last December, he assured your President that a careful and prolonged study was under way, and that the Council was not contemplating the recognition of the Advisory Board nor of any specialty Boards until the study was completed and a definite course of action had been decided upon. Your President then offered the full cooperation of the American Board of Gastroenterology in any way that the Council might see fit to use its experience and prestige in the furtherance of the aims of the Board as expressed in its By-Laws. Aside from encouraging gentle suasion and pressure on those in authority in the American Medical Association to make them favorable to our Specialty, no further work has been done. The efforts of the Board should now be directed to the establishment of recognized post-graduate courses in gastro-enterology in schools, hospitals and clinics.

A. F. R. Andresen, Brooklyn,  
President American Board of Gastroenterology.

#### REPORT FROM AMERICAN BOARD OF GASTRO-ENTEROLOGY TO THE SECTION ON GASTRO-ENTEROLOGY AND PROCTOLOGY OF THE AMERICAN MEDICAL ASSOCIATION

**I**N accordance with a resolution jointly passed by the Section on Gastro-enterology and Proctology of the American Medical Association and the American Gastroenterological Association each appointing committees of four members with instructions to form such a Board and to serve upon it, the American Board of Gastro-enterology was organized on June 14, 1934, at Cleveland, Ohio. A set of By-Laws, which previously had been approved by the Advisory Board for Medical Specialties and which conformed in every way to the requirements of the Council on Medical Education and

Hospitals of the American Medical Association, was adopted, and the following officers were elected:

President, Albert F. R. Andresen, Brooklyn.  
Vice-President, Franklin White, Boston.  
Secretary-General, Ernest H. Gaither, Baltimore.  
Treasurer, Frank Smithies, Chicago.

Additional Members of Board of Regents  
Henry L. Bockus, Philadelphia.  
George B. Eusterman, Rochester, Minn.  
Sidney K. Simon, New Orleans.  
Adolph Sachs, Omaha.

On the same day, the House of Delegates of the American Medical Association, after a hearing and on recommendation of its committee on Education, passed a resolution instructing the Council on Medical Education and Hospitals to add Gastroenterology and Proctology to the list of specialties approved for certification of specialists. Since this time the Council has been investigating the entire subject of certification and has not yet actively entered this field, although, logically, it may be expected eventually to include the certification of specialists in all fields among its manifold activities.

In view of the fact that the rules of our Board applying to the qualifications of candidates for certification, the investigation and approval of schools, hospitals and clinics engaged in post-graduate work and the publication of lists of such schools and specialists, requires the cooperation of and in fact control by the Council on Medical Education and Hospitals, the members of the American Board of Gastroenterology have decided that the Board shall not begin to function without the full approval and cooperation of the Council and have offered their services to the Council in an advisory capacity. The efforts of organized gastroenterology should now be directed to the establishment of recognized post-graduate courses in gastroenterology.

#### CHOLESTEROL

**R**ECENT studies in the blood cholesterol are apparently destined to have a tremendous influence upon the dietary habits of man. Of special significance is a recent article by Rabinowitch (1) on "The Relationship of Plasma Cholesterol and Arteriosclerosis." He concludes that excess blood cholesterol is an important etiologic factor in the production of arteriosclerosis in the young diabetic. Also that treatment with the high carbohydrate—low calorie diet has delayed development of cardiovascular disease in the cases investigated.

The work of Timothy Leary (2) is also of great significance. He was impressed with the high content of lipoids in atheromatous aortae. Cholesterol is the only sterol found in animal bodies. It forms the framework of all animal cells. It combines with fatty acids to form esters. In our dietary, eggs, milk, and pork fats are the main sources of supply. Leary concludes that the lesions of human athero-sclerosis can be reproduced in the rabbit by feeding cholesterol. The inheritance of a poor cholesterol metabolism appears to be associated with the tendency to early death from coronary sclerosis.

Joslin (3) suspects a high cholesterol blood content as the etiological factor in cataract and arteriosclerosis in the diabetic. He emphasizes the importance of

keeping the fat in normal limits in diabetes, at least under 230 mg. of cholesterol per 100 cc. of blood.

Recent studies by Hartung and Bruger (4) are of interest. The plasma cholesterol tends to be low in rheumatoid arthritis and elevated in osteo-arthritis. These observations lend added proof to the theory that rheumatoid arthritis is an infectious disease and osteo-arthritis a degenerative one.

Lockie and Hubbard (5) in their article "Changes in Symptoms and Purine Metabolism produced by High Fat Diets in Four Gouty Patients" conclude as follows: "The development or exacerbation of joint symptoms following the ingestion of a diet high in fat and low in carbohydrate and protein for several days may serve as a useful test in the differential diagnosis of gout. Diets high in fat and low in carbohydrates should be avoided in the treatment of patients with gout."

Perhaps the majority of internists have been in the habit of feeding a diet of low protein content in the treatment of arteriosclerosis. Others have employed the alkaline ash regime. Certainly few have considered the fats, with the exception of Joslin and his followers in their campaign against obesity as a forerunner of diabetes.

Our therapy of vascular disease should include a sharp reduction in the foods containing cholesterol. It does not require much imagination to believe that the reduction in the consumption of such foods may materially prolong life by the prevention or delay in the formation of arterial disease, particularly coronary athero-sclerosis.

The articles cited above are splendid examples of clinical research work. They have inaugurated a new chapter in preventive medicine.

Horace W. Soper, St. Louis.

## SECTION IX—Book Reviews

(This section is open to contributions from any medical reader, whether a member of the Editorial Council or not).

*Radiologie Clinique du Tube Digestif, Publiée sous la Direction de Mm. Pierre Duval, Jean-Charles Roux, Henri Bécélère; Second Edition; 372 pages with 514 radiographs and 516 schematic outlines explaining the Roentgenographic reproductions. Masson et Cie, Publishers, Paris, France. Price, to non-residents of France and its colonies. 330 francs.*

**SUPERLATIVELY**, do the French perform a task when that task is worth-while, when they abandon their *laissez faire* attitude (is such but a national pose?) and when the enterprise under consideration really is along important lines or comprehends unusual pointings.

Whether the project be in clinical medicine (Laennec), microbiology (Pasteur), chemistry and physics (Dubois-Raymond), art (Corot), music (Bizet), literature (Hugo, Loti), armament (the famed "75's"), aviation (Nungesser), or the stern, blood-and-bone-valor and the *clan-demanding* months of a Verdun hell—whatever it be which calls for whole-souled devotion, our French *confreres* have been, and yet are, capable of extraordinary, concentrated effort, magnificently delivered.

Judge not France by those individuals who smirk in the *entresol* of the Folies Bergère, who strut at Long-champs, gesticulate clownishly and jabber incoherently in the "Chamber" or dwaddle on the Bois! Centuries have proved that, from the *habitant* up through the *haute monde*, there runs a fibre of steel, the flame of genius, the patience and intelligent persistence in this, a people sure of its quality and daring in its conceptions and acts. When least expected, these attributes become manifest: epoch-making results follow.

Genius, solid special knowledge, unique planning, vast technical and clinical experience, admiration-compelling perseverance and unrivalled execution are exhibited by Doctors Duval, Roux and Bécélère in their recently issued "Atlas" titled as above. Excellent as was the First Edition of this book, closer team-play, extended experience and unusual cooperation with their renowned Publishers have resulted in the production of what this reviewer considers to be the most important and useful Roentgenologic atlas yet to appear in any country.

For convenience in handling, this stupendous work is issued in two, most attractively and substantially bound volumes. Even before making a detailed study of the books' contents, one is impressed by the beautiful, yet serviceable binding, the artistic title-lettering and imprint, the large, well-printed page, the selection of type-fonts, the assembling and arrangement of material, the sharpness of the Roentgen reproductions, the appropriately-placed index. It is but proper that, before discussing the subject-matter of the volumes one, here, pay tribute to the very evident interest which the House of Masson et Cie has manifested towards enabling the distinguished Authors best to present their out-of-the-ordinary studies to an audience which, on the basis of past contributions to the literature by Drs. Duval, Roux and Bécélère, expects much. Detailed perusal of the volumes disappoints no reader with respect either format or scientific substance. Most certainly, the Authors are indebted greatly to their Publishers for such a marked degree of understanding co-operation.

The plan of presentation is logical, instructive, down-to-date, comprehensive: indeed, we have seen no work on the subject which so thoroughly covers the field. So well is the enterprise carried through that it is sure to command the interest of the general internist quite as much as that of the Roentgen specialist.

Before entering upon special discussion of affections of the stomach and the duodenum, the Authors submit a concise, but adequate chapter dealing with methods of procedure in X-ray study. In addition to listing the procedure common to Roentgenographic examinations with the aid of opaque media, they emphasize methods whereby added information about the viscera may be obtained by combining air-inflation of the organs partly filled with a bismuth-geleline composition. Air is introduced by means of a duodenal tube whose tip may lie in the stomach or in the duodenum; the opaque mixture thus is scattered over all parts of the mucosa as a thin, adherent, adhesive film; Roentgenograms, made after such technic, permit most interesting and, at times, diagnostic, studies of the mucous membrane or of ulcers or of neoplasms. The Authors present many film-reproductions throughout the work which demonstrate the value of these technical innovations.

However, complete as is this "Atlas," we observe that no great space is devoted to fluoroscopy or the advantages to the diagnostician of using localized pressure, during fluoroscopy, and then, while the lesion still is visible, making multiple Roentgen exposures from various angles. Unless we are in error, such compression-Roentgenograms made at fluoroscopy constitute one of the few basic advances of the past decade; witness the last three years' efforts of the Scandinavians. However, in an atlas seemingly devoted largely to the objective reproduction of anomalies, perhaps the Authors considered it not essential to present an elaborate discussion of what the newer fluoroscopic technic has to offer. Yet, there is exhibited so complete a Roentgen coverage of affections of the stomach and the duodenum that, the reviewer for one, would have welcomed a thorough discussion of fluoroscopy by these very evident masters of film-making and deductions therefrom.

In this work of Duval, Roux and Bécélère, the actual Roentgenographic study of the viscera in health and in disease is presented along unique lines. In all conditions possibly affecting the stomach and the duodenum, the page facing the reader carries sharp, clean-cut reproductions of Roentgen films. On the opposite page, are anatomico-schemic pen-and-ink sketches faithfully drawn to correspond with each particular Roentgenogram. These diagrammatic drawings, to the most minute degree, not alone elucidate these Roentgenograms of the filled viscera but carry accurate, concise notes explaining each feature of the film and its corresponding schemic sketch. One need but glance through a few pages to recognize the high degree of conscientious care which has been devoted to both sketches and the legends explaining them, and to the Roentgenograms to which they refer. Not alone to him who is expert in Roentgenology do these data convey a mine of clinical and technical information but to the clinician who is not concerned with the actual making of Roentgenograms, both films and their corresponding interpretative sketches comprise a series of studies invaluable instructive. Undoubtedly, the

Authors have, by their painstaking efforts, driven away from Roentgenology of the viscera considered, much of what previously has been assumed to be the peculiar knowledge of the Roentgenologist and have made it possible for the internist, who previously has been lost in the so-called mysteries of his fellow-consultants' "cult," to attain proficiency in film-interpretation with but a reasonable degree of study and application. A quip supposedly indicating the dense degree of illiteracy of the colored race, has the jovial Negro asking his Master regarding a newspaper: "Pahdon me, Boss!, but which does you-all read, de white or de black paht?" Among physicians looking at Roentgen films, one still finds those to whom the "white paht" signifies quite as little as does the "black"! In this and, doubtless other countries, perusal of this new atlas should render impossible such "film illiteracy."

In the space allotted for this review, one cannot do justice to the various sections of Drs. Duval, Roux and Bécélère's "Atlas"; each page exhibits its individual points of significance. From the Roentgenograms detailing the variations possible to the normal stomach and the duodenum, observations of essential value most strikingly are demonstrated in presentations of "Hypersecretion and Stasis"; "Aerophagia"; "Ptosis, without and with Atony"; "Cascade or 'champagne goblet' stomach"; "Visceral Deformities due to External Pressure"; "Volvulus"; "Gastritis"—an outstanding presentation of anomalies of the mucosa; "Chronic Gastric Ulcer—with a most excellent series exhibiting protected perforative types, with or without hourglass deformity"; "Pyloric Ulceration"; "Perforated Ulcers"; "Pyloric Stenosis"; "Hour-Glass Stomach"—a splendid set of examples of all forms.

It should not be gathered that the above topics are shown by Roentgenogram reproductions and schemic drawings only; on the contrary, each subject is accompanied by a sound clinical as well as Roentgenographic discussion—a procedure which adds much to the illustrations and which demonstrates, too, that the Authors are not just "picture-makers" but are clinicians of greater than ordinary acuteness. It is rather surprising that the Authors exhibit no examples of "Syphilis of the Stomach"—in fact, in a brief statement, express it as their opinions that lues causes no characteristic gastric deformities, Roentgenographically considered. It is the reviewer's experience that, when lues organically involves the stomach, the Roentgen films disclose anomalies which, in his opinion based upon a considerable series of cases, are almost pathognomonic. American clinicians and Roentgenologist would seem to have settled upon a syndrome for gastric syphilis in which Roentgenograms contribute very significant evidence; indeed, the films not uncommonly tip the scales towards the making of positive diagnoses.

Two comprehensive chapters are devoted to gastric malignancy, one to benign tumors, one to gastric foreign bodies, one to gastric diverticula, one to perigastritis, with or without its accompanying visceral deformities. An amazing lot of common and unusual material is presented and the discussions supplementing the illustrations are rich with descriptive and diagnostic data.

One of the most important sections of the work, and one concerned with most clarifying and down-to-date remarks which elaborate upon the Roentgenograms, is that dealing with "Diaphragmatic Hernia" as it affects

stomach, diaphragm and neighboring organ function. An excellent series of schematic anatomic drawings adds force to a most unusual and comprehensive group of Roentgenograms. The whole forms the most complete presentation of the subject which it has been our privilege to see. The distinction between *eventration* of the diaphragm and *actual hernia* of the stomach through it or *via* the *hiatus*, admirably is brought out. The surgical significance of true diaphragmatic herniation is emphasized in the light of recent modern opinion; this seems very much worth-while in view of the new types of operation which Truesdale and others have proposed and are performing—apparently with gratifying results.

The surgeon further is kept in mind by the Authors' presenting a complete discussion and a fine sequence of Roentgen reproductions detailing the "Stomach subsequent to operations." Not alone are alterations in gastric function shown but the degree and position of visceral deformities consequent upon the common types of surgery, masterfully are portrayed and commented upon. To the active abdominal surgeon, this section of the work is invaluable—it, alone, warrants the purchase of the volumes.

Volume 2 deals with Roentgen study of the duodenum, in health as well as in disease. The plan of presentation corresponds with that found so admirable in studying the stomach.

Particular emphasis is placed upon discussion of methods where, at the Roentgen study, all segments of the duodenum may be visualized. This chapter is extremely helpful in the study of both the normal and the diseased viscus.

An all-too-frequently neglected aspect of the duodenum and its "bulb," namely, the effects upon position, contour and mobility consequent upon extra-visceral anomalies, here is given very thorough treatment from the Roentgenological and functional angles. The Roentgenograms are superb. The schematic drawings are most illuminating, while the running-text is enlightening and concise. In no work, have we noted so thorough a discussion of the normal duodenum or the artefacts which, if not appreciated, may tend toward the returning of false diagnoses.

After a complete synopsis of the normal duodenum and its "bulb," the subsequent chapters, which discuss and illustrate all forms of functional disturbance and organic lesion of the viscus, most readily are appreciated. It is in this section of the work, *viz*: consideration of the duodenum, that, according to the reviewer's concept, the Authors have excelled even their thoroughly comprehensive presentation of various Roentgen aspects of the stomach. Such pertains not only to the illustrative features but to the unusual quality of the accompanying text. Deformity, due to all types of ulcer, to simple atonic dilatation, to mucosal striations, functional and in association with disease, to stenoses, perioduodenitis, even to malignant disease, most convincingly is demonstrated and discussed.

A unique section well illustrates the possibilities of stenosis at the duodeno-jejunal angle, simple or in conjunction with anomalous mesenteric attachments. Only occasional, scattered references in the literature previously have emphasized this puzzling condition, but Drs. Duval, Roux and Bécélère demonstrate graphically that the anomaly is commoner than has been considered and that when it is present, a confusing picture, clinical as well as Roentgenological, may arise.

Sections dealing with the effects upon the duodenum when disease is present in the gall bladder and biliary tract, malposition or lesions of the papilla of Vater, and diverticula of the duodenum (a lesion which, only recently, has assumed importance, etiologically, Roentgenologically and as a source of dyspeptic disturbances) receive thorough attention, amplified by striking film reproductions and schematic drawings. In no one volume, published in this or other country, have we seen so complete a presentation of either the common or the infrequent lesions in which the duodenum, primarily or secondarily, is involved.

Excellent sections are submitted concerned with duodenal lesions in infants, the effects of para-visceral disease upon duodenal shape, size, contour or position and the disturbances in the function, location and form of the viscus consequent upon surgical procedures. This last section is most useful to internists, surgeons, physiologists and Roentgenologists in appraisal of postoperative anatomical relations and in assisting to explain why, when following successful, mechanical technique, patients yet may exhibit conditions which permit abnormal physiological sequences—secretory or motor.

An adequate, detailed and correct reference index completes the work.

In his early remarks, the reviewer exhibited greater than ordinary enthusiasm for this "Atlas"—its binding, format, text and illustrations. As he became intimately familiar with the work and tested many of the data in specific subjects, he has become increasingly impressed by the uncommon accuracy, the beauty of the illustrations, the wise and judicious use of material, the soundness of the clinical and technical discussions and the immense amount of patience and fidelity which the Authors have brought to their task. The result not alone is a triumph for Drs. Duval, Roux and Bécélère but a tribute to the high quality of work being done in the clinics of France. This reviewer stated some months ago that no American Roentgenologist could consider that his technical and clinical education was complete unless he had visited the teaching, diagnostic and therapeutic actinological laboratories at the University Hospital, Ann Arbor, Michigan. Now he must amplify that statement: most assuredly, no clinician-Roentgenologist in the world can claim completeness in the art and craft of his specialty who has failed to include a *sojourn* in the laboratories of Drs. Duval, Roux and Bécélère. To all, such study-trip may be not possible: in that event, one may say that unless the clinician-Roentgenologist's library contains this Atlas newly compiled by our French colleagues, its shelves lack today's most interesting, scientific and useful volumes. To attain this objective should not be particularly difficult in view of the astonishingly low cost of the work (330 francs)—and the rates of exchange all in our favour!

Frank Smithies.

*Textbook of Biochemistry* by Harrow and Sherwin, 797 pages, 52 illustrations, and published by W. B. Saunders Company, Philadelphia and London, 1935.

THE new textbook of biochemistry edited by Harrow and Sherwin has been written by thirty-one American and British biochemists including the editors, who have made original investigations in the field of biochemistry indicated by the chapter each has con-

tributed. This gives each chapter the stamp of authority and assures the reader of the importance and up-to-dateness of the subject matter presented.

The sequence of the chapters is logical. The style is terse, but clear. The method of presentation is remarkably uniform and well-balanced for a textbook written by so many authors. This is due primarily to the conciseness with which the various chapters have been written; in fact each chapter constitutes a brief *résumé* or review of the subject matter in its field. Yet, the book is more comprehensive and descriptive than a synopsis. A conspicuous feature of the book is the absence of biochemical methods or frequently even of a reference thereto. A list of references accompanies each chapter which serves as a satisfactory introduction to the literature. The book contains a bibliographic index of authorities cited in addition to a very completely arranged subject index.

The book was written primarily for students and teachers of medicine whom it will serve well. It will

also serve students and investigators in other fields who desire to add to their perspective concerning the chemistry of biological processes. To appreciate completely the value of certain chapters, the student must possess a thorough knowledge of organic and physical chemistry, i. e. he must know more chemistry than the average medical student. The book will be of value to the gastro-enterologist who desires a more intimate knowledge of the biochemical principles of digestion, nutrition and metabolism, but there is little or no allusion to methods for gastro-intestinal diagnosis and principles of therapy. The gastro-enterologist will find other deficiencies in the book, e. g. the words feces, stool and excreta are not found in the index and their biochemical connotations are not found in the text. There is a good chapter on the chemistry of detoxication which will be of interest to the readers of this Journal.

A. C. Ivy, Northwestern University, Chicago.

## SECTION XI—*Societies, Programs and Proceedings*

### THE FOLLOWING CHANGES IN MEMBERSHIP WERE MADE AT THE ANNUAL MEETING OF THE AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION, JUNE, 1935

#### *Advanced from Associate to Active Fellowship:*

Dr. Theodore L. Althausen, University of California Medical School, San Francisco, Cal.

Dr. Everett D. Kiefer, 605 Commonwealth Avenue, Boston, Mass.

Dr. Harry Shay, 265 S. 19th Street, Philadelphia, Pa.

Dr. Edward S. Emery, Jr., 319 Longwood Avenue, Boston, Mass.

Dr. Mandred W. Comfort, Mayo Clinic, Rochester, Minn.

#### *Elected to Active Fellowship:*

Dr. Chauncey W. Dowden, 921 Brown Building, Louisville, Ky.

Dr. Virgil E. Simpson, 321 W. Broadway, Louisville, Ky.

Dr. Carl H. Greene, 889 Lexington Avenue, New York, N. Y.

Dr. Beaumont S. Cornell, 435 Lincoln Bank Tower, Fort Wayne, Ind.

Dr. Clifford J. Barborka, 700 N. Michigan Avenue, Chicago, Ill.

Dr. Adolph Sachs, 525-35 City National Bank Building, Omaha, Nebr.

Dr. L. G. Zervas, Medical School, University of Indiana, Indianapolis, Ind.

#### *Elected to Associate Fellowship:*

Dr. Clarence J. Tidmarsh, Suite 5, 1390 Sherbrooke Street West, Montreal, Canada.

Dr. Edwin L. Gardner, 1629 Medical Arts Building, Minneapolis, Minn.

Dr. David H. Rosenberg, 310 S. Michigan Avenue, Chicago, Ill.

Dr. S. A. Wilkinson, 605 Commonwealth Avenue, Boston, Mass.

Dr. John R. Twiss, 65 E. 55th Street, New York, N. Y.

Dr. L. K. Ferguson, 6390 Drexel Road, Overbrook, Philadelphia, Pa.

#### *Elected to Research Fellowship:*

Dr. Heinrich Necheles, 2900 Ellis Avenue, Chicago, Ill.

#### *Transferred from Active to Senior Fellowship:*

Dr. Dudley D. Roberts, 270 Park Avenue, New York, N. Y.

Dr. Franklin W. White, 322 Marlborough Street, Boston, Mass.

Dr. Seale Harris, 804 Empire Building, Birmingham, Alabama.

#### *Elected to Honorary Membership:*

Dr. Raoul Bensaude, 2, Rue de Penthievre, Paris, France.

#### *Officers of the American Gastro-enterological Association elected at the 39th Annual Session, held at Atlantic City, New Jersey, June, 1935:*

President—Dr. Howard F. Shattuck, New York; First Vice-President—Dr. Chester M. Jones, Boston; Second Vice-President—Dr. Charles G. Heyd, New York; Treasurer—Dr. A. H. Aaron, Buffalo; Recorder—Dr. Sara M. Jordan, Boston; Secretary—Dr. Russell S. Boles, Rittenhouse Plaza, Philadelphia.

#### *Members of the Council:*

Dr. Burrill B. Crohn, New York; Dr. Clement R. Jones, Pittsburgh; Dr. B. B. Vincent Lyon, Philadelphia.

#### *Committee on Admissions and Ethics:*

Dr. Ernest H. Gaither, Baltimore; Dr. Irvin Abell, Louisville, Ky.; Dr. Albert F. R. Andresen, Brooklyn.

*Coordination Committee:*

Dr. Burrill B. Crohn, Chairman, 1075 Park Avenue, New York.

Dr. George B. Eusterman, Mayo Clinic, Rochester, Minn.

Dr. Walter L. Palmer, Albert Merritt Billings Memorial Hospital, Chicago, Ill.

## SECTION XII—"The Clinic"

### A Case of Gastric Polyposis

By

A. C. van RAVENSWAAY, M.D.  
ST. LOUIS, MISSOURI

THE presence of multiple polypi in the stomach is of interest from both clinical and roentgenological viewpoints as one of the more important benign lesions of the stomach inasmuch as it may be confused symptomatically and by X-ray with the more common malignant affections. The following case is reported as being representative of this condition.

#### CASE REPORT

A 52 year old, male, negro barber was admitted to Barnes Hospital complaining of epigastric pain and fullness of 5 years' duration, generalized weakness for 4 years, and 20 pounds loss of weight during the preceding year. He had suffered from asthma since childhood. Twelve years previously he had been in the St. Louis City Hospital for 4 months "with his right leg in a cast." Since that time his right hip had been ankylosed.

Analysis of his complaints at the time of admission to Barnes' Hospital revealed that the epigastric pain was increased by food and could be relieved by massage but not by soda. The pain and weakness were becoming progressively worse. There was no nausea or vomiting. Intermittently a hard lump could be palpated in the epigastrium.

Physical examination revealed a poorly nourished, orthopneic, elderly negro man in no acute distress. The ocular fundi showed moderate sclerosis and tortuosity of the retinal vessels. There was marked dental caries. The chest was emphysematous with numerous

rhonchi, more marked on the left. The heart was of normal size; B.P. 110/72. The liver was palpable one finger-breadth below the costal margin. Its edge was regular. In the left epigas-

gms., and W.B.C. 5200. Differential: Eos. 1%, Staubs 4%, Segments 48%, Lym. 36% and Mon. 10%. The sputum contained 2 eosinophils per h.p.f. Stool and urine examinations were negative.

Fig. 1. The stomach after surgical removal. The pylorus may be seen on the extreme right.

trium there was an indefinite mass, tender to deep palpation. The right leg was ankylosed at the hip and was shorter than the left. The toes and fingers were clubbed. The radial arteries were thickened.

*Laboratory Examinations:* The blood study showed R.B.C. 4.07 M., Hgb. 10.7

The gastric contents contained gross blood and there was an achlorhydria.

X-ray examination of the right hip showed healed tuberculosis with fusion. A gastro-intestinal X-ray examination revealed a rapidly emptying stomach, flexible throughout, the location of multiple filling defects scattered through-

\*Mallinckrodt Institute of Radiology and the Department of Medicine, Washington University School of Medicine.  
Submitted March 17, 1917.

cut the entire stomach and most marked on the lesser curvature. The gall bladder did not visualize by oral cholecystograms. The cecum was inverted. The conclusion and diagnosis by Dr. Joseph W. Larimore was diffuse polyposis of the stomach.

At operation on 12-3-34, Dr. Glover Copher opened the abdomen under intratracheal anaesthesia through a long left rectus incision extending from the costal margin downward. No free fluid was found. The stomach was enormous in size. The serosal surfaces and muscles were not involved. The viscous seemed to be filled with multiple, large mucosal masses, which gave the impression that there was multiple polyposis involving the entire stomach. The liver was free of any pathology. The gall bladder showed chronic cholecystitis without stones. The spleen was of normal size. The duodenum was mobilized, divided, and the proximal end inverted. The entire stomach was removed and the oesophagus was anastomosed to a loop of the jejunum. Because of bleeding, it was necessary to remove the spleen.

On the second postoperative day the patient developed signs of pneumonia at the right base and died in 12 hours.

**Surgical Pathological Examination:** The resected stomach measures 23x14x4 cm., and is distended with dark red blood. Numerous hemorrhagic areas are seen in the mucosa of the cardia. The mucosa everywhere shows a marked polypoid proliferation which is most extensive near the center of the specimen on the greater curvature. The polypi average 2-3 cm. in diameter, and all protrude a similar distance from the mucous membrane. On section, they show a fibrous pedicle and hypertrophied mucous membrane. Microscopical examination gave no evidence of malignant change. Diagnosis: Benign polyposis of the stomach.

#### DISCUSSION

This case exhibits many points of similarity to other reports in the literature and to two other cases of multiple polypi of the stomach previously seen at this hospital. The symptoms usually appear in the late decades of life. They include epigastric discomfort which varies in character from a sense of fullness to severe pain. This may be relieved or accentuated by eating, and is usually not benefited by antacids. Constipation is frequently co-existent. An achlorhydria is almost invariably present and frequently there are signs of bleeding.

At fluoroscopic examination the condition can be recognized by the presence of multiple filling defects in a stomach which organ usually has a soft, flexible wall. If peristalsis can

## ACCEPTED by the AMERICAN MEDICAL ASSOCIATION COMMITTEE ON FOODS

*for the relief of constipation due to insufficient "bulk" in meals*

EXHAUSTIVE RESEARCH in leading nutritional laboratories has discovered the scientific facts about bran.

These tests indicate that Kellogg's ALL-BRAN is a natural laxative food for normal people. As a result, this delicious cereal has been accepted by the American Medical Association Committee on Foods.

ALL-BRAN supplies "bulk" to aid regular habits. This "bulk" does not lose its effectiveness when used month after month. ALL-BRAN also furnishes vitamin B and iron, an element of the blood.

The "bulk" in ALL-BRAN is gentle. It does not break down in the body as much as the "bulk" in fruits and vegetables. So it is often more effective.

ALL-BRAN may be used by most people. There are some individuals with diseased or highly sensitive intestines, where "bulk" in any form is inadvisable.

Kellogg's ALL-BRAN may be served as a cereal with milk or cream, or used in cooked dishes.

It is much more effective than part-bran products. Sold by all grocers. Made by Kellogg in Battle Creek.

## The Practice « of Dietetics »

By L. H. Newburgh, M.D.,  
Professor of Clinical Investigation, Medical School  
University of Michigan;  
and Frances Mackinnon,  
A.B., Dietitian, Diet Therapy Clinic, University Hospital, and Instructor, Dept. of Hygiene and Public Health, University of Michigan.

### Comments of reviewers—

"This is a very complete and scientific text and reference book on dietetics. The book will be of greatest value to the physician, the dietitian, and the medical student."

*The Forecast*

"In this book the place of dietetics and diet therapy in medical therapeutics is discussed in a manner that gives the reader a clear picture of its importance, and, at the same time, impresses him with the need for a sane point of view in its practice."

*Practical Home Economics*

"This book contains all the material necessary for the practice of dietetics. It is both didactic and practical. Dr. Newburgh writes as he practices; so direct, clear, and yet scientific that even the student or busy practitioner can understand."

*Long Island Medical Journal*

be induced, it may be observed to pass over the stomach without impairment, indicating the freedom of the musculature from invasion of the pathologic process.

The complications are: interference with digestion and a resultant cachexia; hemorrhage, seldom mas-

sive; malignant degeneration which apparently is much less common in the case of multiple polypi than it is when there is but a single polypus and, occasionally, pyloric obstruction caused by the prolapse of a juxtapyloric polyp into the duodenum.

Fig. 2. Antero-posterior view of stomach after the ingestion of two ounces of barium suspended in 70 c.c. of water.

## Non-Tropical Sprue: Report of a Case\*

By

JOHN A. REED, A.B., M.D.  
WASHINGTON, DISTRICT OF COLUMBIA

**S**PRUE ordinarily is considered a tropical disease but is being reported in non-tropical climates

with increasing frequency. Recently Snell, Camp, Watkins (1) made an excellent summary of this disease which report should prove to be a reference *arbit* for the future. In

\*From the Department of Medicine The George Washington University School of Medicine. Submitted June 1, 1933.

view of the relative rarity of the occurrence of sprue in this country, and paucity of case reports in the literature, I submit an instance and call attention especially to the treatment used which was followed by marked improvement and apparent cure.

# CASE REPORT

Female, age 41, residence, Cumberland, Maryland.

In June, 1933, began to have a diarrhea which became worse following death of her husband in October, 1933. There were 4 to 5 unformed, watery, white, foamy stools a day, each containing soft, mushy, white fecal material. Other symptoms and signs were as follows: marked loss of weight, 33 pounds, stiffness of the joints, swelling of the ankles, weakness, sore tongue, moderate indigestion (gas and belching), fatigability, and capricious appetite. Sleep was only fair.

*Previous history*—no relevant diseases.

*Family history*—of no value will respect present condition.

## Physical Examination:

Drawn, emaciated, depressed appearance. Height 65 inches. Weight 94 pounds. The knee jerks were equal but slightly sluggish, the tongue was coated, the ankles slightly oedematous. The re-

mainder of the physical examination was entirely negative.

## Roentgen Examination:

With the exception of an atonic, redundant type of colon, gastro-intestinal series was normal.

*Wasserman and Kahn*: Negative.

## Feces:

Many stools were studied, they appeared putty-colored, frothy but with no microscopic or macroscopic blood or mucus. Abundance of bacteria was present. Moderate amount of undigested starch granules, (Lugol's solution), moderate number of yeast cells, no ova or parasites. Benzidine test faintly positive, guaiac negative; *fat present in large amounts*, (Sudan III stain), occasional fatty acid crystal. *Smear*: negative for tubercle bacilli. *Culture*: plates and subcultures show many usual intestinal non-pathogenic organisms with *B. coli communis* predominating. Special Endo media negative for pathogenic micro-organisms. Tubercle bacillus negative on Petroff's medium and guinea pig injections.

## Gastric Contents:

60 cc. well digested material. Free HCl 14, Total acidity 18. No blood.

*Basal Metabolism Rate*—minus 22%.

*Blood picture*: Sept. 22, 1934. R.C.C. 4,010,000, W.B.C. 500. Hemoglobin 80% (12.8 grams) Smear and differential count normal. November 8, 1934—

R.B.C. 4,130,000, W.B.C. 6800, Hemoglobin 82%.

*Urinalysis*—normal.

*Pancreatic Enzymes* (Dr. Thomas R. Brown, Baltimore, Md.): Diastase 96: trypsin 27.6 mgms. (Normal).

## DISCUSSION

It is interesting to note that after 27 examinations and two consultations, diagnostic impressions only were reached and treatment was instituted somewhat empirically. Such cases of steatorrhea are so uncommon in the private practice of gastroenterology that they are apt to be undiagnosed or incorrectly so.

After fair exclusion of tuberculosis and disturbed fat metabolism, a typical or non-tropical sprue was considered and treatment instituted towards its alleviation.

Various forms of management had been used in the cases reported with no improvement. A diet with little or no fat was given and liver extract intramuscularly was started. The protein content was fairly high. Calcium as calcium lactate together with hydrochloric acid and haliver oil and viosterol were administered. Four days afterwards the white watery foamy stools disappeared replaced by

## TILDEN has Kept Faith with Physicians

### MALTO-FERRO (TILDEN)

- **C**ONSISTS of Iron Ammonium Citrate, 80 grs. per fluid ounce, Hypophosphites, Extract of Cod Liver Oil, Malt, and other ingredients, combined in a manner exclusive with Tilden.
- MALTO-FERRO (Tilden) has been prescribed for secondary anemias and general debility, conditions of the system manifesting subnormality in metabolism. The large dose of Iron and other reconstructives is absorbed rapidly, and the blood deficiencies corrected, without gastric upset or constipation.
- Symptoms of nervousness, insomnia, constipation, loss of appetite and weight, yield readily to prescriptions of MALTO-FERRO.
- MALTO-FERRO (Tilden), like all prescription specialties produced by The Tilden Company, is labeled according to law, advertised only to the medical profession, manufactured under strict scientific control, and offered only after years of thorough clinical success.

Literature will be furnished confidentially to physicians only on request.

a soft, unformed, brown, mushy movement. In 10 days' time, normal sausage shaped stools were noted and many of the symptoms had disappeared. About 3 weeks after management had been instituted, the patient went on "a dietary spree" which resulted immediately in a return of the white foamy watery stools. She immediately returned to the "fat free" diet and in two days improvement was noted. Since November past, gain of weight has been steady so that her present weight is 131, a total gain of 34 pounds with subjective complete recovery.

### SUMMARY

A case diagnosed as non-tropical sprue is presented because of the relative rarity of the affection. Authors previously mentioned state that something over a hundred cases are now on record. The treatment suggested, while by no means original, was efficacious.

SAMUEL MORRISON, M.D., AND MAURICE  
FELDMAN, M.D.

*The Effect of Bacteria on the Normal Stomach and on Acute Experimental Gastric Ulcer in Dogs. Am. Jour. Med. Sc., Vol. 189, No. 5, May, 1935.*

Experimental work of the authors deals with the effect of bacteria upon the normal gastric mucosa and with the mucosa of acute ulceration produced by hydrochloric acid.

It was found that large amounts of bacteria mixed with food did not produce ulceration when fed to the dogs. When bacteria were fed to the animals in which acute ulcers had been produced by hydrochloric acid, no infection of the ulcer took place, the ulcer healing completely.

The administration of sodium bicarbonate did not produce any effect upon the gastric mucosa or ulcers.

The investigators injected potent cultures of bacteria into the gastric wall usually without the formation of abscess or necrosis.

The authors concluded that the acute hydrochloric acid ulcer is clean-cut, non-infected, and apparently does not lend itself to bacterial infection. Some other factor must play an important role in the production of chronic ulcer.

H. W. Soper, St. Louis.

ALVAREZ, WALTER C., AND HINSHAW,  
H. CORWIN.

*Foods That Disagree With People. J. A. M. A., 104:2053, June 8, 1935.*

Five hundred patients of fair or good intelligence who were complaining of indigestion, were questioned about foods that they could not eat or could only digest with discomfort. Onions, apples,

cabbage, milk, chocolate, radishes, tomatoes, cucumbers, eggs, fats, cantaloupe, beef, strawberries, coffee, lettuce, dried beans, cauliflower, melons, pork, corn, and pickles were common offending foods.

A number of patients with migraine incriminated certain foods in connection with their headaches. Among the foods were chocolate, onions, milk, peanuts, cabbage, and eggs.

Transient urticarias were commonly ascribed to the following foods: Strawberries, tomatoes, eggs, fish, milk, and chocolate.

Foods that are seldom mentioned by patients with indigestion as having any bearing on their discomfort are lamb, gelatin, butter, sugar, rice, rye, barley, arrowroot, tapioca, sago, lima or soya or string beans, cooked apple, pineapple juice, beets, asparagus, peas, Irish or sweet potatoes, egg plant, turnips, parsnips, pumpkin, artichokes, cooked pears and weak tea. These foods can be used as a basis for elimination diets.

The authors stress that the digestibility of foods has received but scant attention, that food sensitivity is not all on an allergic basis; that each individual must be studied as to his dietary requirements, and that ready-made diet lists and general instructions against fried or greasy foods are inadequate.

Francis D. Murphy, Milwaukee.

Error: In the July issue, on page 330, in the article by Dr. George B. Dorff, on "An Instance of Marked Abdominal Distension," the two half tones showing the colon should be interchanged to suit the present legends.

# SECTION I—*Clinical Medicine: Diseases of Digestion*

## A Philosophic, Clinical and Retrospective Discussion of Certain Major Problems in the Digestive Field\*

By

THOMAS R. BROWN, M.D.  
BALTIMORE, MARYLAND

DIGESTION dates back to the beginning of life, to the primitive needs of the first unicellular organism in the primordial ooze. It has been worshiped and deified; it has been damned and its followers reviled in the high places. But it is neither god nor devil, for no god would endure the insults to which it is subjected from the cradle to the grave; no devil would fail to utilize to the full the almost hourly opportunities to raise its dysfunction into consciousness. In reality it is a faithful, willing, hard working beast of burden, doing its best to carry on under an ever-increasing load. To lessen this load, to make the burden lighter, many men in many lands have striven mightily and not altogether in vain. Knowledge has come from many sources, from the chemist and physicist with their newer ideas of molecular structure and their better knowledge of the chemistry of digestion; from the physiologist and the pharmacologist, test tube in one hand, guinea pig in the other; from the pathologist, the surgeon and even from the clinician.

We are still ignorant of much for, as Chaucer quaintly sings—

*"The Lyfe so short;  
The craft so long to learn."*

But we do know a little and with this knowledge and with what experience has taught me from many years in general medicine, in not a few of which this special field has had my major interest, may we journey together through the digestive tract with a few side trips into certain of its backwaters and estuaries.

I will speak only from my own experience, rarely quoting from others, and while there will be many moot questions brought up and some where much controversy lies, at least you will know at the end of the voyage what I have learned to believe and disbelieve, what has helped me and what has not, what I have discarded and to what I have clung in this *voyage digestif*.

First the *oesophagus*, then a few side trips into the realm of referred symptoms from heart, from lungs, from renal and genital apparatus; then touching upon the major problems below the diaphragm—carcinoma, ulcer, pancreatic and biliary disease and diseases of

the intestine; a trip that must perforce be very rapid but which I hope will not be entirely devoid of interest.

*Mouth:* It is needless to state that before leaving port it is essential that we be sure its superstructure is in good order. Unquestionably far too much stress has been laid upon teeth and tonsils as foci of infection in disease elsewhere. Thousands of teeth and tonsils have been extracted for a vast variety of pathological conditions, which were not in the least benefited by such treatment. Now, when we recommend such procedures it is in the spirit of humility,—tempered hope in the place of blind faith. Nevertheless, irrespective of what rôle the mouth plays in disease elsewhere, it is wise to have a clean mouth, with good teeth and plenty of them, so that the complicated process which we call digestion and metabolism may have a fair start.

*Oesophagus:* The functions of the oesophagus are so simple that its problems are few, but these few are interesting, especially new growth and so-called cardio-spasm, better termed "oesophagospasm," as the constriction, as a rule, does not occur at the cardia but just above it where the gullet passes through the diaphragm. Is this a true neurosis? I have seen certain cases following immediately upon profound shock which would suggest it. Is it reflex in origin from elsewhere—appendix, gall bladder, marked visceroptosis? Is it due to degenerative changes in the plexus of Auerbach or Meissner at the lower end of the tube? Is it really not oesophageal but diaphragmatic in origin, and if extremely severe, should phrenicotomy be considered, and would it help? Is it really not a spasm but an absence of normal relaxation—an achalasia?

Most of these are considered in our therapy—sedatives, psychotherapy, a smooth diet, anti-spasmodics and lubricants, perhaps operative treatment on appendix or gall bladder if diseased, an attempt to put on weight in high grades of visceroptosis, but these forms of treatment are often very disappointing. At the present time in many cases a series of dilatations, repeated at varying intervals, is the only thing that will bring about relief until some better method of attack is discovered.

As regards cancer of the oesophagus, its diagnosis is usually easy. The progressive, occasionally intermittent dysphagia of the old should always arouse sus-

\*From the Division of Digestive Diseases, the Johns Hopkins Hospital and Dispensary.  
Submitted July 5, 1935.

picion and radiological studies, oesophagoscopy and biopsy should give us our diagnosis. These cases should be diagnosed early; they metastasize late. Like almost all the digestive neoplasms, with the possible exception of colloid growths, they are not ray sensitive and in my experience ray therapy has been extremely disappointing. Therefore, while their symptoms may be ameliorated by dilatation or gastrostomy, cure is only possible by radical surgical procedures. So far these have been disappointing in the extreme, but I firmly believe that with the tremendous strides in chest surgery, a successful technic will be found, possibly, as Rienhoff has suggested, by decompression of the lung, the production of a diaphragmatic hernia, and the anastomosis between the upper end of the oesophagus and the stomach well up in the thorax; thus minimizing excessive traction on the oesophagus, which is met with in other operations and which makes the anastomosis breakdown and death come from mediastinal infection and pneumonia.

*Referred Symptoms:* And now before we leave land and sail away below the diaphragm, may we take a short side trip into other nearby channels, all having one thing in common, their ability to project the symptoms of their pathology into the digestive sphere. The whole question of referred symptoms is a fascinating one. Its basis of course is the peculiar innervation of the abdominal and thoracic viscera, their double nerve supply; an autonomic system made up of two sets of essentially antagonistic fibres, sympathetic and parasympathetic, and the practical lack of pain fibres; that is, a mechanism which renders exact localization difficult or impossible. While this is the major factor in most referred symptoms, one must not forget that these may also be brought about by other conditions, such as proximity of certain organs. For instance, the diaphragm is all that separates heart and lungs from stomach and upper abdominal viscera; while both the genital and urinary apparatuses are in such close proximity to appendix and to colon and their nerve supply so intimately and intricately interrelated, that it is no wonder that the symptoms in either field may extend into the other.

One other factor, the chemical, must not be forgotten—the effect of the products of disease, toxins, normal substances in excessive amounts or the abnormal products of disease, which for some inexplicable reason select some special organ or tissue for their major manifestations. For example, the acute abdomen of diabetic ketosis, the appendicitis-like picture of certain of the infections—measles, influenza, typhoid, rheumatic and undulant fevers—the simulation of carcinoma of the stomach by certain cases of chronic interstitial nephritis, for its achylia, anorexia, loss of weight and tendency to mucosal hemorrhage sometimes present a very puzzling picture; the functional dyspepsia of early tuberculosis, the chronic constipation of certain of the often unrecognized cases of hypothyroidism, the diarrhoea met with occasionally as the earliest symptom of the overactive thyroid and the number of extra gastro-intestinal conditions associated with achlorhydria or true achylia, sometimes with, often without, digestive symptoms, such as pernicious anemia, the arthritides, both infectious and metabolic, chronic cardiorenal disease, sprue and pellagra, disease of the gall bladder and after a certain number of cholecystectomies. Finally the emotions whose reper-

cussions upon the digestive sphere play the major rôle in that enormous field so difficult to treat successfully—the so-called digestive neuroses.

I have been singularly interested for many years in the inter-relation of cardiac and gall bladder disease; not the well known increased incidence of gallstones in cardiopaths or the fact that certain cases of myocarditis seem to be due to chronic biliary tract infection, but certain rarer associations, as for example coronary thrombosis, with symptoms so entirely below the diaphragm, and so closely resembling acute gall bladder disease that operation has been performed on that assumption, and the even rarer cases of unsuspected gall bladder disease usually associated with stone, where we may have as the only symptoms the almost classical syndrome of stenocardia or coronary thrombosis or the failing heart. Here, if we get but a clue to justify it, cholecystectomy may make the cardiac picture clear up as if by magic. Perhaps the production of anoxemia by rebreathing may help us to decide what is the fundamental pathology in these two groups of cases.

The first signs of a failing heart may be a simple banal dyspepsia, presumably due to a passive congestion manifesting itself first in this viscus. Here digitalis will succeed when diet and other drugs have sadly failed. Of more than passing interest are the extremely rare cases of rapidly dilating heart with intense upper abdominal pain, possibly due to sudden stretching of the capsule of liver and spleen; while rupture of the heart may have only abdominal symptoms.

In the case of the lungs, the most interesting examples of referred symptoms are those of the acute abdomen usually simulating appendicitis or intestinal obstruction, met with in certain cases of central pneumonia or diaphragmatic pleurisy, while I have been much interested in the atonic dyspeptic picture seen after certain phrenicotomies in tuberculosis. Incidentally it is worth remembering that in almost a quarter of the cases of pulmonary tuberculosis, the earliest symptoms are not pulmonary but digestive. Early pregnancy may often be undiagnosed and treated as a gastric neurosis; it is not unusual for a retroflexed uterus in a neurotic girl to have severe digestive symptoms, usually anorexia or intractable vomiting; while of course we all know how often salpingitis, an ovarian cyst with twisted pedicle or a ruptured extrauterine pregnancy is mistaken for an acute appendicitis.

The gastro-intestinal symptoms in diseases of the urinary tract are met with with great frequency. A renal calculus or a true ureteral stricture or a floating kidney may simulate peptic ulcer, gall bladder disease, colitis or appendicitis. An acute or subacute right-sided pyelitis so common in children, especially in girls, may be very difficult to differentiate from appendicitis, especially as the urine may be clear for some little time due to the plugging of the ureter on the affected side.

Finally there is that great number of digestive symptoms met with in organic and functional disease of the central nervous system. Hysteria simulating anything and everything; the crises of tabes giving us a picture of ulcer or gall bladder disease, sometimes even leading to operation—an unpardonable error for a complete physical examination will practically always

give us our diagnosis—the digestive aura of epilepsy, migraine and Meniere's disease.

Verily to sail this sea safely one must be no mere specialist, but must know something of every other path as well, if one hopes successfully to solve these puzzles; to unravel the tangled skein of organic and functional disease with their myriad manifestations and to interpret the significance of abdominal pain.

*Cancer:* And now, back again to the main channel. Of course the most important disease in the digestive tract is cancer. It causes more deaths than cancer of any other system. It has been known since the beginning of recorded time. It is mentioned in the Rig Veda and Eber's papyrus. It seems to be definitely on the increase, but whether this is due to better methods of diagnosis, and to greater longevity or whether it is real and due to something in our modern civilization—mental strain, new forms of trauma, or the modern diet—one cannot say. It is singularly insensitive to all forms of ray therapy, to colloid metals or to lead; there is but one potentially effective treatment—surgery. To increase the percentage of cures by operative treatment, early, or relatively early, diagnosis is necessary, relatively early, alas, because in many cases, especially in growths in the "silent" area—the lesser curvature of the stomach—there may be a long symptom-free period and what we think is the first or second, is, in reality, the third or fourth act of the drama. The life cycle of gastric carcinoma and, to a lesser extent of intestinal carcinoma, must be often much longer than usually supposed—two to four years instead of six months to one year.

We know something, but very little about the cause of cancer. There are certain agents which in the laboratory or in clinical experience frequently seem to produce the disease; parasitic infection as in the cancer of rats—due to *spiroptera neoplastica*; chemical and physical agents such as tar, oils, exposure to various rays, sun, X-ray, radium—incidentally a step forward has been taken in the case of chemical irritants by the demonstration that the carcinogenic substance in tar corresponds closely to compounds of the Dibenz anthracene series—and finally the virus of the filterable tumors of birds. Heredity unquestionably plays a rôle in certain cases, probably as a Mendelian recessive.

But the fundamental question is: is there some unknown underlying mechanism common to all? In other words, is cancer one disease or several? In some cases, the embryonal rests of Conheim seem to offer a perfect explanation, in other cases the theory is hard to accept. Not knowing the cause, how then can we make an early diagnosis in carcinoma of the stomach or intestine? There is but one answer—the careful analysis of the patient's symptoms, however slight, however commonplace, if they appear in middle or later life, if they appear without cause and if they do not yield to the ordinary therapy based upon the idea that they represent a functional disorder. In the stomach, this is usually a simple, banal dyspepsia without pain; in the small intestine, relatively few or no digestive symptoms. But fortunately neoplasms here only represent a little over one-half of one per cent of the total cases of digestive new growths; in the colon, progressive or intermittent constipation, occasionally alternating with diarrhoea, or attacks of colic, almost always diagnosed as "nervous indigestion" or "mucous colitis."

But through it all—the one common finding—the symptoms come out of the blue as a thief in the night, usually with no previous history of indigestion and not yielding to symptomatic treatment. Intensive diagnostic methods—X-ray plates and fluoroscopic examination, digital rectal examination and sigmoidoscopic study, study of the stool for occult blood, gastric analysis, palpation in the hot bath, all will add to our knowledge and may give us our diagnosis, but without the primary suspicion such studies would never be inaugurated.

In our experience as regards the stomach, an ulcer syndrome or symptoms of a subacid or achylic gastritis have been present in only a small percentage of the cases—about 15% in our series. About 85% of cancers appear spontaneously without evidence of previous gastric disease or dysfunction.

While the general principle that success of surgery depends on the relative earliness of the diagnosis is a sound assumption, it is well to remember that the size of the growth and its operability are not always necessarily associated. Some of our most successful cases have been in extremely large, palpable tumors, while in certain other cases, the original growth may be extremely small, but its metastases extensive and apparently early.

What are the results of surgical treatment so far? Not too encouraging as yet. Our series gives considerably lower figures of relief than the reports from the Mayo Clinic; but 18% of the gastric cases operated upon lived approximately two years or more; about one-eighth over five years; while in growths of the colon our results, while again not so good as Rankin's, are far from discouraging.

Frankly, I would far rather advise operation on a well grounded suspicion than to wait until a definite diagnosis can be made, but where as a rule surgical removal is impossible. Delay means simply that a condition potentially responsive to treatment in its early stage has become so extensive or so disseminated that radical removal is impossible.

*Peptic Ulcer:* And now to the great battlefield of the abdomen—peptic ulcer—its cause, its diagnosis, its treatment! I have often wondered if Cruveilhier does not stir uneasily in his grave when he realizes the century of conflict that has followed in the wake of his epoch-making description—between surgeon and clinician; between the proponents of the many types of diet and operation suggested; and between the champions of the so-called specific methods of treatment.

*"Each champion to the other's virtue  
blind  
And thinks his treatment only cures  
mankind."*

And yet, *mirabile dictu*, all claim practically the same percentage of cures—75 to 80%; in all the same time, between three to six weeks, to bring about a cure. All seem to have forgotten that uncomplicated ulcer is a self-limited disease and only the most pernicious forms of therapy will prevent it from healing in its self-appointed time. Certain simple rules should of course be followed. The diet should be non-irritating, of high caloric value, non-stimulating to acid secretion, capable of combining with hydrochloric acid in considerable amounts, the meals at relatively frequent intervals; this is all! If unnecessarily restricted, it may lead to marked malnutrition and very occasion-

ally a pellagra-like picture. Personally I feel that hourly feedings are absurd. They are a great hardship to the patient and to the nurse and utterly unnecessary, as I am convinced that the ulcer heals better in a low acid than in an alkaline medium as Bolton showed so beautifully in his experimental work. Rest is essential, but not necessarily physical rest; mental placidity is far more important and this is often better brought about by ambulatory treatment, especially if there is an economic factor, than by hospitalization.

I am certain recurrence of ulcer comes much more frequently from psychic than from physical trauma. We do not know the cause of ulcer, we do not understand the *rational* of its characteristic pain, nor why the mucous membrane is sensitive, at certain times, to stimuli to which it is insensitive at other times. But barring complications, the great problem in the treatment of ulcer is not really the cure, but the *aftercure*. How to make the patient for weeks, for months, even for years, follow the proper regime—psychic, hygienic, dietetic, possibly medicinal—that reduces to a minimum the chance of recurrence. This is not so much a question of the knowledge as of the personality of the doctor.

Hydrochloric acid is of course essential in the production of ulcer—Mann's and Williamson's experiments have shown this beautifully, but this is a far cry to saying that hyperchlorhydria is the primary cause of ulcer.

What is this primary cause? Is it infection or trauma, congenital tendency with characteristic body form? Is it allergy or lack of certain vitamins? Is it vagal-sympathetic imbalance? Is it of reflex origin from appendix or gall bladder? Is it of psychic or endocrine origin? Is it due to local vascular disease or disturbance? Is it brought about by heteroptic intestinal mucosa or is it due to an insufficiency of neutralizing alkaline duodenal secretion? Does omental infection or adrenal dysfunction play a part? Is it in reality a secondary condition to a preceding gastritis or duodenitis—a very popular view at present among the German investigators? Experimental work does not answer these questions for ulcers produced in animals by a variety of agents are not like the peptic ulcer of man in their behaviour. Until we know the primary cause of ulcer, if there be such a primary cause, prevention is difficult and treatment often unsatisfactory and symptomatic. After all, in the treatment of most digestive diseases it is not so much the pathological process itself as its associated functional disturbance that we must attack if we hope to get relief. For instance, nothing is of more interest than the unraveling of what seems to be a high grade pyloric or duodenal obstruction, to determine—how much is due to organic change, how much to oedema and inflammation, and how much to associated spasm? In this condition always try rest, a soft diet and submaximal doses of belladonna before advising surgery.

Unquestionably the tendency is more and more towards treating ulcer by medical, physical and dietetic, rather than by surgical means, but of course certain conditions such as true marked organic obstruction, deforming adhesions preventing normal physiological function, repeated hemorrhage probability of malignant degeneration and of course perforation, require operative treatment. As in every other form of abdominal disease, however, it is a wise thing to re-

member that the more clearcut the diagnosis, the more definite the need—the more successful will be the result of surgery. Gastroenterostomy does not stop hemorrhage, but it does help immensely in the obstructive cases. Large resections seem to me unjustifiable. Pyloroplasty is often technically impossible and few can do it well. Gastroduodenostomy or small resections would seem to me often the best operation especially in the non-obstructed group. But there is not, and probably never will be, an ideal operation for ulcer. Each has its defects but each, to make the chance of its success greatest, must have the proper preoperative and long post-operative care.

**Gall Bladder:** And now to that other great field of conflict, the gall bladder—alas, also a land of flux with doubt as to etiology, correct diagnosis and proper treatment. We probably operated upon too few gall bladders before cholecystography; we certainly operate upon far too many since it has become almost a routine diagnostic procedure. Here, as in the case of ulcer, the best results are always obtained where the history is clearcut and where the cholecystographic picture shows stones or very gross deformity; the greatest proportion of failures where the history is vague, the surgical indication is not definite, and the X-ray study shows either no shadow or faint shadow and delayed emptying. In the former group, the percentage of cures is probably over 90; in the latter group, the percentage of failures is extremely high, 40 in Graham's series, over 50 in ours.

Rous has shown us that in the dog, the concentrating power of the gall bladder varies from three to elevenfold; it is probably the same in man, and therefore variations in density should not be taken too seriously; while lack of filling may be of intestinal rather than of hepato-biliary origin.

We have found from a careful analysis of all of our cases that there is an error of approximately 20%, both positive and negative, in cholecystograms as shown by the subsequent history of the case. This, incidentally, is not much less than if the diagnosis were made from a careful history of the case, through physical examination and the utilization of the usual laboratory studies by a competent clinician.

I am sure that it is wrong to consider the gall bladder as a separate entity and not as a part of the entire biliary tree, although in a considerable proportion of cases, the major portion of the pathology is concentrated there. It is in this latter group where surgical attack upon the gall bladder is likely to be most successful. I am convinced that, in analyzing the symptoms, we must determine how many are referable to the gall bladder itself, how many to liver, ducts and biliary tract, for on the results of such analysis, must rest our decision as to medical or surgical treatment; and, if the latter is decided upon, what is the best operative procedure.

I am quite sure that cholecystectomy is the operation of choice in the vast majority of cases in which surgery is indicated, and, that in a good many of these cases, complete relief may be obtained by the removal of the gall bladder. I am equally convinced that where there is evidence of extensive liver and biliary tract infection as well, it is far wiser, if surgery is to be done, to employ cholecystostomy, possibly followed later by cholecystectomy; or cholecystgastrostomy.

It is true that cholecystgastrostomy and cholecystoduodenostomy have their dangers in possible ascend-

ing infection, but it is the lesser evil. Quite frankly, when I am convinced that hepatitis and intrahepatic biliary tract infection are playing a large rôle in the picture, even with the knowledge that the removal of the gall bladder usually brings about a compensatory dilatation of the entire biliary tree, I am loathe to suggest cholecystectomy and often advise one of the operations which promotes constant drainage because the more radical operation takes away a crutch upon which later we may want to lean.

Even cholecystectomy has its dangers and disappointments. I have had recently two patients in hospital who have had to be operated upon for gross pyloric obstruction secondary to extensive post operative adhesions following this operation, while I see a number of cases where partial post operative common duct obstruction is met with due to this same cause.

To learn most about the problems of gall bladder disease and ulcer it is essential that the clinician should be present at the operative cases if the treatment be surgical. He will learn a little from his successes and a great deal from his mistakes. He may even sometimes aid the surgeon a bit in his choice of the proper operative procedure.

Our newer knowledge of gall bladder and biliary tract pathology should be tremendously helpful to us in the medical handling of these cases and there are more and more cases which we are trying to relieve if not cure by non-surgical means. Our debt to the physiologists, notably Ivy and Mann, is very great. We know something of the rhythmic tonus and the tonic contractions of the gall bladder, and of the function of the sphincter of Oddi. It has been shown that the gall bladder itself can contract and incidentally, if associated with a simultaneous contraction of the sphincter of Oddi and the duodenal musculature may produce a picture exactly simulating gallstone colic.

We know the hormone which brings about the normal mechanism, "cholecystokinine," and that fats, especially egg yolk, and to a lesser extent olive oil and butter liberate this perhaps better than anything else. We know the effect of bile salts, dihydrocholic acid and various salines, notably the magnesium salts, on the elimination of bile. From this knowledge we can plan a scientific treatment which is often surprisingly successful in a number of these cases: A smooth diet with plenty of the proper fats, frequent feedings, a saline in the morning or before meals, the clearing up of upper respiratory and mouth infections, the avoidance of constipation, the use of various substances to increase bile elimination, possibly antispasmodics and the proper use of exercise and rest, mental and physical.

As in the case of ulcer, the proper balance between non-surgical and surgical attack is being better and better established.

*Pancreas:* No organs play a larger role in digestion and absorption than pancreas and small intestine, but in no organs are their minor diseases and dysfunctions less well understood. Carcinoma of the pancreas with its progressive painless jaundice, sometimes, however, almost exactly simulated by painless common duct stone or pancreatic cirrhosis; acute hemorrhagic pancreatitis, with its striking picture of circulatory collapse, and cysts of the pancreas are practically all of the conditions we diagnose. And yet there must be innumerable cases of subacute or chronic pancreatitis, usually associated with gall bladder disease, and of functional disturbances which are never suspected.

I am quite sure that many of the vague upper abdominal syndromes met with in the old, usually associated with slight rather vague pains, are of this origin. Certain of the diarrhoeas with excessive fat in the stool, I believe are due to functional pancreatic disturbance, while I am convinced that in certain cases of sprue a pancreatic hyposecretion is associated with the intestinal hyposecretion and muscular hypotonus so characteristic of this disease and that in these cases pancreatin is a helpful adjuvant to liver and other forms of therapy.

Certain cases of carcinoma of the pancreas or even cases of chronic pancreatitis—conditions sometimes extremely difficult to differentiate from each other even at operation—may closely simulate cancer of the colon, a point, incidentally, insisted upon by Dr. Halstead. In all of these pancreatic problems, carcinoma, pancreatitis, functional disturbances, I believe quantitative and qualitative ferment estimations from duodenal contents or stool may prove of real help in many instances.

*Small Intestine:* The small intestine—that laboratory where digestion and absorption go hand in hand—is still a land of mystery. We can learn little from X-ray or laboratory studies. It is almost impossible to estimate its ferments. We have no test by which to gauge its absorptive powers. Now and then by repeated fluoroscopic studies we are able to diagnose or suspect a neoplasm; occasionally we can recognize the rare localized tuberculosis of the intestine, a quite different picture of course from the terminal diffuse tuberculous enterocolitis almost invariably present in the final stages of pulmonary tuberculosis.

The veil is lifted a bit by our study of celiac disease in children, of sprue and sprue-like disorders in the adult. We know that in these cases, fats are badly borne, but, in addition, that the higher molecular fats such as meat fats and those having a higher degree of saturation, are far less well absorbed than the lower molecular unsaturated fats such as olive oil; that the monosaccharides are well borne, the disaccharides and polysaccharides often not well borne.

We do not understand why bananas help certain of these cases. It does not seem due to any ferment which they contain. It may be due to their high content in invert sugars or to the softness of their cellulose; possibly they contain an essential principle. But it is an undeniable fact that in this group of cases a diet of protein, egg white, skimmed milk, minced liver, etc., with marked restriction of animal fats, di and polysaccharides, and with a large amount of monosaccharides, olive oil and bananas, will prove extremely beneficial.

Finally, what is the cause of that peculiar inability to take care of carbohydrates—not fats—met with in intestinal carbohydrate indigestion, the so-called "fermentative dyspepsia" of Schmidt, with its large yellow acid stools, showing many starch granules, but where fat and protein are both well digested? It is probably not pancreatogenous. We have found normal pancreatic diastase readings in all of these cases. It seems to be one of those complex intestinal problems, where both deficient digestion and deficient absorption play a rôle and where the only really successful treatment is a long period of protein-fat diet.

*Appendix:* Only a moment's stop in the lower right quadrant. Is there such a thing as "chronic appendi-

citis" with no history of acute attacks, sometimes with local but more often with referred symptoms elsewhere, especially in the epigastric region simulating ulcer? I believe so, though many of my surgical friends disagree, for although the diagnosis is unquestionably incorrect in the vast majority of cases and surgery almost always unsuccessful and disappointing; nevertheless I am sure that there are a few cases where the condition is present, where the symptoms are due to the condition and where the removal of the appendix gives brilliant results.

I have been helped in diagnosing this small group by multiple fluoroscopic studies, before and after purgation; by palpating the appendix is visualized under the fluoroscope and attempting to reproduce the symptoms, and by repeated study of the leucocytes and the temperature readings. In acute appendicitis, as in every other acute abdominal condition, until the diagnosis is made and the treatment planned, there is no safer rule than this—absolute rest, complete starvation, no medication.

*Colitis:* The next stop in our voyage is one that I approach with a great deal of trepidation. The colon is worshipped by many as the cause of multitudinous diseases elsewhere but I, alas, am not among its worshippers, nor am I blinded by its new effulgence. Perhaps the most interesting problems in regard to it are its bacteriology, its rôle as a focus of infection and the many problems connected with ulcerative colitis.

It is worth remembering that years ago Cushing and Livingood showed that the ileum usually contains a preponderant number of streptococci, that Garrod later found that by active purgation the normal streptococcal content in the rectal stool of from 1% to 2% can be raised to 30% or more; that Lyons in England demonstrated that in the bits of mucus in the stool in colitis, many more streptococci could be found than in the fecal mass; while Paulson in my Clinic has shown that blood as met with in ulcerative colitis is the perfect culture medium for streptococci and incidentally for certain other organisms rarely found in the intestine—*pyocyaneus*, *proteus* and Frielander's bacilli—while it markedly inhibits the growth of the usual colonic flora, especially the colon bacillus.

From our Clinic, Paulson has also shown that in the normal intestine, at various levels, one can obtain every micro-organism to which has been ascribed pathogenic properties, including the gram positive diplococcus, which some have regarded as the cause of so-called "non specific ulcerative colitis."

Incidentally I am still ignorant of the cause of this condition. I am not sure it is primarily an infection and that it may not represent changes in the mucosa or gut wall which lower their resistance to infection. I do not believe it is responsive to so-called "specific therapy," nor that in the vast majority of cases it is an aftermath of bacillary dysentery. I cannot accept any specific micro-organism as its cause and I still think that general hygiene, a high caloric, low residue diet, rest, good care and upbuilding treatment are the main factors in its treatment. Non-specific protein therapy sometimes gives relief, but it is not curative. Irrigations, I think, are fundamentally unsound, and probably do more harm than good in many cases.

I believe that many apparent successes under so-called "specific cures" are simply expressions of the natural remission peculiar to the disease. I am sure

rest of the gut is the great *desideratum* and I feel that if operation is necessary, the best is that which gives the maximum quietude to the diseased gut, ileostomy if the entire large bowel is affected; colostomy if the ulceration is confined to sigmoid and rectum as it is in a certain proportion of cases.

In regard to the so-called "*mucous colitis*," I feel that the irritable colon may be purely psychogenic in origin and in its earlier phases best treated by re-education and psychotherapy, though not always successfully as many cases represent a true congenital autonomic imbalance, where certain drugs, especially belladonna, will have to be used as well. On the other hand, when that stage is reached, when mucus is found in large amounts in the stool, there is probably added to the neuropsychogenic factor a true catarrhal inflammation of low grade, and this must be considered in the treatment;—a smooth diet, oil by rectum, perhaps small doses of castor oil, anti-spasmodics and mild sedatives.

It is well to remember that in mucous colitis the whole colon is not always involved, that the left side is more likely to be involved than the right, but that if the condition is rather sharply localized in the upper right, or the lower right, quadrant, it may almost exactly simulate appendical or gall bladder disease. It has even lead to operative treatment which is always unsuccessful and usually harmful.

One has no time here to even touch upon the problems connected with amoebic dysentery, so much in the medical mind at the present time, but it is worth remembering that the chances of finding motile forms or cysts are increased more than threefold if the stool is obtained through the sigmoidoscope and examined immediately rather than by the usual procedure. Incidentally, as regards the treatment of chronic amoebiasis, we have found a combination of carbarzone or stovarsol by mouth, Yatren or vioform by rectum, and possibly emetin hypodermically, most effective. If properly administered, the last drug has not harmed the myocardium in our experience.

*Treatment:* And now at a prolonged last, a short excursion into that most unsatisfactory realm, treatment! Yet after all, it is successful treatment that the patient wants more than diagnosis, for he often believes, with Mahomet, that "*God has not inflicted disease upon us without at the same time giving us the remedy.*"

Treatment, unfortunately, is built upon shifting sands, it is swayed by the cult of the moment, it changes with the tide of public opinion, it is singularly liable to exploitation, it is often unscientific and unsound, it is sometimes dishonest. Our best help must come from the simpler things, from rest and exercise, from encouragement and suggestion, from re-education and simple physical measures. The same rule should apply to diet, but alas, this is not true, for in no field is there so little science, so much fad and foolishness. For example, it is not interesting that after millions of years with people living healthily and in the main happily on a mixed diet, it is suddenly discovered that foods that have hobnobbed happily together for aeons of time, suddenly became anathema to each other? Is it comedy or is it tragedy that Beaumont labored in vain and that Pavlov's epoch-making experiments are so soon forgotten; that the story of digestion torn from the jealous breast of Nature in

that conflict between the creative will of man and the hidden wisdom of the world, which seems to thwart it, should be cast aside? I often think, with Josh Billings, that it is better to know a little than to know a lot of things are not so.

Put not thy faith in newer fads in diet; diets with no meat, diets of lettuce and orange juice, diets where protein and carbohydrates never meet at table! I like to remember what my friend, Robert Hutchison, the English master of dietetics, once wrote: *'The man who retires from business having nothing else to do, makes his health his hobby and collects new diseases as another man collects stamps. The food faddist is perhaps the most malignant of this type. Vegetarianism is harmless enough though it is apt to fill a man with wind and self righteousness.'* After all, a wise man is the best judge of his proper diet and a man cannot be a perfect physician save of himself alone.

I often wonder what the God of Medicine, Aesculapius, would say to his father, the great Apollo, if he looked down from high Olympus upon us little mortals in the world below. Would it not be—"Why, my Father, has man not profited more from all the knowledge that has come to him, born of the centuries of striving of the great, spelling their travail, their struggles, their many failures, their few successes, wrung from the very womb of this old Earth that guards her secrets so jealously."

"These, the great leaders, have taught men the principles of diet and the physiology of food, and yet every new dietetic fad is followed madly. They have told them that peace and serenity are necessary for perfect digestion and yet they drive ever more madly through this mechanical age. The normal intestinal flora has been shown to them, and yet to these harmless organisms have been ascribed the cause of many diseases, and from them vaccines prepared, supposed to be imbued with divine power. The normal function of the colon has been shown them and yet mighty rivers have been diverted from their courses to supply the needs of one great city alone, the new Bagdad on the Hudson; a treatment supposed to wash away impurities, to cure and prevent disease and bring back eternal Youth. Even the humble colon bacillus is plucked from its

home where it has slumbered peacefully for generations and transplanted, that sickness may be abated and death postponed."

"How can this be, my Father?"

And I can hear Apollo reply—"Be not worried, my son, for while there is much that is false and much that is absurd in all this, there is perhaps also a grain of truth. The food faddist is not always mad! Change of intestinal flora may sometimes help; irrigation is not always harmful; and even a vaccine of intestinal origin may sometimes do some good. Did it not take millions of years for man to emerge from darkness to the first faint glimmerings of dawn? Did the next six thousand years bring more than a few stones for the foundation of knowledge and have not some of these already crumbled away? While in the last century, knowledge has come so fast that Man, blind, groping Man, cannot digest it."

"For a hundred years is but a drop of water in the ocean of life, a grain of sand in the desert of Time. Knowledge has come in great abundance, but Wisdom lags far behind."\*

And now our voyage is over and we are safe at anchor. We have visited many parts and sailed many seas. Some clearly marked and easy to navigate; others still so shrouded in fog that we must travel them slowly and with the utmost care—a voyage which, if it has taught us nothing else, should have told us that to traverse safely its main channel, its tributaries and its backwaters near and far, we must not only know well our main route, but know something of all the other paths that altogether make up this cosmos which we call man. After all, the body is not the mere summation of its constituent parts—physical, psychical, spiritual; each has some tangible or intangible connection with every other. In no system is this more true than in the digestive tract, for it is a glass in which may be mirrored any disease or dysfunction elsewhere. In no system is that wisest of all medical rules more absolutely true—first study the whole, then the part.

## Migraine: A Common-Sense Approach

By

LIBBY PULSIFER, M.D.\*  
ROCHESTER, NEW YORK

### 1. GENERAL STATEMENTS

IT is not common for a single patient to have all his attacks go through the complete syndrome of prodromata, headache, nausea, and vomiting. Such occurs occasionally. Instead, usually the patient suffers from a fraction of the syndrome, perhaps two of the above features, the pattern of each attack being very similar to the pattern of other attacks except in severity.

As evidence of the considerable degree of disturb-

ance in the nervous systems of some patients during attacks of migraine, I have prepared charts illustrating the change one patient had in his fields of vision. (Chart No. I).

Additional support of the idea that the restless, hypersensitive, migrainous type of person is found mostly in the upper strata of society lies in the fact that during several years experience in the charity clinics of two hospitals, I have encountered not more than two dozen patients in whom migraine was recognized, while in eight years of private practice, I have

\*Associate Physician, Rochester General Hospital; Instructor of Medicine, School of Medicine, University of Rochester. Submitted May 17, 1935.

made this diagnosis more than three hundred times, or in 13% of all patients seen.

The tendency to have migraine is an inheritable characteristic which seems to behave like a dominant in Mendel's Law (1). However, I believe that the in-breeding of migrainous individuals with each other, or with allergic, depressive dipsomaniac, epileptic or otherwise mentally unstable individuals, usually may result in the production of offspring more migrainous, allergic, depressive, etc., than is the case when migrainous persons have children by those whose ancestry is quite free from these disorders. (Chart No. II).

## 2. GENERAL MEASURES EFFECTIVE IN TREATMENT

Granting that migraine is "the most baffling and dramatic form of all headaches, a snag over which the medical profession has stumbled for centuries," and granting the hopelessness of avoiding the tendency to suffer with the exasperating and disabling malady by choosing parents who are entirely free from this disorder, it does not follow that there is nothing to be done for the unfortunates who are afflicted. In dealing with these sufferers, the single therapeutic endeavor which, I believe, will bear the most fruit is a determ-

Chart 1-B. Fields of vision when no migraine. Patient L. J. 1/2° test object for white, 1° for other colors.

ined effort to maintain in the patient, nervous and emotional equilibrium and tranquility. Many of these people, when first seen, are nervous and emotionally disturbed with a consequent high degree of affectivity. There is very little doubt that this state of being in "high gear" renders them much more likely to have attacks of hemicrania, just as others in such a state are more likely to have peptic ulcers, angina, asthmatic attacks, bowel spasms, and the like.

As soon as the diagnosis is certain, it usually is highly worthwhile patiently and considerately to tell the patient in some detail the nature of his affliction, since, as Alvarez has quoted, the successful "conquest of fate is not by struggling against it, nor by trying to escape from it, but by acquiescence." (2) The peace of mind that accompanies this understanding may in itself seem to lessen the frequency of attacks. He may

sponsibility for the machinery which delivers illuminating gas to his city. He has had attacks of hemicrania since age sixteen, in recent years at least once a week. Pain starts usually in the morning in one eye, and, increasing in severity, extends over the side of his head. This is soon followed by nausea and vomiting (sometimes vomits as much as fifteen times). The whole attack lasts one day. Next day, he feels quite well again. Sister has similar attacks, as also had mother.

No other findings of note save tender transverse bowel and fermentative stools.

The situation was thoroughly talked over. The diet was slightly modified and coffee was omitted. A program of relaxation at meal times and recreation was advised. He started to take phenobarbital 1 grain each night.

On November 8, 1934, he reported that he had had only three very slight headaches in the six weeks since first seen. Each of these was relievably by a simple analgesic.

Chart 1-C. Fields of vision when suffering from severe migraine. Patient L. J.  $\frac{1}{2}^\circ$  test object.

so be persuaded to stop seeking "cures" in physics, doses, faddish diets, and operations (any of which may be contributing to his disability) and instead accept a common sense approach to his trouble.

Besides psychotherapy, a period of daily sedation may be indicated. I find most valuable for this purpose the administration of small doses of phenobarbital or bromide, never to the point that the patient may be conscious of sleepiness or depression.

An example of the result of treating a proper patient by these principles alone is seen in the following case history. (Only those cases are included in my series in which every reasonable means has been employed to make an accurate diagnosis. A complete history and physical examination with blood counts, blood Wassermann and urinalysis have been done on every patient studied. X-ray examinations, other laboratory tests, and consultations with various specialists have been freely resorted to whenever indicated).

*Case 1.* A thirty-one year old engineer, seen September 26, 1934, works long hours and takes very seriously his re-

There had been no nausea or vomiting or necessity for staying home from work. Patient was very pleased.

His condition remains equally good to date (six months).

The "ultimate prognosis in such a case must depend upon the physician's success in "selling" an intelligent enough patient an understanding of himself and his malady so that an altered attitude and behavior toward his environment and toward his affliction may be assumed. Relapses may be expected occasionally when the rate of nervous activity again may be raised in response to insufficient rest, coffee, or environment difficulties beyond the patient's control, but improvement usually may be expected by psychotherapy and resumption of management. Others who are more unstable and less intelligent, or whose environmental difficulties are insurmountable are, accordingly, increasingly difficult to relieve.

*Second Point in Therapy: Precipitating Factors:* A diligent search for them will, in many instances, reveal definite factors which precipitate individual attacks in individual patients. I am convinced that these factors induce attacks in susceptible individuals be-

cause they disturb the nervous and emotional balance in sensitive patients.

*Example:* There was the case of the conscientious, thirty-five year old assistant to a fussy dentist, who also kept house for an euphoric, worthless husband. She suffered, as did her mother, frequent, severe, often prostrating attacks of unilateral headache which she was able to avoid only when she escaped from job and husband for several weeks.

A man who ran a storage-battery sales and service station was compelled to stay away from work about one day a week because of attacks of severe pain starting deep in the right eye, which extended over half his head, and cul-

A housewife, who tended to gain weight, had scanty eyebrows, a dry skin, and a basal metabolism of -22%, has obtained relative freedom from attacks for a year while taking a daily ration of thyroid extract.

Attacks commonly occur in women at menstrual time. These may often be eliminated or controlled by appropriate measures. I have tried various endocrine substances in such cases with no encouraging results.

Chocolate may seem frequently to induce attacks. One young mother whose prostrating sick headaches came four or five times a month had only one attack in two years when she omitted eggs from her diet. In my series there was discovered allergy or a family history of allergy in

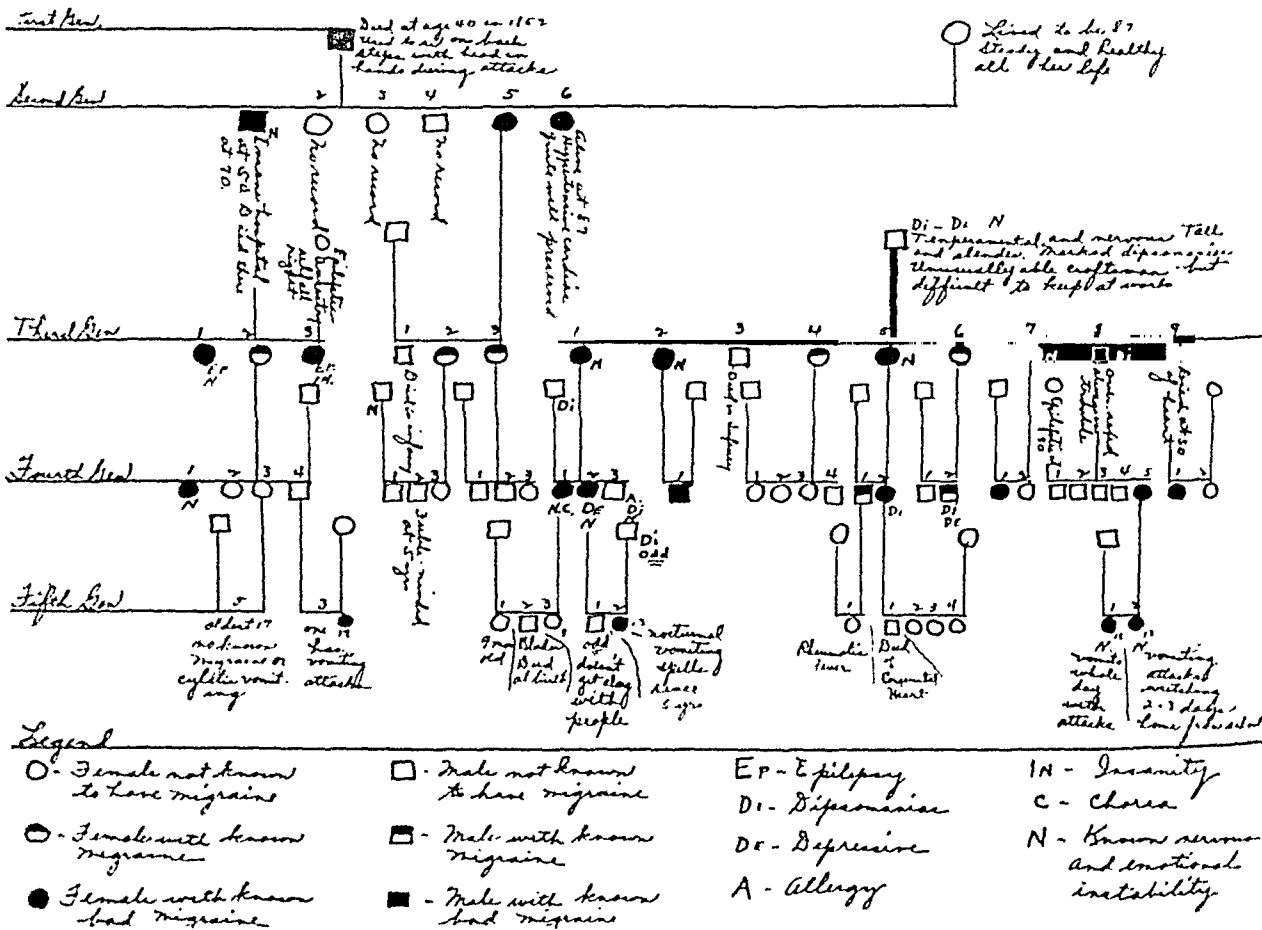

Chart 2. An authentic migraine family inbred with dipsomania.

minated in repeated retching and vomiting. These attacks occurred over a period of ten years, during which time he had taken almost daily catharsis with consequent abdominal distention and pain. In 1927 gall bladder (no stones) and appendix were removed; 1928, all teeth removed; 1929, \$100 was paid to a doctor and \$100 to a chiropractor; 1930, a tonsillectomy was done. All these things were undertaken in the hope of curing his "bilious attacks." He was seen in 1931 and put on bowel and migraine management with complete relief of all his symptoms. Two or three times a year he needs aspirin and amidopyrene; he secures relief from these remedies.

A lawyer was relieved of migraine by teaching him to avoid dyschezia.

Relief came to a doctor's wife when her peptic ulcer was successfully managed.

An ice man had no more attacks when a gross refractive error was corrected.

only 5%. This is not in line with the reports of Balyeat, Rowe, and others, but these men, known as "allergists," must see patients who are predominately allergic. Many of that class of people probably also have inherited true migraine and their attacks may be induced by the upsetting effect of ingesting proteins to which they are allergic.

A telephone line man who smoked thirty cigarettes a day obtained relief from his migraine, his hypotension (100.60 to 116.70) and his lowered basal metabolism (-23 to -1%) when he stopped smoking.

*Measures to Relieve Attacks.* At the onset, attacks may often be relieved by one of several simple analgesics (3). Some patients should have such a remedy always on their persons. Strangely enough, difficulty is sometimes encountered in persuading the sufferer promptly to take his remedy, although he may have it

in his pocket and know it will bring relief. Here, then, the "salesmanship" of the physician is again put to test. After attacks are in full bloom, many patients can obtain no relief at all except with "knock-out drops." In the last five months, we have used "cibal-gine" (4) intravenously thirty times in twenty-six cases suffering with all stages of the migraine syndrome with results so good as to be astounding. With a few exceptions, the headache disappeared immediately, and the patient felt relaxed and comfortable. Ergotamine tartrate (marketed as "gynergen") may increase menstrual discomfort, and cause vomiting. Three patients of mine have reported it as ineffective. However, the encouraging reports of others warrant continued trial of this preparation.

Although daily rations of calcium are said to help some patients, I have not seen any that I felt were benefited by its use.

For "the migraine state," sodium thiosulphate (5) or sodium bicarbonate (6) *i.v.* at intervals of five to seven days, sometimes may seem to help, or perhaps this relief is due to the repeated contact with the physician.

*Treatment Fails in Three Types:* There are in my experience just about three classes of migraine sufferers of whom the treatment is usually discouraging.

One of these is illustrated by the case of a housewife seen four years ago. All of her relatives seemed to have migraine. She was perfectly well otherwise, and her attacks, lasting two or three days, were always prostrating. I studied her for eight months without ever finding precipitating factors, or giving her any relief whatever, even though she cooperated splendidly. Such cases are really uncommon.

Secondly, eighteen percent of my series of migraine patients were definite "insanity equivalents." (7) Such are so unstable and so poorly equipped mentally that they are beyond much help.

Fortunately only a few patients fall into this third class which is very difficult to treat. It is exemplified by a fifty year old lumber dealer, who, in spite of the fact that his sister, brother, and mother had similar attacks all their lives, insisted that he must have a physical cause in his abdomen for his ailment. He was garrulous and hard to manage. He never cooperated and no relief was obtained. Subsequently, against my advice, he had a normal gall bladder removal. He died post-operatively. Unfortunately a surprising number of these patients who suffer with migraine come to believe that their disorder is referable to the liver or gall bladder, or sinus, nose, tonsils, teeth or even appendix. Considerable numbers of them have had surgery without adequate indications and without any relief.

### RESULTS OF TREATMENT

The results of our treatment in 150 consecutive cases, chosen only because they had been followed suffi-

ciently long (none less than six months—most more than three years) that a fair judgment could be made, showed that 2.5% seemed to be worse, 22% were not improved, and 73% showed a very gratifying improvement. Usually the interval between attacks has been very much lengthened, and the attacks themselves are much less severe. 2.5% had no more attacks. This improvement in 73% of all cases seemed certainly to warrant the painstaking effort of the physician, and the effort and expense to the patient.

### SUMMARY

Charts illustrating the changes in the fields of vision of a patient suffering from migraine are shown.

A chart is presented showing the incidence of migraine in an authentic five generation study of a family; which also illustrates the presumed effect on the offspring of inbreeding a dipsomaniac with a person who suffers with severe migraine.

In 13% of my private patients migraine was a major problem.

General measures effective in treatment are outlined and illustrated by a number of case histories.

As factors which may precipitate trouble with migraine, the following were pointed out: Environment, cathartics, dyschezia, peptic ulcer, refractive errors, hypothyroidism, menstruation, food allergy, excessive smoking; there must be many others.

Means for the relief of individual attacks, especially by "cibal-gine" gr. *i.v.* were suggested.

Treatment failed in the case with unusually strong migraine heredity, the insanity equivalent, and the uncooperative.

73% of our cases showed a gratifying degree of improvement.

### CONCLUSIONS

Migraine is an inherited malady and inbreeding of migrainous individuals with unstable individuals increases the likelihood of the occurrence of migraine in the offspring.

Migraine is common.

Migraine attacks are precipitated by disturbing, in a variety of ways, the nervous and emotional tranquility in susceptible persons.

In treating migraine, one must be content with lessening the frequency and severity of attacks and the discovery of a remedy which will bring relief when attacks occur.

Simply to hand a migraine sufferer a diet or a prescription and send him on his way is bad medicine. A migraine case is a challenge to the thought, understanding and "salesmanship" of the physician. Hard work on such a problem, may, in more than seventy percent of cases, yield gratifying results.

# The Validity of Fractional Gastric Analysis\*

By

FRANCES A. HELLEBRANDT, M.D.

and

ELIZABETH BROGDON, M.S.

MADISON, WISCONSIN

THE function of the digestive processes is to change the foodstuffs introduced into the gastro-intestinal tract physically and chemically, so that they may be assimilated and made available to the tissues of the organism as a whole. Changes in the consistency and composition of the foodstuffs administered should be a gauge of the adequacy of these processes under varying physiological conditions. This approach has been largely ignored. The attack has been one of differentiating from the gastric contents the components poured out by the various types of secreting cells present in the mucosa, and of measuring functional competence in terms of enzyme strength or acid concentration. Clinical observations have been limited almost wholly to the latter procedure. A stimulus to the secreting cells of the stomach is administered and their response is measured during its effective period. Such a procedure is valid only if the intensity of the stimulus is controllable, and if the part under study may be freed from augmenting and inhibiting influences other than those attributable to the specific substance administered.

Both of these criteria of validity have been abundantly attacked since the introduction of fractional gastric analysis. The first has been adequately met as is evidenced by the evolution of the test meal. The stimulant has been gradually made more constant. That to at least one type of gastric secreting cell, may now be introduced parenterally in a quantitatively measurable dosage.

More serious difficulties arise in meeting the second criterion. The complexity of the processes involved may be illustrated by summarizing the factors which must affect the acidity of the gastric contents, which is the aspect of gastric activity most used as a measure of functional sufficiency in man. First, if a meal is used as the stimulant, it has a diluting and neutralizing effect which adds itself to that already produced by saliva, regurgitated duodenal contents, and the secretions of the chief and mucus cells. The fluid under study is evacuated from an organ which cannot be isolated from contiguous parts of the alimentary tract, and which contains more than one type of secreting cell. Second, the secreting cells are susceptible to stimulating in a variety of different ways, reflex, humoral, mechanical, vascular, motor and chemical. We do not yet possess practical selective stimulants capable of calling into activity isolated secretory mechanisms. Third, the secreting cells are in addition affected by extragastric reflex and humoral influences which may be either inhibitory or stimulatory. One may con-

clude, a priori, that with methods applicable to man, the repeated administration of a *constant* stimulus cannot call forth a quantitatively reproducible response. If the results of gastric analysis are significantly variable, they cannot be used for diagnostic purposes. However, the contour of the acidity curve has been taken as the basis for the classification of the behavior of the stomach (Bennett and Ryle, 1921), and various types of curve are looked upon as pathognomonic of specific diseased conditions (Lyon, Bartle and Ellison, 1921; Rehfuess, 1927).

Bloomfield (1932) has vigorously defended the physiological soundness of the results of human studies. He believes that accurate measurements of gastric secretion can be made in man. In his hands (Bloomfield and Polland, 1933) repeated tests of the same person have yielded almost identical results. These are reported to be so constant, "that they can almost be used, like finger-prints, as marks of identification." Evidence in support of this is not presented. The technique of Bloomfield and Polland differs from that usually employed in two major respects. Histamine is used as the secretory stimulant, and the gastric contents are continuously aspirated during the test period (1929). Even before the development of these refinements in technique, Bennett and Ryle (1921) reported identical curves after the repeated administration of oatmeal gruel. This, however, has not been the usual experience, and the reliability of fractional gastric analysis as an acceptable method of study has been repeatedly questioned (Crohn and Reiss, 1917; Lyon, Bartle and Ellison, 1921; Kopeloff, 1922; Baird, Campbell and Hern, 1924; Van Zant and Alvarez, 1931).

There is little objective evidence in the published literature demonstrating ranges of normal gastric secretory variability. The most extensive observations are those of Bell and MacAdam (1924) who studied one man on 20 consecutive days and who present a statistical analysis of their data. Although the standard deviations and coefficients of variation are large, these findings have been repeatedly cited in support of the reliability of fractional analysis as a diagnostic procedure. The observations were made after the ingestion of gruel. No similar series have been reported for other meals. The object of our study was, therefore, to make an investigation of the comparative reliability of three different types of secretory tests in common use.

## METHODS

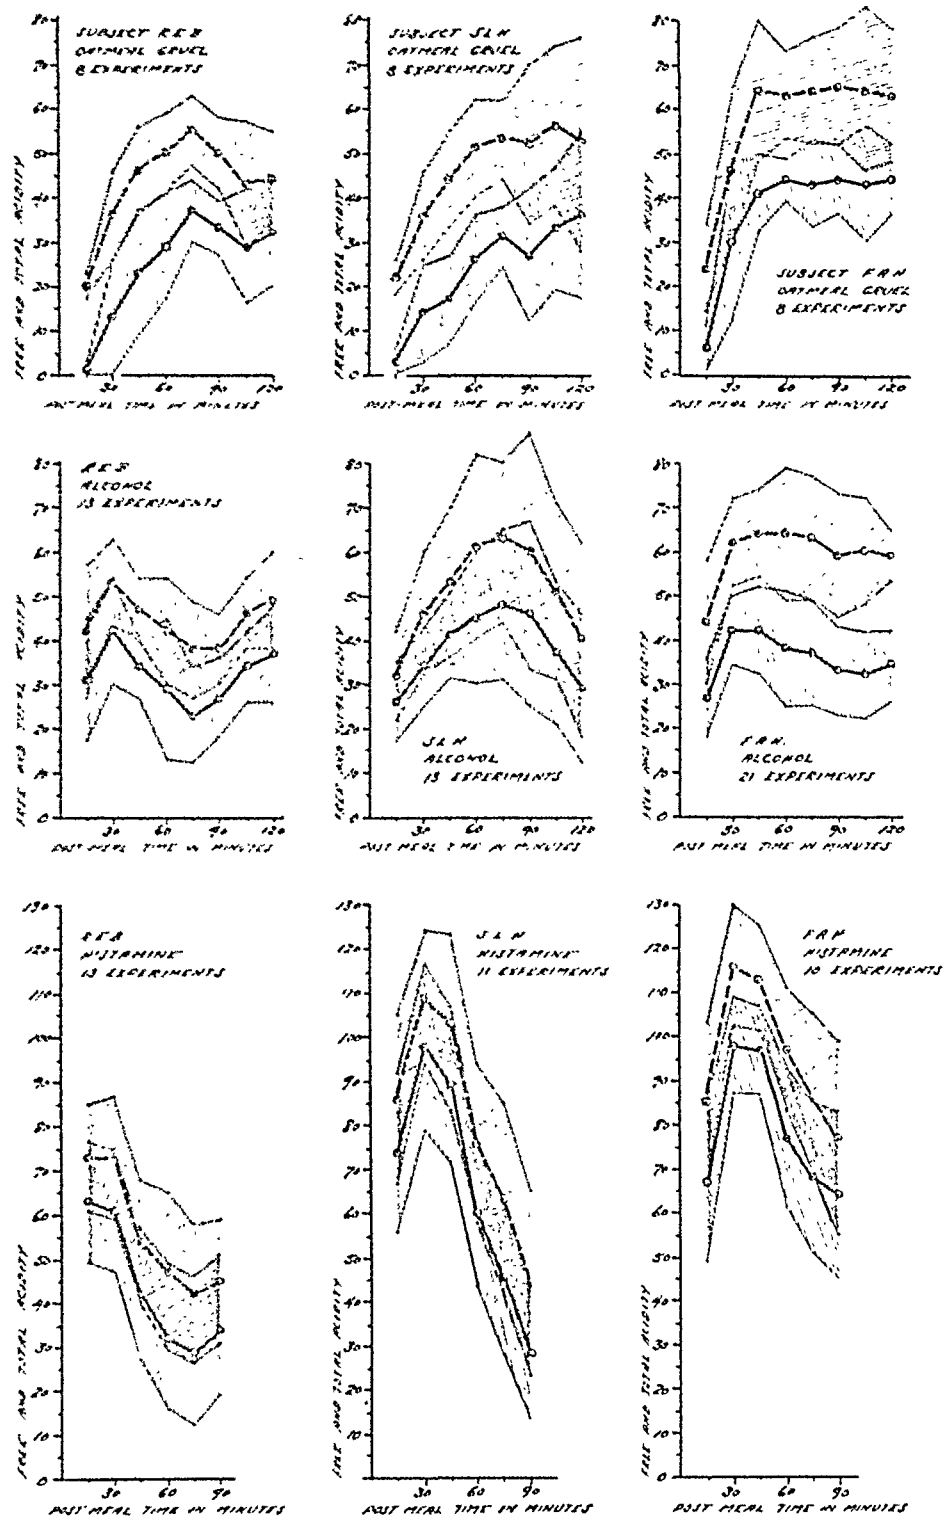

Observations were made on normal, healthy young adult women, accustomed to gastric intubation and without history of gastro-intestinal disease. A standard duodenal tube (Rehfuess) was swallowed without lubrication or the ingestion of fluid until the metal tip reached the most de-

GRAPHS SHOWING THE DISPERSION ABOUT THE AVERAGE GASTRIC SECRETORY RESPONSE OF THREE SUBJECTS TO THREE DIFFERENT TYPES OF TEST MEALS

○—○ TOTAL ACIDITY—ARITHMETIC MEAN      ○—○ FREE HCL—ARITHMETIC MEAN  
 ——— 6 OF THE DISTRIBUTION—TOTAL ACIDITY      ——— 6 OF THE DISTRIBUTION—FREE HCL

pendent pole of the stomach. Observations were commenced 14 to 20 hours after the last meal. The fasting contents were completely aspirated before the administration of the stimulant. Secretion was induced by 400 c.c. of strained, warm oatmeal gruel, taken by mouth with the tube in situ; by 50 c.c. of 7 per cent alcohol introduced through the tube; and by histamine in a dosage of .1

When secretion was stimulated with histamine by the parenteral route, the full gastric contents were withdrawn at quarter hour intervals. Free and total acidity were determined by titration with N/10 NaOH, using dimethylaminoazobenzene and phenolphthalein as indicators. Results are expressed in terms of the number of cubic centimeters of decinormal sodium hydroxide necessary for the

mg. 10 kg. A 1:1000 solution of ergamine acid phosphate was used by hypodermic injection. Saliva was either continuously expectorated or removed by suction. The subjects refrained from mental and physical activity during the periods of observation, which varied from 90 to 120 minutes. When meals were used as the secretory stimulant, samples of the gastric contents were aspirated every 15 minutes. Since the gastric contents are not a homogeneous mixture, samples were aspirated and re-introduced several times before removal for purposes of analysis.

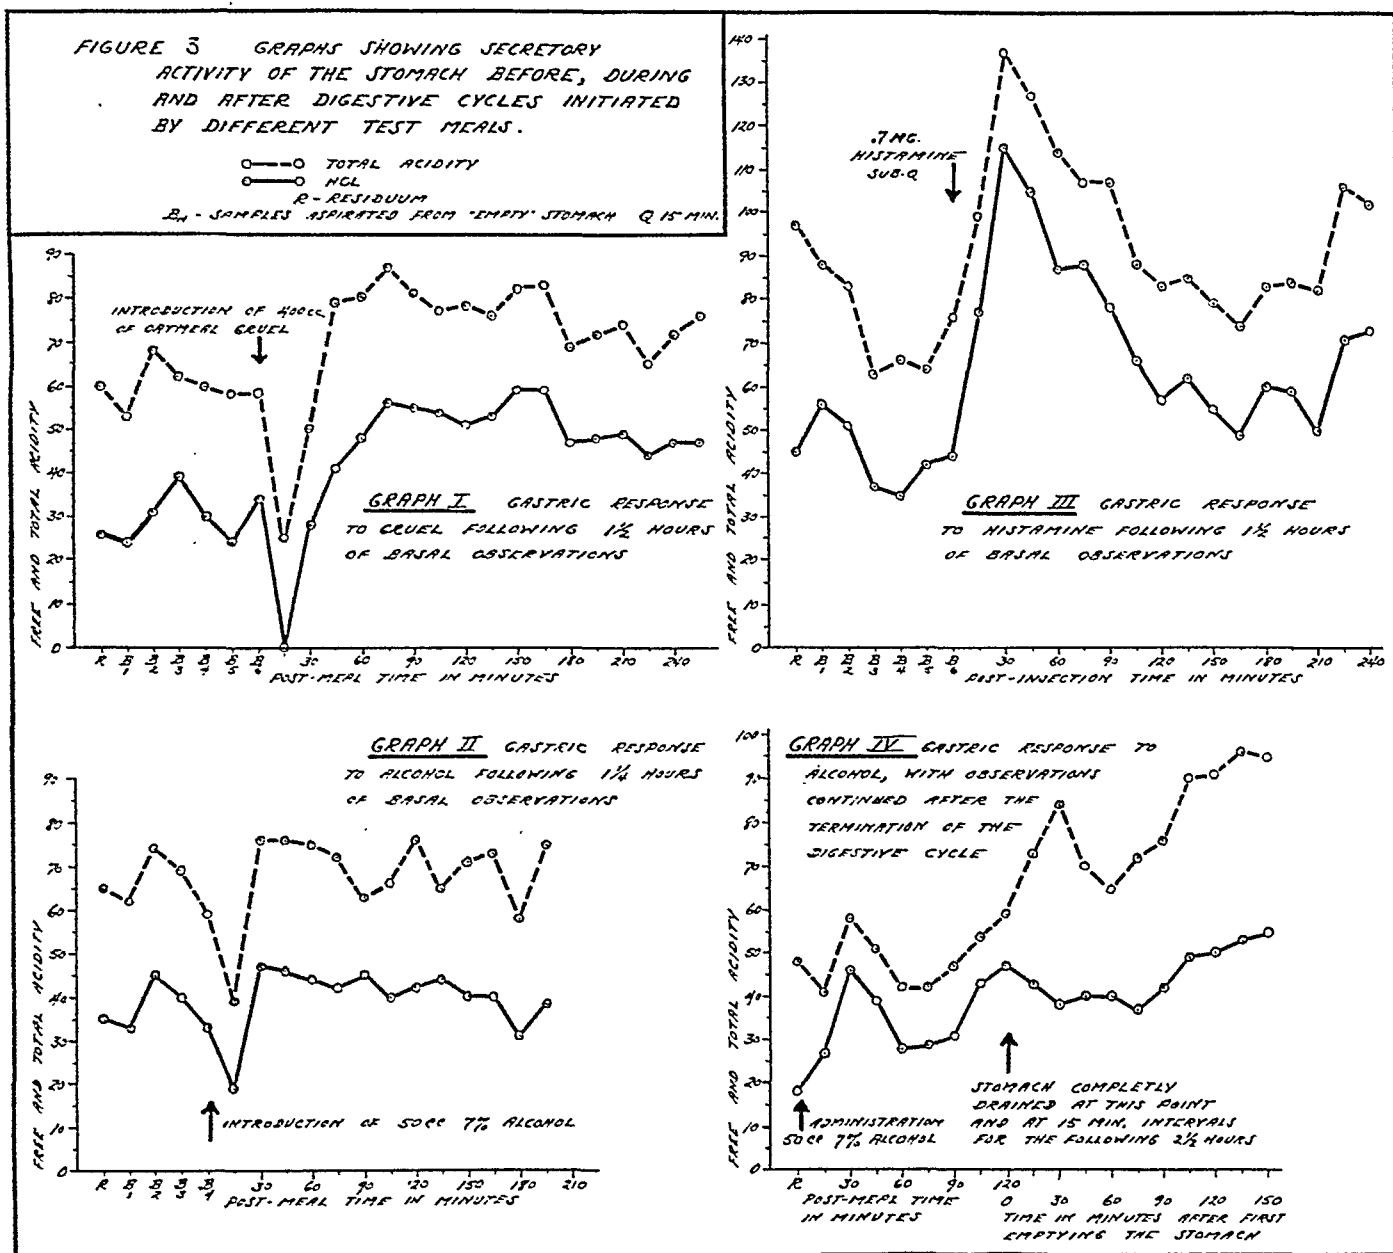

neutralization of one hundred cubic centimeters of gastric juice. To measure the degree of dispersion, the standard deviation of the distribution was calculated in the usual way.

## RESULTS

A total of 105 experiments were performed on 3 different subjects during a period of 8 months, 24 after the administration of gruel, 47 after alcohol and 34 after histamine, as illustrated in Figure 1. Both the

average secretory response and the standard deviation of the distribution have been graphed for each subject and for each stimulant. Examining the figure vertically, the response of one subject to the three different secretory stimulants may be compared; examining the figure horizontally, the response of three normal subjects to a single meal may be compared. It is evident at a glance that variations are great when healthy human subjects are examined repeatedly under identical conditions and by a rigorously controlled experi-

nating series of active and quiescent cycles, instigated by the intermittent ingestion of stimulating foodstuffs. Our findings are not in accord with this hypothesis of gastric secretory function. First, the curves which result from the plotting of acidity values do not invariably rise and then fall. The predominant trend may be quite the reverse. If Graphs I and II of Figure 2 were superimposed, the height of secretory activity in the former would roughly correspond in time to the period of lowest acidity in the latter. Further, the

mental technique. The scatter of the gruel series is comparable with that demonstrated by Bell and MacAdam. The small alcohol meal is almost as strong a secretory stimulant as is gruel, and the acidity response to it approximates that of gruel in its variability.

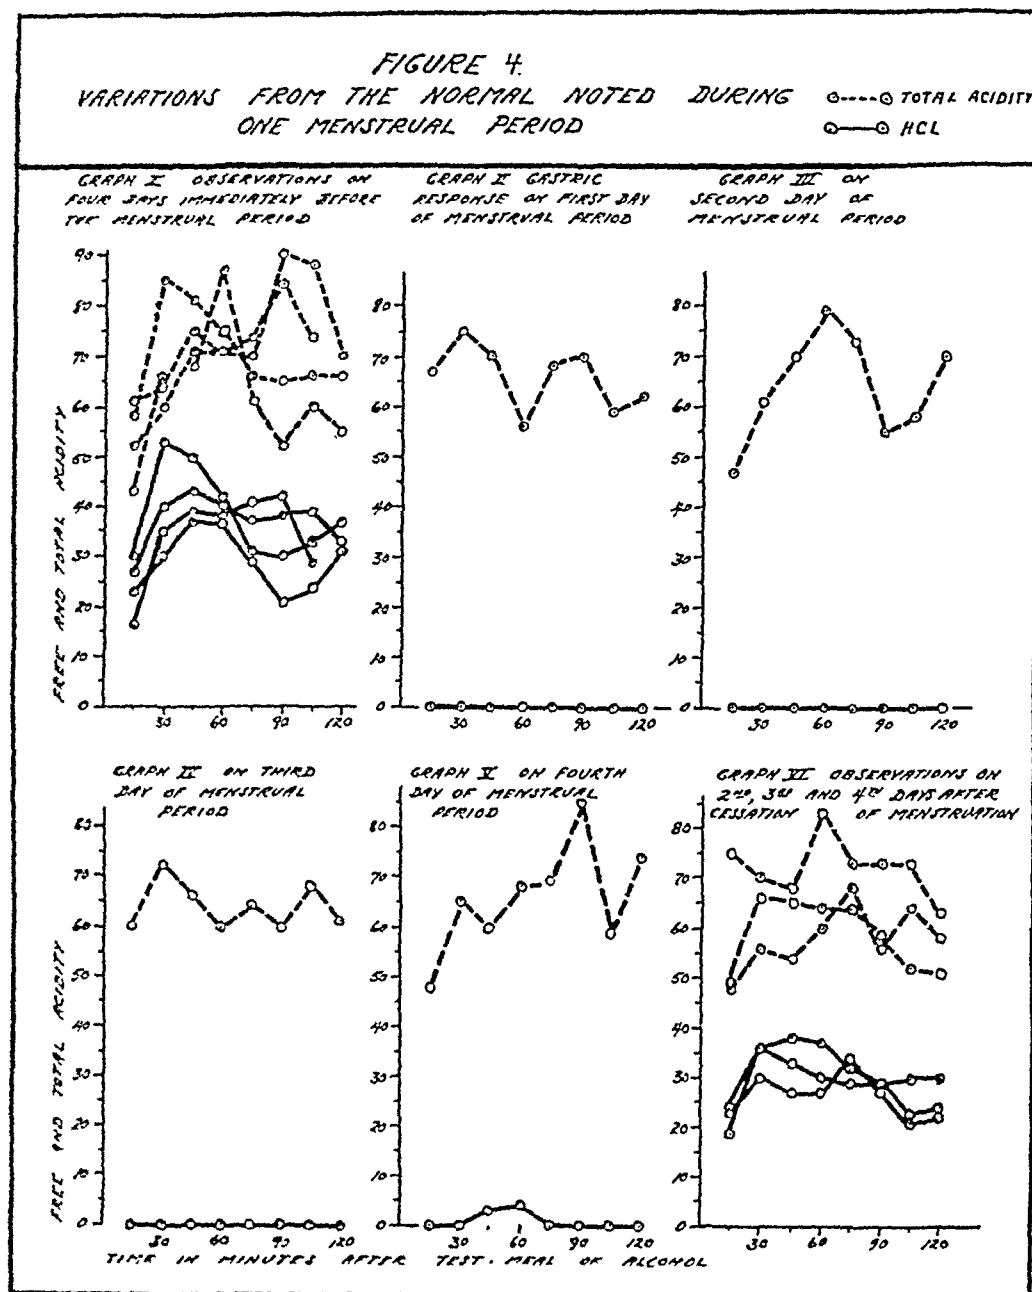

Rehfuß (1927) divides the secretory aspects of digestion into three phases, the periods of adjustment, the acme and the readjustment. They correspond to the intervals of increasing, peak and falling secretory velocity. He conceives gastric function as an alter-

curves show that the initial functional state following the aspiration of the fasting residuum during the interdigestive phase of Rehfuß is not constant, and that they strongly suggest that the post-prandial response may be related to the pre-stimulatory condition of the stomach. This, however, is not substantiated by the curves presented in Graphs III and IV of the same figure but may be deserving of further study. Second, Rehfuß describes the ideal, normal, terminal period as one of declining activity, approaching that of the so-called interdigestive period of relative secretory quies-

cence. Many of our curves show no tendency to fall, as illustrated in Figure 1, and in Graphs I and II of Figure 3 where the post-prandial observations are continued for longer intervals. Not infrequently a delayed rise follows the post-prandial decline. Such spontaneous augmentations are demonstrated in Graphs III and IV of Figure 3. They may markedly exceed

of dispersion. Variability is very nearly equally great during all phases of the secretory cycle.

Histamine is the most powerful stimulant known to the ocyntic cells of the stomach and the peak acidity attained under its parenteral influence is appreciably higher than that following the ingestion of a test meal. The closer parallelism of free and total acidity and the

the heights to which acidity is stimulated by the administration of a test meal. According to Rehfuß, the digestion of vegetables is characterized by a rapidly declining acidity, that of meat by a slow decline. It seems unjustifiable to us, to give so specific an interpretation to the contours of such inconstant curves. Third, Rehfuß reports the period of adjustment as the most unstable. This is not borne out by our graphs

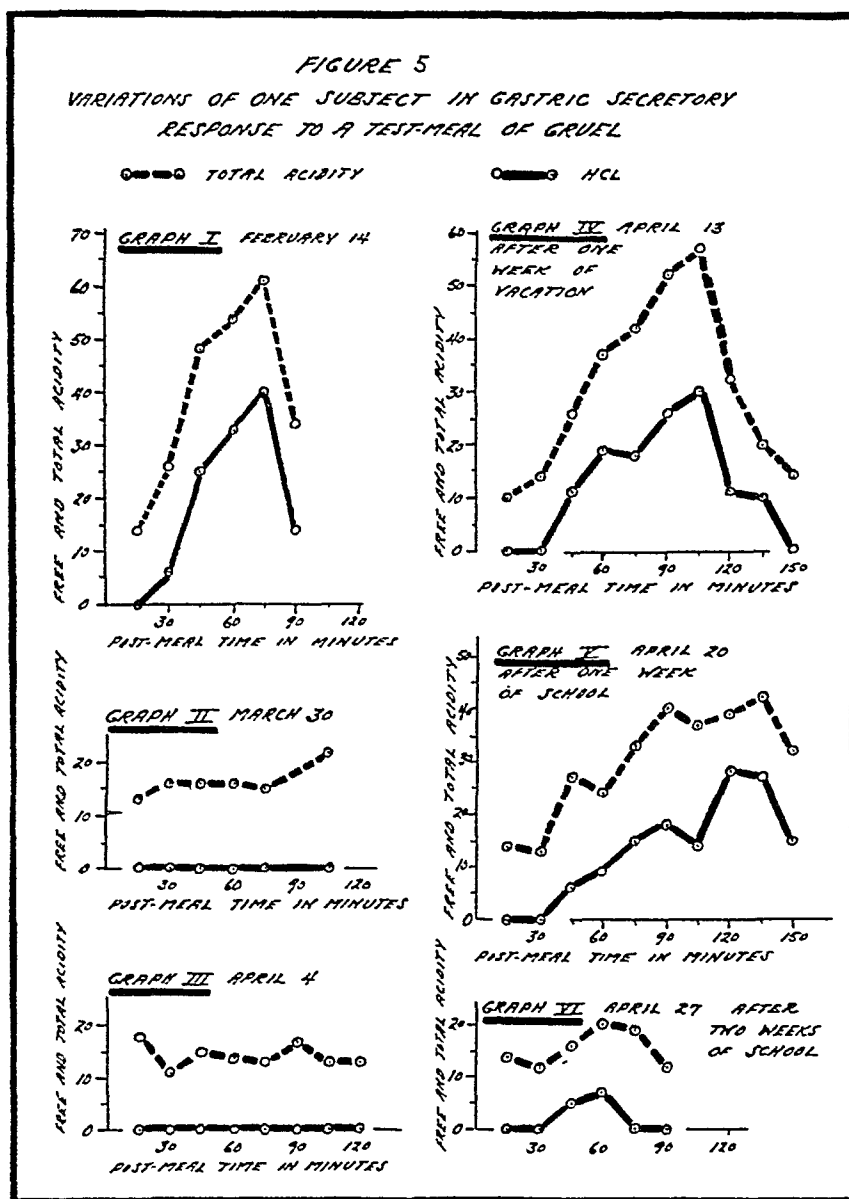

consequent overlapping of the areas mapping out dispersion, give a false impression of improved stability. In reality, histamine curves are scarcely more reproducible than those following the administration of stimulants less susceptible to exact quantitative duplication. The results of R.E.B. are atypical in that peak acidity was reached within the first 15 minutes and never approached the high levels consistently attained

by both S.L.H. and F.A.H. Unlike the experience of Bloomfield and Polland (1929), the hypodermic injection of a fresh 1:1000 solution of ergamine acid phosphate in the recommended dosage of .1 mg./10 kg. invariably was associated with unpleasant symptoms, brilliant flushing, a sensation of heat, and throbbing headache. These were especially evident in R.E.B. and it was deemed inadvisable to increase her dosage.

Secretory variability also may be a reflection of changes in general bodily condition. Two groups of

natural foodstuffs. Histamine adequately may measure the limits of the latent secretory capacity of the parietal cells, but it is of equal interest to know what percentage of their full functional power these same cells exhibit under changes in the physiological condition of the organism *in toto*.

The daily, single aspiration studies of Van Zant and Alvarez (1931) demonstrated a tendency for gastric acidity to be cyclic, low during menstruation and higher between periods. Figure 4 shows the sudden

data demonstrate the development of transient an-acidity and illustrate the extreme sensitivity of gastro-intestinal mechanisms to insensible gradations in fitness. Bloomfield and Polland (1933) classify this type of anacidity as "false" and predict that such oscillations in function will cease to appear when test-meal methods are discarded in favor of the histamine technique. In this respect histamine may be looked upon as masking a condition of considerable interest. Even though the parietal cells possess the ability to secrete free HCl when stimulated by as powerful an agent as histamine, they do not always do so when under the influence of less stimulating chemical substances or

appearance of achlorhydria in a normal healthy young woman with the onset of a menstrual period which was unaccompanied by any signs or symptoms of disturbed function. Free HCl promptly reappeared with the cessation of menstruation.

The subject whose graphs are illustrated in Figure 5 was a healthy young professional student in physical education. She had been under observation continuously for about 4 months prior to the date on which Graph I was obtained. Her gastric secretory response to oatmeal gruel had been in all respects normal. With the beginning of the second semester of the school year gradually she developed an hypochlorhydria until total

achlorhydria finally supervened. Her response to oatmeal gruel immediately before the spring recess is presented in Graph III. The succeeding graphs demonstrate the return of acid secreting ability after a week's vacation and the progressive re-development of hypoaclidity with the resumption of school work. The subject was conscious of no change in condition and there were no objective evidences of variation in fitness. Observations made during the long summer vacation showed widely oscillating degrees of acidity. Free hydrochloric acid was totally absent on 4 different occasions without detectable cause.

### SUMMARY AND CONCLUSIONS

Gastric fractional analyses were repeated from 8 to 21 times on 3 normal subjects after stimulation by oatmeal gruel, 7 per cent alcohol and by histamine. The average acidity values and the standard deviation of the distributions were plotted to show the reliability of the procedure.

From the results of 105 experiments, we conclude

that the secretory response of the stomach is highly variable in the normal subject, irrespective of the quantitative reproducibility of the stimulant used. Because secretion is affected via motor, mechanical, chemical, vascular, humoral and reflex paths beyond satisfactory control and by changes in general condition or fitness, the estimation of functional capacity in terms of the acidity response to a test-meal or to histamine as administered in these experiments is not a valid procedure.

These theoretical considerations substantiate the probable accuracy of the experimental observations. The contour of an individual acidity curve has little meaning, and deviations from it produced by conditions under study must be extreme before they can be considered statistically significant. Although fractional gastric analysis is of questionable value for quantitative studies of gastric function, it remains the method of choice for qualitative determinations of gastric acidity and for approximations of secretory capacity.

## Studies on the Relation of Non-Specific Ulcerative Colitis to Bacillary Dysentery (with Particular Reference to the Dysentery Bacteriophage)\*

By

A. WINKELSTEIN, M.D.

and

C. HERSCHBERGER

NEW YORK CITY, NEW YORK

IN a recent discussion of non-specific ulcerative colitis (1) it was concluded that neither the cause nor the cure of this disease has satisfactorily been demonstrated. Therefore, we have been carrying on in recent years some special bacteriologic, immunologic, and therapeutic studies in patients affected with non-specific ulcerative colitis. Because of the opinion expressed by Hurst (2), Strauss (3), Crohn (4), Thorlakson (5) and others that the disease is acute or chronic bacillary dysentery, we have turned our attention to that possibility. In this communication, only studies on the relationship of bacillary dysentery to non-specific ulcerative colitis will be presented.

### BACTERIOLOGIC STUDIES

*Method 1.*—The scrapings from the mucosa were placed in meat infusion broth pH 7.1. The broth culture was then streaked out on five Endo plates. After incubation at 37° for 24 hours the non-lactose fermenting colonies were in-

oculated into sugars, i.e., lactose, saccharose, glucose, maltose, and mannite. Micro-organisms showing sugar reactions characteristic of *B. Dysenteriae* were agglutinated with five different types of anti-dysentery serum i.e., Shiga, Flexner, Mt. Desert, Hiss and Sonné.

Routine cultures were taken through the sigmoidoscope directly from the mucous membrane lesions. In many instances the mucosa was first scraped and then the culture taken and in some cases biopsy specimens were cultured. Also repeated cultures were taken from fresh stools. These cultures demonstrated the following organisms from the ulcerated areas (Table I): in 60 consecutive cases studied, *B. coli* was present in all; in 26 cases *B. coli* predominated; in 23 cases *B. coli* and *Enterococcus*. *B. Alkaligenes*, *B. Friedlander* and the various strains of streptococcus (*alpha*, *beta* and *gamma*) were only occasionally encountered. Apparently the bacteria found in ulcerative colitis stools are those usually encountered in stools of normal individuals. It is of course possible that special strains of

Bacteriology of the stools in 60 cases of ulcerative colitis.

these organisms are involved. Anaerobic studies were not carried out. In 7 cases which were considered clinically typical instances of chronic non-specific ulcerative colitis, strains of bacillary dysentery organisms (1, Shiga; 3, Flexner, and 3, Mt. Desert) were isolated and confirmed by agglutination tests.

In addition to the 7 cited above, 20 other cases were encountered in 120 consecutive ulcerative colitis patients with a positive agglutination of laboratory strains of dysentery organisms by the serum of the patient. In these cases, agglutinins for the Flexner, Mt. Desert, Hiss, Sonnè, and Shiga strains appeared in dilutions of 1:80 to 1:1280. (See Table II). In a very comprehensive survey of what may be considered the normal agglutination *titer* for the various strains of dysentery organisms, Lentz and Prigge (6) arrived at the following conclusions: (1) For the Shiga strain, normals are either negative or range from 1:20 to 1:40. A *titer* of 1:50 is necessary for diagnosis. (2) For the Sonnè strain, even 1:20 is sufficient for diagnosis. (3) For the Flexner strain, normals may demonstrate agglutinins in dilutions of 1:50 to 1:80. These authorities consider 1:100 necessary for the diagnosis of Flexner dysentery. Accepting their conclusions, 3 of our cases who had a *titer* less than 1:100 may be considered questionable. It is also possible that agglutinins in some cases of bacillary dysentery are present only for the homologous or harbored strain of dysentery organisms. Of course, it is well known that agglutinins may disappear rapidly or may not appear, or appear late and disappear rapidly, hence they may be missed very easily.

Apparently careful bacteriologic and serologic studies will reveal that some cases of non-specific ulcerative colitis are indeed true epidemic bacillary dysentery, more or less chronic in nature. Recently, on the

| 1     |                                                                       |         |                                          | 1 : 80 |         |
| 1     |                                                                       |         |                                          |        |         |
| 1     |                                                                       |         | 1 : 80                                   |        | 1 : 160 |

Agglutination of various strains of *B. Dysenteriae* with the serum of 10 cases of ulcerative colitis.

basis of cultural and agglutination studies Bargaen (7) has denied this possibility.

### BACTERIOPHAGE STUDIES

In view of the almost constant findings of bacteriophage in the stool of convalescent bacillary dysentery cases (D'Herelle), the idea occurred to Gregory Schwartzman to examine the stools of colitis patients for the presence of an anti-dysentery bacteriophage. Such studies have been carried out by the authors of this paper in 41 cases of non-specific ulcerative colitis (Table III).

*Method III.*—One loopful of stool was inoculated into 100 c.c. of meat infusion broth pH 7.4. After incubation for 24 hours at 37 degrees the broth culture was centrifuged at high speed and the supernatant fluid filtered through a Seitz filter. One half of 1 c.c. of the filtrate was added to the first of a series of 6 tubes containing 4.5 c.c. of meat infusion broth. The contents of the first tube were thoroughly mixed and 0.5 c.c. of the mixture carried over to the second tube. This was repeated for the third and fourth tubes, using a new sterile pipette with each tube.

TABLE III

*Dysentery Bacteriophage in the Stools of Fifteen Patients*

| Cases  | Flexner | Shiga | Hiss | Mt. Desert | Sonnè |
|--------|---------|-------|------|------------|-------|
| G. N.* | +       |       |      |            |       |
| C. S.* |         | +     |      |            |       |
| R. P.  | +       |       |      |            |       |
| F. P.* |         |       | +    |            |       |
| D. S.* | +       | +     | +    |            | +     |
| R. G.  |         | +     | +    | +          |       |
| G. A.* |         |       | +    |            |       |
| F. N.* |         | +     |      |            |       |
| K. V.* |         | +     |      |            |       |
| B. L.  |         | +     | +    | +          | +     |
| F. K.  |         |       |      | +          |       |
| T. R.  |         | +     |      |            |       |
| G. W.  | +       |       |      |            |       |
| N. B.  | +       |       |      |            |       |
| E. C.  | +       |       |      |            |       |

\*In these patients, the bacteriophage appeared in the stool as they were recovering and disappeared when they were well.

One-tenth c.c. of a 24 hour broth culture of one of the strains of *B. Dysenteriae* was added to each of these four tubes. One half of 1 c.c. of filtrate was added to the fifth tube as a bacteriophage control and 0.1 c.c. of the broth culture of the *B. Dysenteriae* strain to the sixth tube as the micro-organism control. The tubes were incubated for 24 hours at 37 degrees C. The above described titration was carried out against each of 5 strains of *B. Dysenteriae*, i.e., Shiga, Flexner, Mt. Desert, Hiss and Sonnè. The presence of bacteriophage was indicated by the appearance of lysis in one or more of the first four tubes containing the specific strain.

From these studies, it is apparent that in 15 cases out of 41 (36%) a bacteriophage, active against one or more of the laboratory strains of dysentery organisms, was found. In a certain number of cases, the stools repeatedly were examined for bacteriophage throughout the course of the disease. In 7 cases the bacteriophage was absent during the acute stage of the disease, appeared during the convalescent or recovery period, and disappeared when the patient was entirely well. In 2 cases the bacteriophage which had disappeared on recovery from a previous attack again appeared during a second attack of the disease. Only 3 cases with bacteriophage in the stools had dysentery agglutinins in the serum. Control studies on the bac-

terriophage were made on the stools of 45 patients who were suffering from miscellaneous diseases other than non-specific ulcerative colitis. Several cases of diarrhea from other causes (amoebic dysentery, pancreatic insufficiency, Graves' disease, functional diarrheas) were also studied. A dysentery bacteriophage was not found in any of these 45 cases.

It is very interesting to note that in a small epidemic of bacillary dysentery where 21 sick members of 4 families were studied in The Mount Sinai Hospital (the features of this small epidemic will be reported elsewhere) and in whom the diagnosis was confirmed by the finding of the Flexner strain, 10 of these patients, when convalescing, also developed in the stools a bacteriophage potent against dysentery organisms and lost it when well.

Recently, Feemster (8) reported similar findings in an epidemic of 100 cases of Hiss bacillary dysentery. He found the Hiss organisms only in 5.6% of the cases, whereas, the active bacteriophage was demonstrated in the stools of 80% of the cases. None was found in controls. He concluded, as we also believe, that the detection in the stool of a bacteriophage active for the bacillus causing the dysentery seems to be a valuable procedure for determining the etiology of cases of diarrhea.

In view of the finding of the bacteriophage in these epidemics of proved bacillary dysentery, and considering its absence in a fairly large group of controls and other diarrheas of known etiology, the demonstration of an anti-dysentery bacteriophage in 36 per cent of a series of 41 cases of non-specific ulcerative colitis seems to have some significance.

### INTRADERMAL TESTS WITH TOXINS

A further attempt to ascertain whether some cases of non-specific ulcerative colitis were bacillary dysentery was directed as follows:

Utilizing the exotoxins of stock Shiga and Flexner dysentery organisms, skin tests in the manner of the Schick tests were carried out in patients with ulcerative colitis and in controls. The toxins were prepared by growing the Shiga and Flexner stock-organisms on solid culture media and then centrifuging and filtering the saline washings. The toxins were tested in rabbits using the "Shwartzman phenomenon." A tenth of a cubic centimeter of a 1:5 dilution in saline was injected intradermally in the patients and the site inspected 24 hours later. A central area of deep red or reddish-purple induration surrounded by a zone of 2-5 centimeters of erythema was considered positive. The findings are represented in Table IV.

TABLE IV

|                    | No. of Patients | Toxin   | Positive | Negative |
|--------------------|-----------------|---------|----------|----------|
| Ulcerative Colitis | 19              | Shiga   | 14 (73%) | 5 (27%)  |
|                    | 4               | Flexner | 3 (75%)  | 1 (25%)  |
| Controls           | 19              | Shiga   | 23 (69%) | 11 (31%) |
|                    | 47              | Flexner | 16 (52%) | 3 (15%)  |

Skin tests with dysentery toxins in ulcerative colitis patients and controls.

Apparently, the percentage of positive skin tests (indicating an absence of a neutralizing antitoxin) and negative skin tests (indicating the presence of sufficient antitoxin) in patients with non-specific ulcerative

colitis is approximately the same as in the controls. However, this negative study is inconclusive. It seems necessary to carry out such skin tests using toxins of the various strains of dysentery organisms during the acute stage, during the convalescent period and in the period of complete recovery. Should these skin tests show a changing dysentery antitoxin content of the blood and if this is confirmed in rabbits using the "Shwartzman phenomenon," it would offer additional evidence that the cases of ulcerative colitis showing this sequence of events are really bacillary dysentery. Such a study is being carried out on the colitis patients.

### SUMMARY

Summarizing these studies on the relationship of non-specific ulcerative colitis to bacillary dysentery, it seems permissible to state (1) that a small number of patients affected, presumably, with non-specific ulcerative colitis, have definitely been proved to have bacillary dysentery by the finding of *B. Dysenteriac*, according to method described above.

(2) The finding of a bacteriophage active for one or more strains of bacillary dysentery organisms in 36% of one series of 41 cases of non-specific ulcerative colitis is indirect but suggestive evidence that the patients have had or are suffering from bacillary dysentery.

(3) The positive dysentery agglutinations in high titer in 27 cases is strongly suggestive. The negative instances are, as already pointed out, for various reasons, inconclusive.

(4) Only 3 cases revealed simultaneously a bacteriophage in the stools and agglutinins in the blood serum. If their etiologic significance is accepted, this would indicate that the finding of either is helpful in establishing the diagnosis of bacillary dysentery.

(5) The relation of the intradermal tests with the toxin of the dysentery organisms to the antitoxin content of the blood during the course of the disease requires further investigation.

### THERAPEUTIC IMPLICATIONS

1. *Serum.* The therapeutic implications of these studies are clear. Hurst (2), Crohn (4) and others advocated the use of polyvalent anti-dysentery horse sera in the treatment of non-specific ulcerative colitis. The results in the cases treated by us were not very striking. There are several possible explanations for this failure, viz. (a) The cases may not have been bacillary dysentery. (b) The mode of administration (25 to 50 c.c. b.i.d. intramuscularly) both as to quantity (150 c.c.) and location (intramuscular) may not have been ideal. Perhaps larger doses, 300 to 400 c.c., given intravenously in a short period of time (48 hours) may give better results. Two cases, both patients with bloody diarrhea for one year and with the typical sigmoidoscopic and radiographic findings of ulcerative colitis, were treated with 300 c.c. of anti-dysentery serum given intravenously within 48 hours with excellent results. (c) The serum may not be potent. Some batches of commercial sera did not reveal agglutinins or antitoxin. Occasionally, as mentioned, a favorable response to anti-dysentery serum therapy is seen. This is indicated by a rapid drop in the temperature, an improvement in the general condition of the patient, a lessened number of stools with a more solid consistency, and a healing of the mucous membrane as evidenced by the sigmoidoscopic and

radiographic picture. Such an improvement may be (1) specific (2) non-specific (foreign protein shock?) or (3) coincidental improvement. It is indeed very difficult to draw conclusions as to the efficacy of therapeutic measures in a disease which has, as one of its characteristic features, sudden spontaneous remissions. Improved agglutinative and antitoxic polyvalent antidysentery sera are being prepared in this laboratory for further clinical trial.

2. *Bacteriophage*. It seems logical to use bacteriophage therapy in this disease. We have utilized a polyvalent dysentery bacteriophage which is powerfully lytic against the following laboratory strains of dysentery organisms: Flexner, Shiga, Hiss, Mt. Desert, and Sonn  strains. In a group of cases, from one to three ounces of this bacteriophage solution has been instilled daily into the rectum as a retention enema following a one per cent bicarbonate of soda enema. Some patients have improved while undergoing this therapy but since the instillations were carried out for weeks, during which time a spontaneous improvement may have occurred, it is not permissible to draw a conclusion as to the therapeutic value of this procedure.

3. *Active Immunization*. An attempt to actively immunize the patients with increasing doses of dysentery toxin is now being made.

## CONCLUSIONS

1. In a small number, 7 out of 60 typical cases of non-specific ulcerative colitis, the organisms of bacillary dysentery have been found.

2. A bacteriophage potent against one or more strains of dysentery organisms was present in the stools in 15 (36%) of 41 cases of non-specific ulcerative colitis. Miscellaneous controls and other diarrhea cases (a total of 45 cases) did not reveal a dysentery bacteriophage in the stools.

3. In 27 (22%) out of 120 non-specific ulcerative colitis patients there was a positive serum agglutination for dysentery organisms.

4. Intradermal tests in ulcerative colitis patients with dysentery toxin gave approximately the same per cent of positive and negative results as did normal controls. This question requires further study.

5. The therapeutic implications of these studies, particularly the use of anti-dysentery sera and bacteriophage, are discussed.

6. These studies strongly suggest further work on the etiologic r  le that bacillary dysentery may play in some cases of non-specific ulcerative colitis.

# ABSTRACTS

EDWARD S. EMERY, JR., AND ROBERT T. MONROE, M.D.,  
Boston, Mass.

*Peptic Ulcer, Nature and Treatment. Based on a study of 1435 cases. Arch. of Int. Med.*, Vol. 55, No. 2, Feb., 1935, p. 271.

The writers present an analysis of 1435 cases and have come to the following conclusions:

1. The nature of the disease is fundamentally unknown.
2. It occurs only in the regions of the gastro-intestinal tract, which are in contact with the hydrochloric acid.
3. It is essentially a chronic disease, and the factors influencing relapse are: emotion, fatigue and infections elsewhere in the body.

In 500 of this group, remissions occurred spontaneously in 131 patients. The usual length of such remissions being weeks to a few months. In 161 death ensued, due to hemorrhage in 20, perforation 28, obstruction in 4, and associated diseases in 35.

Peptic Ulcer does not tend to shorten the victim's life, the average age of death in 87, who died, was 59 years, which is the life expectancy for the general population.

32% of the patients treated medically had few symptoms thereafter. An almost equal number were moderately improved, and about 5% to a minor degree. About 13% showed that the treatment definitely failed. Thus about 81% of the patients responded in a favorable way to the medical treatment. A comparison of the medical and surgical treatment showed an appreciably higher percentage of continuous relief, but that surgical failures more than doubled the medical failures. Jejunal ulcers

followed in about 11% of the Gastro-Enterostomies. In 12% of the Gastro-Enterostomies with resection of the pylorus or a portion of the stomach. In 23% of those in which there was excision of the ulcer and in 16% of transsection of the pylorus, in which jejunal ulcers perforated into the colon, producing gastro-colic fistula.

The necessity of following up medical care with the avoidance of fatigue, infection and more careful attention to general hygiene is emphasized, as there is a tendency to over-emphasize the results secured by surgery. The maintenance of a rigid schedule is still a most important factor following operative procedure. The posterior gastro-enterostomy proved as effective an operation as excision of the ulcer. Removal of the antrum on the basis that it possessed a hormonal secretion which would decrease the Hydrochloric Acid has been shown to be an error.

The successful treatment has been based on recognition on thorough examination of other diseased conditions and their effective treatment. Emphasis on the chronic nature of the disease, with frank explanation to the patient for his intelligent cooperation, rest and diet form the basis of the treatment. The diet must meet all of the necessary requirements, with an avoidance of roughage, condiments, alcohol and tobacco. A modified Sippy plan of treatment the Authors considered was still the most successful.

Their attitude towards peptic ulcer located in the stomach is that the patient requires stay in the hospital for three weeks, under the required schedule of treatment. Then the Roentgenographic studies were repeated, and if these show no healing as compared with the first exami-

nation, immediate operation is advised. If healing is definite, and the ulcer crater smaller, medical treatment is continued and frequent X-ray studies are made over a period of one year.

The therapy of the peptic ulcer case with obstruction, occurring in 169 of their cases, brought out the fact that there was agreement as to the clinical and Roentgenological evidence in 141 of the cases, that is there was a large residue present. Medical treatment was effective in only 5.6% of the cases where there was definite obstruction and a large residue. It helped in those cases in which the X-ray alone suggested obstruction. Surgical treatment produced the best result where there was a high grade of obstruction present. It seemed from their evidence, it was worth while to treat the obstruction case for a short time in a medical manner.

Hemorrhage occurred in 384 of their patients at some time. There was no way to determine which case would bleed. In 95% of the cases the bleeding stopped spontaneously, which leaves a small group in which surgery may be necessary. The performance of a surgical operation does not avoid the incidence of further hemorrhage. Of 155 patients who received surgical treatment, 17% had further hemorrhage following the procedure.

The acute perforation is definitely surgical at once. Perforation occurred in 111 of this group, and the simplest surgical procedure at this time seems to be the most reliable way of treating them, and simple closure with or without gastro-enterostomy has proved most effective.

MACMILLAN, A. S.

*Statistical Study of Diseases of the Oesophagus. S., G. and O., Vol. 60, No. 2A, Feb. 15, 1935, pp. 394-402.*

The author reviews 1600 cases in which the patient sought relief from dysphagia or some other symptom relative to the passage of food from the mouth to the stomach. Very careful X-ray examinations were made with the patients, following thin and thick barium preparations.

Foreign bodies were found in 181 cases. More than 90 per cent of the foreign bodies were found in the pyriform sinuses or the upper one-third of the oesophagus. The types of foreign bodies found in these cases were, in order of their frequency of occurrence: chicken bones, fish bones, open safety pins, small lead toys, pieces of wood, glass and a variety of hardware.

In 350 cases the cause of the dysphagia was found to be a malignancy. The ages ranged from 30 to 78 years; men predominated over women 6 to 1. In this series malignancy occurred in the oesophagus as follows: upper third, 124 cases; middle third, 103 cases; lower third, 132 cases.

Cardiospasm was found in 135 cases. Radiological examination reveals typical findings. Mosher has definitely proved that in cardiospasm there is a fibrosis and degeneration of the muscle of the oesophagus with a stenosis and secondary twist due to the dilatation and elongation of the oesophagus. The ages varied from 16 to 68 years; women predominated over men 3 to 1.

In 96 cases there was a fusiform narrowing of the upper portion of the oesophagus. The symptoms of such narrowings is the inability to swallow a large bolus of food. Treatment is practically unavailing, but the passage of bougies is reassuring to the patient.

The next most frequent cause of dysphagia was found to be the formation of partial diaphragms of mucous membrane, or webs, with central or eccentric openings. They usually follow trauma, or ulceration of the pharynx and mouth. They frequently occur opposite a cervical exostosis. The roentgenological picture is diagnostic. Spectacular relief can be given by rupturing the thin diaphragm with instruments. This condition was found in 114 patients.

Extrinsic causes of dysphagia occurred in 31 cases. Metastatic carcinoma in the glands of the neck, and medi-

astinal tumors, present the most difficult diagnostic problems.

Burns of the oesophagus and their resulting strictures were found in 40 cases. Such strictures are usually located in the middle of the oesophagus.

Paralysis of the oesophagus was not found, but paralysis of the muscles of deglutition was noted in 46 patients. The paralysis is always of central origin and may be due to any one of several etiological factors: an infection such as poliomyelitis, a localized central hemorrhage, brain tumor, fracture of the skull, and Parkinson's disease.

Pouches of the oesophagus are rarely recognized during life because they do not produce obstruction. They are discovered during a routine examination, or at autopsy.

Pharyngeal diverticula were found in 32 cases. The ages varied from 45 to 83 years. Males predominated over females 4 to 1. The diagnosis is readily made by X-ray. The treatment is surgical elimination of the diverticulum.

Ulcers of the oesophagus were found in patients. It occurred most commonly in the lower part of the oesophagus. Substernal pain and dysphagia were the most common symptoms. X-ray findings are characteristic.

ROZENDAAL, HENDRIK M.; COMFORT, MANDRED W., AND SNEEL, ALBERT M.

*Slight and Latent Jaundice. J. A. M. A., 140:374, Feb. 2, 1935.*

A study was made to determine the meaning of a slight increase in the value of the serum bilirubin and the true meaning of the indirect van den Bergh reaction. An analysis of 214 cases showing an indirect van den Bergh reaction and a serum bilirubin of 2.0 mg. per hundred cubic centimeters or above comprised the study.

Evidence of hemolytic disease was present in seventy-six cases.

The authors feel that in those cases in which there is no hemolytic disease present increased serum bilirubin means hepatic dysfunction. Also in those cases where hemolytic disease is present and excessive hemolysis is the accepted explanation of the increase in serum bilirubin, the almost universal presence of some hepatic injury suggests that it may also be partly responsible for the elevation of the bilirubin concentration.

That the indirect van den Bergh reaction does not rule out hepatic injury is maintained by the authors who have seen the van den Bergh reaction change from direct to indirect during convalescence from hepatic injury while an elevated serum bilirubin was still present.

Another interesting finding the authors mention is the fact that some patients who complain of being bilious actually have slight hepatic dysfunction.

The secretion of bilirubin is a sensitive mechanism. Emotion, disturbances in the sympathetic nervous system, as well as minor degrees of hepatic injury may influence this mechanism.

Francis D. Murphy, Milwaukee.

WINKELSTEIN, ASHER.

*Peptic Esophagitis. J. A. M. A., 104:906, March 16, 1935.*

The author presents five patients, all elderly men complaining of dysphagia, substernal pain, heartburn, and sour eructations. In three of the cases, duodenal ulcer was present, in the fourth case a peptic ulcer of the esophagus had been present previously, and in the fifth case a gastric ulcer developed subsequently. All cases showed hyperchlorhydria. Esophagoscopy was done and biopsy specimens were obtained in all cases to rule out suspected carcinoma of the esophagus. The biopsy reports were "acute and chronic purulent inflammation."

Ulcer therapy with employment of antacids gave prompt relief in all cases.

Exacerbations and remissions resembling those seen in peptic ulcer tend to occur.

Francis D. Murphy, Milwaukee.

## SECTION II—*Experimental Physiology*

### The Pancreas and General Metabolism\*

#### A Physiological, Metabolic and Philosophical Concept of Nutritional Unity and Interdependence

By

W. N. BOLDYREFF, M.D.†

BATTLE CREEK, MICHIGAN

THE report falls into two parts: 1. Metabolism in the whole organism and 2. Metabolism in the separate cell.

#### 1. *Metabolism in the Whole Organism.*

When we discuss metabolism in connection with the function of the pancreas we involuntarily think of carbohydrate metabolism long ago studied and described in detail by the great Claude Bernard, then Minkowski and finally by many other French, German, English, Italian, American and Russian investigators. We recall also the more recent work of Macleod, Banting and their associates dealing with insulin which has so much relieved the suffering mankind in the struggle against diabetes mellitus. From this angle we shall discuss metabolism in the whole human and animal organism and the rôle of digestive hormones. But I am going to describe the relationship of the so-called external pancreatic secretion to the general metabolism.

If the introduction of the conception 'hormone' were necessary and useful in the past, it is now not infrequently abused. Hormones have so multiplied in recent years as to create much confusion in the study of physiology. Some substances are classed as hormones without having been sufficiently studied so that their content and action are fully understood. Physiology is thus turned into *philology*—no new facts, no explanations, but simply new words.

Even with the finely studied hormone, insulin, the ground is not perfectly sure.

Recently Ephraim Boldyreff (Pavlov Physiological Institute and University of Michigan) has established that (1) the amount and distribution of islet tissue in the pancreas apparently do not have any relation to the blood sugar; (2) the effect of insulin upon the digestive system invariably precedes its hypoglycemic action, and (3) insulin affects carbohydrate metabolism through the nervous system (Report to this Congress).

The newest findings on the duodenal hormone, similar to insulin, and found by the American doctors A. B. Maccallum and N. G. Laughton, also shake the faith in the specific action of insulin as a product of the islands of Langerhans, as well as the fact that many

authors have obtained insulin, or a substance similar to it in physiologic action, from various bodily organs and even from plants (Collip).

Further, a whole series of laboratory investigations and clinical observations have shown that insulin affects not alone the carbohydrate metabolism as was formerly believed, but the fat (Bloor) and the protein metabolism as well. Hence the conclusion that our views on the physiological effect of insulin, which seemed so definite, simple, and well founded, must undergo revision. Therefore (1) insulin in reality is not 'insulin' at all, *i.e.* it is not restricted to the islands of Langerhans, but found in the whole body of the pancreas; (2) moreover, it has other effects than upon carbohydrate metabolism inasmuch as it influences also the metabolism of other substances; (3) that, as is accepted for typical hormones, insulin acts not directly on carbohydrate metabolism but through the nervous system. (For details see the works of E. Boldyreff and others).

The correctness of this view is also confirmed by some earlier work: for instance, by the fundamental and original work of de Dominicis in Italy on the influence of pancreatic juice (so-called external secretion) on the metabolism, and also my work on the same subject supplying new data and offering new explanations, first reported at the VI Congress at Brussels (in 1904) and later described in detail in *Ergebnisse der Physiologie* in 1911 and 1929 and elsewhere.

The term 'external' secretion for pancreatic juice secreted into the intestine in distinction from a supposed, though never seen and not proven 'internal' pancreatic secretion, entering directly into the blood, is unfortunate and incorrect. In former times it would perhaps serve to describe the secretion of pancreatic juice outside in animals with pancreatic fistulae. But this term should now be abandoned in order to avoid harmful and even dangerous confusion in conceptions, since it has been proven that normally this secretion is soon absorbed into the blood and thus becomes *internal*. My experiments and those of my associates have shown that in man and vertebrate animals, when hungry, there is an abundant, regular and uniform periodical secretion of pancreatic juice into the intestine about every 1 or 2 hours (described in detail by me elsewhere). In 24 hours there are from 5 to 10 such "secretion periods" depending upon the subjects diges-

\*Reported at XIV Internat. Physiol. Congress in Rome, Aug. 30, 1932, and at Mechnikoff's Medical Society in Paris, Oct. 27, 1932.

†Director of Pavlov Physiological Institute of the Battle Creek Sanitarium.

Submitted February 12, 1935.

tive activity. The more time there is taken up by digestion, the less there is left for the periodical secretion, just as the longer the night, the shorter the day.

The periodically secreted pancreatic juice, or rather its ferments, are immediately absorbed from the intestine into the blood where the proteolytic ferment is detected by means of Abderhalden's reaction (work of Dr. Kniazeff in my Laboratory). The glucolytic (work of E. Boldyreff in my Laboratory) and lipolytic ferments are also detected by other fitting and generally known methods. Prawdich-Neminsky in Russia noticed a similar periodical appearance of catalase in the blood simultaneous with the above named ferments.

E. Boldyreff in my Laboratory has proven in his published experiments that pancreatic juice in general, both the portion secreted on food and the periodically secreted portion, possesses a glucolytic action. He has also established that the sugar content in the blood of a living being falls during the periodical pancreatic secretion and rises in the absence of it. I do not doubt that such pancreatic juice is the main source of insulin. The pancreatic juice secreted in digestion possesses the same property.

According to our data, the ferments of the pancreatic juice always, though periodically, enter the blood in the absence of digestion and during it and then are carried throughout the organism to supply the needs of all the organs, tissues and cells of the body. The general metabolism—carbohydrate, protein and fat—is effected with the aid of these ferments. They supply the energy for the functions of the body and the chemical work in the organism, under constant and exacting control of the nervous system. The importance of them was first indicated and studied by Claude Bernard and later insistently stressed by E. Pflueger.

The correctness of the theory presented is confirmed by the following considerations.

(1) There is a parallelism between the work of the digestive organs and the general life processes in the organism. In the young organism with good digestion, there is rapid growth, quick recovery from injury or disease, resistance to fatigue and so forth; in old age, the digestion is poor and all other vital phenomena are slow and dulled.

(2) In severe sickness, all the bodily forces are concentrated for the struggle against the disease; digestion is at times stopped for lengthy periods or may be inhibited (due to lack of appetite), thus permitting the digestive ferments to be mobilized for intracellular work which is more important at such times since it assists the fight against the causes of disease.

(3) If the pancreas is the mainspring of the general metabolism, then in cases of pancreatic affections or outside secretion of pancreatic juice, the metabolism is greatly unbalanced. This is precisely the case in *diabetes mellitus* and in the animals with pancreatic fistulae as well as in pregnant women with pernicious vomiting. In these cases, a pronounced disturbance of carbohydrate and other metabolism is very apparent.

In *diabetes mellitus* we often observe presence of gangrene, poor healing of wounds, weak resistance to infection and a generally lowered vitality of cells and tissues of the whole body. This is a consequence of the affection of the pancreas and poor supply of bodily cells by the pancreatic ferments, necessary for correct nutrition and normal life. If each cell prepared its

own ferments, affections of the pancreas would have no injurious effect on the cells of the whole body. This connection between the weakened work of the pancreas and the mentioned diseased condition of the whole body, observed in *diabetes* serves as the best confirmation of the correctness of my theory on the supply of ferments to the entire tissues and cells of the organism by the pancreatic gland.

Thus the pancreas is the chief chemical agent for all general manifestations of life in the human and animal body, as the heart is the main motor agent for the circulation and the brain for the control of coordination in the functions of all organs and adaptation to life of individuals to the surrounding conditions and environment.

## 2. Metabolism in the Separate Cell.

There are almost no definitely proven data concerning general chemical process in the cell, *i.e.* the phenomena of destruction and reconstruction of the proteins, fats and carbohydrates. We must therefore rest satisfied with hypotheses. There is no doubt, however, that the chemical processes in the cell depend upon the work of the ferments similar to that which takes place in the digestive tract during digestion; in other words, assimilation and dissimilation of protein, carbohydrate and fat, both in the cell and in the digestive tract, are effected by the same agents.

Claude Bernard said: "Ferments treasure the mystery of life." Later, Emil Fischer repeated the same thought in other words: "Wir dürfen . . . mit ziemlich grosser Wahrscheinlichkeit annehmen, dass sie (Fermente oder Enzyme, W. N. B.) bei allen Verwandlungen in der lebenden Zelle betheilt sind."

Each cell must contain all the main digestive ferments, proteolytic, lipolytic and glucolytic. Thirty years ago Professor I. P. Pavlov proved that proteolytic, digestive ferments are capable not only of splitting proteins, but also of recreating them from the split-products. Even earlier, Croft Hill, in England, found the same to be true for carbohydrate ferment, and later Kastle and Loevenhart in America found it to be true also for the fat ferment, which was also mentioned by Claude Bernard. To sum up, all these ferments possess a twofold property: to split and to reconstruct.

In the life economy of some cells (muscle cells) carbohydrates play the main part; in others, such as brain cells, the fats; and in others (cells of red blood corpuscles) the proteins. They all, however, must at times split and reconstruct all of the three basic substances which make up any living cell and which also serve as the main food for the whole organism, *i.e.* carbohydrates, fats and proteins.

It follows that each cell must have in it all three kinds of ferments. What is the source of supply for them? Are they made in the cell itself or borrowed from elsewhere? Only the cells of the pancreas and small intestine (perhaps also leucocytes) are capable of making all the named ferments. Even the cells of the digestive glands, which specialize in the production of ferments, are restricted to their particular product. The gastric gland cells make only pepsin; the salivary gland cells only ptyalin (in man), but neither one can make lipase or any other ferment. The less probably, then, is the assumption that the specific cells which do not participate in the elaboration of ferments, such as the muscle cell, nerve cell, kidney cell,

connective tissue cell, etc., can create for themselves all three kinds of ferments or even one of them. They are supplied to them ready made. Where is the origin of this supply?

Essentially, as stated above, the process of splitting and reconstruction of protein, fat and carbohydrate in the digestive tract and the processes of their dissimilation and assimilation in each cell are perfectly alike. Hence in both cases the same ferments are at work.

Now the main source of supply of ferments for all the bodily cells becomes clear: the main "factory" would appear to be the pancreas.

All the main digestive ferments—proteolytic, lipolytic and amylolytic—enter the blood current in profusion both during absorption of digested food and in the absence of digestion during the before mentioned phases of periodical pancreatic secretion, and are carried in the blood stream throughout the body. Thus, every cell of every organ is supplied with them. When no more useful, the ferments are cast back into the blood stream or the lymph and are either carried outside in the urine and other excretions or absorbed by the leucocytes for their own needs.

This investigation would seem to designate the pancreas as the large "factory" where ferments are being prepared for the general metabolism in the whole body. But the pancreas is not the only source of these ferments. Intestinal glands (in the small intestine), prepare a juice very similar in its properties and in ferments and their action, to the pancreatic juice and second to it only in its strength. Thus, the intestine assists the pancreas. Therefore, it is clear that removal of large sections of small intestine in various operations is not without effect on the body.

In the limited space of an ordinary report one is perforce restricted to the general points of the problem, indicating its main stages, and it is impossible to take time for discussion of even important details. I trust the reader will pardon the incompleteness and the schematic nature of this paper.

I sincerely hope that the ideas here expressed will find response in some of my readers, at least among the younger generation of physiologists whose minds are more open to the reception of new suggestions than

are those of the older generation who may be prejudiced by their interests and previous conceptions in favor of the already accepted and established theories in the field of science. Therefore again I make an appeal, as I did in 1911, to all who are interested in metabolism to apply their efforts to this so fruitful and as yet so little studied field.

### CONCLUSIONS

1. Apparently the general metabolism (carbohydrate, fat and protein) in the whole body as well as in each separate cell, is effected with the aid of certain pancreatic ferments. These ferments are being secreted in the pancreatic juice and are absorbed into the blood (and hence into the cells) during digestion and in fasting (during the periodical activity).

2. The "external" pancreatic secretion with all its ferments is quickly absorbed from the intestine into the blood, and constitutes the true "internal" pancreatic secretion which controls not only the carbohydrates, but also other metabolism. There is no other "internal" pancreatic secretion in the old sense of the word, i.e. there is no direct absorption into the blood from the pancreas of a specific substance controlling the carbohydrate metabolism, independently from the external secretion.

3. There are no endogenous ferments prepared by the cells themselves for the needs of general intracellular digestion (splitting and reconstruction of carbohydrates, fats and proteins). Only specific substances and specific ferments can be prepared in the cells of special organs (adrenalin in suprarenal glands, thyroxin in the thyroid apparatus, and so forth).

4. The pancreatic and the intestinal ferments, entering the blood very soon leave it, being absorbed by the cells and tissues of the whole body (in the liver, lungs, muscles, etc). Experiments of Ludwig's laboratory have shown that the blood loses its ferments in about 4 hours. For this reason, all digestive periodical ferments, such as pancreatic and intestinal, usually are secreted every one or two hours, otherwise the blood would become "fermentless."

5. There is evidence to support the view that the pancreas is the main agent of all general chemical processes in the organism.

## SECTION III—Nutrition

### What Should be the Per Capita Per Day Milk Consumption of Our Population?

By

LLOYD ARNOLD, M.D.\*  
CHICAGO, ILLINOIS

IT is significant, and very encouraging, to note that this official publication of the American Gastroenterological Association has an important section on Nutrition. No single group of the medical and allied professions is in such an advantageous position to evaluate nutrition as members of this Association. The gastroenterologist sees more instances of maladjustment to nutritional environment than any group in medicine. Man, as well as other forms of organized protoplasmic life, must adapt himself to three major environmental influences, nutritional, meteorological and parasitic. The last is taken in its broadest sense, meaning bacteria, parasites, viruses, etc. The successful adaptation to these three factors constitutes a normal or healthy person. Maladjustment to any one leads to abnormal physiological symptoms. These three environmental or external factors are, therefore, interrelated with each other. The author (1) dealt with this subject in a previous publication. It is the purpose of this paper to mention one of our common foods, and to indicate the need of the gastroenterologist's experience and influence in aiding the public health authorities in their educational programs in nutrition.

The value of milk as a food has been established and is recognized by all students of nutrition. The public has become "milk conscious." The value of the proteins, sugar, fat, inorganic salts and the vitamins has been repeatedly and thoroughly studied by many investigators. Milk is considered as one of the almost complete foods; that is, it supplies a large number of the essential factors for nutrition.

The per capita consumption of milk in this country is said to be approximately one pint per day. Tobey (2) states that there are fifty-six gallons of whole milk consumed per person in this country per year. This would, therefore, figure out to be approximately a little less than one-half quart per capita per day. The Pennsylvania State College of Agriculture and the United States Department of Agriculture carefully investigated the whole fluid milk consumption in Philadelphia and certain suburbs in 1924, 1929 and 1934 (3). Table I is reproduced from this report. The last column of this table needs some explanation. After the investigators had ascertained the estimated milk consumption

per capita per day from each family, an accurate check was made by examining the milk dealers books who supplied this product to the families. It was found that there was usually an over estimate given the investigator by the housewife. The last column represents the deduction according to the amount of milk sold by the dealer. It was found, for instance, that during the 1934 survey, 8.3% of the 3004 families in the city of Philadelphia did not use milk and 2.9% of the 409 suburban families did not use milk. Health authorities recommend one quart per day for children up to thirteen or fourteen years of age. Milk in this country always means fluid fresh whole cow's milk. Authorities on nutrition and public health refer to the relatively large milk consumption by the population of

the dairy producing countries of northern Europe, such as Holland, Denmark and Finland. Tigerstedt (4) and Sundstroem (5) are most frequently quoted in this connection. The food habits of any particular folk are rather complicated when one tries to analyze the nutritional status from a purely scientific standpoint. Most of the ingredients of the diet of the peoples in northern Europe go back much further in history than can be obtained in this country. The inhabitants of many European countries have ingested a rather constant diet for many years. Sundstroem (5) has made the most painstaking survey of the actual diet ingested by a given folk over a considerable period of time. He has tabulated very carefully the diet consumed by the Finnish people in various walks of life, as well as for different age groups.

\*Professor of Bacteriology and Public Health, University of Illinois, College of Medicine, Bacteriologist in charge of the Research Laboratories of the Illinois Department of Public Health.  
Received June 16, 1937

Table II is a reproduction of Table XII, p. 148 from Sundstroem's monograph (5). There were large enough samples in each respective age group to give trustworthy data. Table III is taken from Tigerstedt's publication (6) as the average composition of the diet of the Finnish folk. Table IV is from the Sundstroem's work (7) and deals with the ratio of milk to the total diet for the various age groups. We have compiled in

Whole cow's milk contains certain essential constituents for the rapidly growing calf. The cow in the undomesticated state ordinarily delivers her calf during the early spring. The calf is exposed to sunlight, begins eating green grass very early and supplements the milk with other food. The milk, however, contains the inorganic salts for rapid osseous tissue formation. Cow's milk, therefore, contains more alkaline sub-

Graph 1

Ordinate indicates pH and viable bacterial count of aspirated, fasting gastric contents. The continuous heavy line represents the number of viable bacteria per c.c. of gastric sample. The crossed barred column represents the pH of the gastric samples. Abscissa indicates time. The arrow indicates the time when 100 c.c. of a 1% HCl in warm water were introduced in the stomachs through the tube. Two tests are shown on following days in the graph. Gastric contents remained acid for two hours and one hour and forty-five minutes after introduction of dilute acid. Note correlation between pH and viable gastric bacterial flora.

Table V the essential data on milk consumption from Table II from Sundstroem's work (5).

The per capita consumption of milk in Finland is, according to the above-mentioned reports, close to 1000 grams per day, divided as follows: 97.5 grams as whole milk (10%), 568 grams as skimmed milk (58.2%) and 309 grams soured milk (31.7%) making a total of 974.5 grams per capita milk ingestion. It should be noted that only ten per cent of this is fresh whole cow's milk. Almost one-third is acidified or soured milk, the remaining is defatted or skimmed milk.

stances than does human milk. Many of the feeding formulas for infants are based upon a reduction of the alkaline content of cow's milk (Arnold (6) and (7)).

It is general knowledge that adults in this country do not drink so much milk as children; this is particularly true for the older adult group. The reason may be physiological and due to changes in gastro-intestinal function with age. Friedenwald and Morrison (8); Friedenwald and Brown (9); Poeschel (10); Keefer and Bloomfield (11); Davies and James (12); Bloomfield and Kiefer (13); Pollard and Bloomfield

(14); Pierce and Bogan (15); Van Zant, Alvarez, Eusterman, Dunn and Berkson (16), and Hartfall (17) are a few of the workers who have recorded a decreasing gastric acid secretory function with advancing age. These investigators do not agree on the reasons underlying this diminished response of the gastric mucosa to physiological stimuli. Arnold (18) called attention to the influence of this hypoacidity of

be living in large numbers in the stomach, duodenum and upper jejunum, (Arnold (1)).

Arnold and Hood (19) reported observations upon the relationship of gastric acidity and viable bacteria within the human stomach. Physicians have known for many years that oral administration of acid was advantageous in aiding the correction of certain abnormal symptoms in patients with hypoacidity. The

advancing age on the intestinal flora and the retrogressive diseases so common in this age group.

Those folk in northern, eastern and southern Europe who ingest milk in relatively large quantities do not use much whole fresh milk, but soured milk, skimmed milk and various kinds of cheeses. The physician interested in nutrition should recognize the changing pattern of gastro-intestinal secretory function with age and adjust the diet to meet the needs of such age groups.

Most gastroenterologists think of hypoacidity in terms of various abnormal physiological manifestations, due probably to interference with proper diges-

amount of acid was too small to explain the benefits enjoyed by the patient upon orthodox physiological knowledge of digestion. Arnold and Hood (19) offered an explanation for the clinical results experienced by physicians after administering dilute acid to these cases. Graphs 1 and 2 show the relationship of gastric acidity and the number of bacteria growing from one cubic centimeter of gastric contents. The administration of dilute acid by mouth gives the patient a variable time (one to three hours) of a normal gastric and duodenal bacterial flora. A person in the older age-group with a gradually decreasing gastric acid secretory power has an associated change in the bac-

tion. These patients do not usually show evidence of malnutrition; many times they are well nourished or overweight. When the gastric contents are completely saturated with acid and an excess of free acid, over and above the amount needed for buffering both chemically and physically the ingested food, there are very few viable bacteria in the stomach, duodenum and upper part of the jejunum. If this does not take place, that is, the concentration of acid is not enough to completely saturate the gastric contents, then oral and ingested food bacterial flora, as well as coli-aerogenes strains from the lower intestinal levels can be found to

terial flora of his stomach, duodenum and upper jejunum. When the gastric mucosal glands secrete acid in a normal manner, that is, the hydrogen-ion is concentrated within the gastric lumen so that all the contents are acid-buffered and free acid as such exists, then the bacterial flora of the stomach, duodenum and upper jejunum is normal. Hypoacidity brings about systemic changes more by a loss of control of the bacterial flora than by an interference with hydrolysis of ingested food. It would seem that acid-buffered foods would be physiological in these cases.

Soper (20) suggests sterile milk to be fed in the

place of raw and pasteurized milk. If sterile milk is ingested it will not be sterile when it passes through the oral cavity. It will contain many more bacteria than originally present in pasteurized milk before it reaches the stomach. Arnold and Stuart (21) have

TABLE IV

*The Proportion of the Amount of Milk to the Total Diet*

| Adult men             | 0.94 : 1 |

shown the dorsum of the tongue to have a rich endogenous bacterial flora. Next to the colon this area on the top of the tongue supports the most densely populated bacterial population we have encountered in our studies. The stomach is being constantly seeded with a variety of bacteria carried down with saliva, as well as in fluids and food. The bacteria Soper mentions in pasteurized milk are nothing to become excited about. No bacterial counts are recorded, the strains mentioned were not identified bacteriologically. He produces no evidence whatever to show the bacteria are of human origin. Pasteurized milk is safe and wholesome. Practically all the food we ingest contains bacteria. These bacteria are not superimposed upon our intestinal flora, but are killed before they become adapted to intra-intestinal conditions of life. The by-products of bacteria growing in food are the real health factors. The development of irritating chemical substances in food such as milk, by bacterial growth, is one of the reasons for low bacterial counts. The application of our tried and experienced knowledge of sanitary science plus refrigeration make pasteurized milk safe.

The fate of ingested bacteria as brought out by Hanszen (22) is of greater significance than the elimination of saprophytic air and bovine strains from food. This worker has shown, subsequent to the above mentioned publication, that when viable bacteria leave the stomach they can be found in the upper part of the large intestine several hours later. The fat content of whole milk (3.5% butter fat), the buffer value (requiring approximately equal volumes of normal gastric juice, pH. 2.0, to cause the appearance of free acid) both influence the rapidity of gastric acidification and hence allow viable bacteria to pass into the lower levels of the intestinal tract.

The most important question for gastroenterologists is not the technical and detailed problems of milk hygiene, but the directed public health movement to increase milk consumption in adults. It is taken for

granted that one quart of milk per day for the growing child is advantageous. There is some question whether a quart of fresh, whole fluid cow's milk per day for adults is advantageous. The writer knows of no population or country where this has ever been done. No experience can be cited to show this amount of whole milk ever has been consumed by a given adult population for any period of time.

The mineral elements in food required for proper nutrition make milk an outstanding product. These salts are present in all milk products except the butter-fat. Skimmed milk, soured milk and various cheeses contain the inorganic elements of whole milk, as well as do dried and condensed milk products.

Gulbrandsen and Arnold (23) are studying the *gastric response to milk and certain milk products*. The following data can be quoted here from our protocols. Two hundred cubic centimeters of whole milk (3.5% butter-fat) leave the stomach of healthy young men (18-22 years of age) in three hours and twenty-five minutes. The same amount of skimmed milk, top cream removed, (containing approximately 1% butter-fat) leaves the stomach three hours after ingestion. The aspirated samples show that after fifteen minutes the hydrogen-ion concentration had dropped from 7.2 to 4.3 after whole milk and to 1.8 after skimmed milk was ingested. The above data were obtained from eight subjects, six experiments on each subject, making an average of forty-eight experiments. The milk above was ingested into a fasting stomach. These experiments are not original in any way. The inhibitory action of fats on gastric acid secretion and the influence of fats upon the emptying-time of the stomach are well known to physiologists and gastroenterologists. The buffer values of whole and skimmed milk in *in vitro* experiments do not differ beyond the range of experimental error. This would be expected because

TABLE V

*Average Daily Consumption of Milk by the Finnish People. (Sundstroem)*

| Age Group   | Total Grams | Whole Milk |         | Skimmed Milk |         | Sour Milk |         |

of the chemical composition and reactions of the fat. The difference between the *in vivo* and *in vitro* hydrogen-ion concentration observations are due to the inhibiting action of fat on gastric acid secretion. These factors are only mentioned to indicate the complexity

of any problem involving a public health program in nutrition.

The *butter-fat content of milk* has been used for so long as the criterion of undiluted fresh whole milk that almost everyone uses the visible cream-line as an index as to the quality of the product. The butter-fat content can be determined easily and accurately, hence

vitamin B and G remain in the milk after removal of the fat. Vitamin A is widely distributed in nature, such as the fat of animal tissues as well as the liver and many leafy and tuberous vegetables. The biological significance of butter-fat resides in its vitamin A content; other than this factor it is a fuel food and can be replaced by any carbohydrate or fat.

Graph 2

Ordinate indicates pH and viable bacterial count of aspirated, fasting, gastric contents. The continuous heavy line represents the number of viable bacteria per c.c. of gastric sample. The crossed-barred column represents the pH of the gastric samples. Abscissa indicates time. The arrow indicates the time when 100 c.c. of a 1% HCl in warm water was introduced in the stomachs through the tube. Two tests are shown on following days in the graph. Gastric contents only remained acid for one and one-half hours and again for one hour and fifteen minutes after introduction of dilute acid into stomach. Note the close correlation between gastric bacterial flora and hydrogen-ion concentration.

public health regulatory boards have accentuated the popular idea of the importance of the cream content of milk. The basic reason is to prevent dilution with water, but the dairy industry has become so well organized that this safeguard against the addition of water is not so important. The bacterial count or the hygienic quality is more important now than is the fat content. The consumer, as well as the public health official and physicians, all regard the butter-fat content of major importance in fresh whole milk.

Butter-fat contains the fat soluble vitamin A;

The gastro-enterologist has a responsibility in the whole problem of the food habits of the general population. He best can correlate the theoretical, scientific and practical aspects of human-nutrition. The nutritive value of defatted milk has received little attention in this country. Present economic conditions warrant giving careful thought to the diet. The per capita per day milk consumption is a subject not yet settled and one that should receive the attention of gastro-enterologists.

## ABSTRACTS

DR. GRAUMANN.

*The After Treatment of Ulcer Patients Following Resection of the Stomach.* *Munch. Med. Wochen.*, 82, No. 4, Jan., 1935.

Many patients display identical complaints following resections of the stomach as they had before operation. Evidently this is mostly due to the persistency of gastritis preceding the operative procedures.

Ulcer complaints are due partly often to an accompanying gastritis and as such can not be obviated suddenly by operative measures. In fact such pathology becomes more accentuated in view of the mechanical handling of the stomach wall itself. An increase of hyperacidity in such cases is also the consequence of increased irritation of the mucosa.

The feeling of fullness owes its presence to a decreased capacity of the stomach. Post-operative vomiting is often the consequence of mechanic disturbances although incarceration of loops of the mesocolon must also be thought of. Occasionally a self torsion of the afferent loop or a strangulation is to be looked for. A submucosal swelling with a tendency to reduce capacity of the loops involved in the anastomosis may also be responsible for regurgitation of food.

Therapeutically the administration of "Gastro-Sil" seems to help greatly. The drug is a calcium silicat jel which forming a jelly-like mass protects the mucosa from undue irritation. The neutralization of the acids lasts longer and there are no astringent irritations encountered with this drug as seen with other alkalies. It seems that the calcium content embodied in this drug also reacts favorably in that it reduces inflammatory tendencies in the tissues having a haemostyptic action also. A decrease of chlorides is greatly diminished with this drug, another reason why it can be given without the fear of producing uremic symptoms.

M. E. Gabor, Milwaukee.

FOGELSON, SAMUEL J.

*Gastric Mucin Treatment of Peptic Ulcer; a Report Based on Questionnaires.* *Arch. Int. Med.*, Vol. 55, No. 1, pp. 7-16, January, 1935.

For five or six years past Fogelson has been trying to determine the efficacy of gastric mucin in the treatment of

gastro-duodenal ulceration; and this paper reports the results in approximately 555 cases observed during the past three years. These patients were followed not only by Fogelson himself but also by a Gastric Mucin Committee appointed by the Northwestern University Medical School of Chicago and by all other physicians sufficiently interested to co-operate by reporting, on a questionnaire furnished them, the data at outset and during the progress of treatment.

Detailed statements were given by these different men, to whom mucin was supplied for use in treatment, after the material had been accepted by the Committee as suitable and proper in every respect. These statements covered the history of the case, the X-ray findings, recurrences, incidence of hemorrhage and the effects of former treatment, including surgical procedures; as well as the progress of the case and the effects of treatment by mucin. The average dose was 80 to 100 grams of dry mucin powder, suspended in a mixture of milk and cream, at frequent regular intervals, as often as every hour in acute cases. The diet was limited to the bland substances usually prescribed in ulcer. The treatment was continued for at least six months, the dosage, however, being reduced during the late stages.

The results were highly satisfactory, considering the fact that only cases were selected for treatment that were previously considered intractable, because they failed to respond to ordinary methods. Of 555 who took mucin from six months to three years, 348 were rendered free from symptoms, 114 were partially improved and 93 failed to secure relief. Of the latter, however, only 32 were counted true failures, because the other 61 for various reasons would not continue the use of mucin for an adequate period. Recurrence of symptoms while still receiving mucin was noted in six persons, acute massive hemorrhage in four and perforation in one. In 56 patients with a recurrence of symptoms after gastro-enterostomy, suggesting a new ulcer at the gastro-enterostomy stoma, complete control of all the subjective symptoms was obtained by the use of mucin in 36, partial relief in 16 and no relief in 4.

The one important question not yet answered is the permanence of the results obtained; and this can not be answered until more time has elapsed.

Wm. Fitch Chaney, San Francisco.

## SECTION V—*Therapeutics*

### The Treatment of Food Allergy and Indigestion of Pancreatic Origin with Pancreatic Enzymes

By

ANTON W. OELGOETZ, M.D.

PAUL A. OELGOETZ, B. A. (Chem)

and

JUANITA WITTEKIND, R.N.

COLUMBUS, OHIO

**I**N a previous communication (1) we reported the results of an investigation concerning the rôle of the pancreatic enzymes in the etiology of food allergy and indigestion of pancreatic origin. The present paper will concern itself with the use of the pancreatic enzymes in the treatment of these conditions.

It was indicated in our previous studies that, contrary to present teaching, the stomach and duodenum are not the essential organs of digestion. Food is not completely digested in the stomach and the duodenum. The function of the stomach is to act as a receiving and mixing hopper, where, under the influence of acid-pepsin the food mass is reduced to a homogeneous, semi-liquid state.

Probably a small amount of absorption takes place directly from the stomach, but most of the stomach contents pass into the duodenum where they combine with the pancreatic enzymes.

The function of the duodenum and jejunum is absorption of the food mass combined with pancreatic enzymes, and of free pancreatic enzymes. During the process of absorption in the duodenum some of the food is split to the various derived proteins and amino-acids, but the bulk of the duodenal contents, changed in varying degrees all the way from alkali-metaproteins to amino-acids, but principally as alkali-metaproteins, pass into the blood stream. Hydrolysis or digestion in the duodenum may be incidental, much of the essential process of digestion taking place in the blood stream.

We have pointed out that, in order to exhibit optimal enzyme activity, enzymes must function under certain standard conditions. The concentration of enzymes must be constant; the concentration must bear a definite relationship to the quantity of substrate (food); the pH of the medium must be approximately 7.6; the temperature must be 98.6. None of these necessary conditions always is present in the stomach or duodenum.

In the blood stream however, normally conditions are perfect for optimal enzyme activity. Here the pH is always 7.6; the temperature always 98.6; the concentration of enzymes always constant, namely 0.2 as

determined by the test suggested by us; and the substrate (serum proteins and fats) always constant, except for short periods immediately following meals. Here we have conditions entirely perfect for optimal enzyme action, with none of the disturbing factors, such as intake of water (which dilutes the enzymes and substrate), the taking of irritating drugs and other substances, which inhibit the action of enzymes.

We have shown that normal serum always contains the three pancreatic enzymes, amyllopsin, protease and lipase, and that these enzymes would seem always to be present in a definite and constant concentration which is uninfluenced by intake of food, exercise or sleep. In short, the blood which is continually "digesting itself" is an essential organ of digestion.

Because the main degree of final digestion does not take place in the stomach and duodenum (except incidentally) we believe that it is irrational to test for and attempt diagnostic appraisal as to capacity of these enzymes in the secretions of the duodenum. The pancreatic enzymes pass into the duodenum, where, when food is present, they combine with the food and thence pass into the blood stream. If no food is present, we believe that we have shown that the free enzymes pass into the blood stream where they circulate, (as free enzymes) acting as buffers, combining with and splitting any food derivatives which have gained entrance to the blood stream uncombined with enzymes.

Thus, in our opinion, based upon extensive studies, the duodenal secretions at any given time contain but a small fraction of the total daily pancreatic secretion, (external secretion). The duodenum at any given time contains only those enzymes which are in process of being absorbed, which are "en route" through the duodenum, on their way to the blood stream. Testing the duodenal secretions for enzyme concentration therefore is at best but a rough qualitative test. The question is not whether or not enzymes are present, but in what concentration. The only place in which the actual concentration of enzymes can be determined is in the blood stream. It is in the blood stream where the enzymes find their field for action, where, in health,

they are always found in a definite, constant concentration.

The serum enzymes can be qualitatively determined by the usual tests, but this requires that three tests be made; necessitates too large a quantity of serum; and is too time-consuming and too technical to be used in daily practice. Consequently, we have devised a more practical test which can be more quickly and easily done. The test is based upon the fact first noted by us, that serum assumes an increasing iodine value as digestion advances. Our test, described in detail elsewhere, gives a moving picture, a cross section of the continuing hydrolysis as it takes place in the blood stream.

As has been noted, the serum enzymes are always present in the serum in a definite and constant concentration. Likewise, if the tissues and organs of rabbits are ground with quartz sand and extracted with distilled water, it will be found that every tissue and organ in the body, with the exception of the heart and brain, contains the serum enzymes in a concentration exactly 100 times that of serum. It therefore appears that the cells of the body live in a solution of enzymes, making it impossible for any substance to reach the cells without first having run the enzyme gauntlet, which splits the substance to a harmonious form which can be used as food by the individual cells.

On the other hand, if, as a result of pancreatic hypofunction, the concentration of serum enzymes falls below normal, so there are not sufficient enzymes to split all of the food taken, whole, unracemized proteins reach the cells and exert their own physiological action which is essentially that of "irritation," using the word in a broad sense. In our opinion, it is this irritation caused by whole, unsplit, "disharmonious" proteins which causes the symptom-complex which has been called "food allergy." When truly foreign substances such as bacteria or bacterial products which cannot be split by the serum enzymes, gain entrance to the blood and thence to the cells, there follows the other type of allergy which results in the formation of specific anti-substances or antibodies.

If the serum from a patient is found by our test to show an iodine index of 0.2, that patient exhibits the enzymes in normal concentration, indicating that the pancreas is secreting its enzymes (the external secretion) in normal quantity. Such individual will not suffer from allergy because sufficient enzymes are present to completely split and reduce to a "non-irritative" form all of the food which is taken.

If however, the patient shows an iodine index of minus 4, for example, the serum enzymes are not present in normal concentration, evidently because the pancreas is not secreting its normal, daily complement of enzymes. In such instance, the blood stream contains varying quantities of whole, unracemized proteins which exert their irritative action on the cells and thus produce the allergic state.

Thus it will be seen that according to our conception, allergy to foods is caused by an excess of food—not an excess from the viewpoint of bodily requirements (indeed, many of these patients are underweight) but an excess with reference to the ability of the pancreas to secrete the necessary quantity of enzymes for complete digestion. In short, the food intake exceeds the pancreatic threshold. This excess may be in the form of one particular food, beef, for example, but more often it is the combined excessive

intake of *all* foods which causes the anomaly. This is the reason why one observes such contradictory results from the skin scratch tests; why an allergic patient will react positively to beef at one sitting and a week later, though still allergic, will react negatively to beef, and positively to some other food which was negative in the first instance. It is the *excessive total food intake* which surpasses the pancreatic threshold, which is the cause of food allergy.

Thus, if the iodine number of serum gives a minus index, the patient is allergic, is taking too much food, more food than can be split by the available enzymes. However, in many instances this pancreatic hypofunction is merely latent, that is, the pancreas secretes sufficient enzymes for all of the usual food requirements, and a shortage only occurs from an occasional excessive food intake. For example, consider a certain patient, a sales' manager. Ordinarily, when on his regular ration, this man is free from digestive or allergic disturbances. But once each month he is required to preside at a sales' meeting, which is always concluded with a big dinner. At such times he overeats (and drinks) and temporarily, in our conception, exceeds his pancreatic threshold. The next day invariably he turns up with a marked case of angio-neurotic oedema. Our interpretation is that his pancreas is equal to all normal food-intake demands when on customary rations but proves quantitatively inefficient when his food intake temporarily becomes excessive.

When this type of case is tested during an attack, he will show a minus index. But if he is tested in the interim between attacks, when on his regular ration, he will show a normal index. In order to uncover this type of case, usually seen after the attack when the serum again is normal, we have devised an *overfeeding test*. The serum is tested the first day in order to determine the normal index. The patient is then directed to overeat—take an excessive quantity of food. We make no effort to have him take a definitely increased caloric ration, but simply direct him to double his customary ration. If he is in the habit of eating one egg for breakfast, we have him take two; if he usually eats but one helping of meat, we direct him to double the portion. In this manner we have him take a definitely increased quantity of all food substances.

He returns the next day when his serum again is tested. If the pancreatic index is normal, shows the normal concentration of serum enzymes, we conclude that his pancreas is exhibiting a normal threshold and is able to digest a normal quantity of food. Such patient will never suffer from indigestion (secondary to pancreatic hypofunction) or food allergy. However, if on the second day, the serum enzymes are found in a definitely reduced concentration, it indicates that the pancreas was unequal to the extra demand; in short, the patient suffers from latent pancreatic hypofunction. It is these latent cases of hypofunction which would seem frequently to account for acute allergic states, such as urticaria, angio-neurotic oedema, etc., which only result occasionally, usually following dietary indiscretions.

The word "indigestion" has been used in this paper. This word generally is rather loosely used and usually indicates any disturbance of digestion which might result from a host of factors which interfere with the digestive processes. For instance, indigestion frequently accompanies gall bladder disease, ulcer of the

stomach, etc. But the indigestion referred to in this paper is that form which results from a shortage in the serum concentration of enzymes or pancreatic hypofunction. In many cases a latent hypofunction is of mild degree, not sufficient to give an allergic response. Such patients simply complain of "indigestion" which however, is a true indigestion resulting from a shortage of pancreatic enzymes. In cases suffering from a greater degree of pancreatic hypofunction, many of the symptoms complained of as "indigestion" are true allergic manifestations which promptly clear up when the underlying pancreatic hypofunction is corrected.

Hypofunction of the pancreas results from many causes. Thus we find hypofunction secondary to gall bladder disease, with secondary infection of the biliary and pancreatic ducts; following such general infections as syphilis; accompanying congestive states, such as a defective myocardium. In many instances, however, the hypofunction is primary.

Frequently, in borderline cases the pancreas is equal to everyday demands and only shows evidence of hypofunction when under unusual stress, as after a food debauch. It follows therefore that each case should be given a thorough physical examination so as to uncover and correct any other associated trouble, in addition to correcting the pancreatic hypofunction. In many cases, hypofunction and the resulting allergic state is the cause for the continuance of a primary trouble. For example, only recently we saw a woman who was suffering from oedema of the ankles, secondary to a defective myocardium. She also experienced a distressing asthma, in our opinion of pancreatic origin. Because the asthma threw an additional burden on the crippled heart, it increased her cardiac difficulty. When the causative pancreatic hypofunction had been corrected her heart carried on very decently.

### TREATMENT

In cases of *acute allergy following occasional excessive food intake*, the only treatment necessary is temporarily to reduce the total food intake, and perhaps give a saline purge to remove the excess unsplit food from the bowel. In the course of a day or two the pancreas "catches up" and the trouble subsides. In chronic cases, however, in which the serum enzymes can be shown objectively to be continually below normal, and in which correction of any primary trouble does not restore the pancreas to normal function, it becomes necessary to help the overworked pancreas by the exhibition of pancreatic substance—i.e. "substitution therapy" as is to commonly exhibited when the thyroid gland proves unequal to physiologic demands. When given in the usual doses, pancreatic substance has not been found effective in restoring the serum concentration of serum enzymes. This is due in part to the fact that much of the pancreatic substance on the market is physiologically inert. In the test tube, when set up under conditions making for optimal activity, the quantity of pancreatic substance usually given is sufficient to digest all of the food usually taken. The reason why pancreatic substance when given by mouth is not so effective as in the test tube is because a large part of the dose taken is destroyed by the pepsin in the stomach, and only a fraction of the dose reaches the duodenum in an active state. It has been believed that because pancreatic substance is a protein substance, it is digested by the pepsin. This

however, is not correct, because when added to pepsin, pancreatic substance, so far as its physiologic action is concerned, *instantly* is destroyed before it could possibly be digested. It has been believed that the acid of the stomach destroys the action of pancreatic substance. This view likewise is incorrect. Many times we have permitted pancreatic substance to remain in solutions of hydrochloric acid for many hours without destroying it. It is true that pancreatic substance does not exhibit its optimal activity in an acid medium, but acids do not completely stop its action; nor do they destroy the enzyme; they do however, slow up its action. When the necessary conditions of alkalinity for optimal activity are restored, pancreatic substance again becomes normally effective. What then is the answer? The following experiment will make clear the problem.

Place a quantity of egg albumin in a "U" tube and congregate. Now fill both arms of the tube with pepsin solution. Connect the arms of the tube with an electrical current. It will be found that in the positive arm the pepsin digests the albumin, the pepsin passing deeper and deeper into the albumin. However, in the negative arm it will be found that digestion does not take place. It will also be noted that the pepsin travels toward the negative pole. This indicates that pepsin in colloidal dispersion carries a positive electrical charge. If pancreatic substance is substituted for the pepsin in the same experiment it will travel toward the positive pole, indicating that pancreatic substance in colloidal dispersion carries a negative electrical charge. If a solution of pancreatic substance is added to a solution of pepsin, the positively charged pepsin particles are electrically discharged by the negatively charged pancreatic particles, and therefore, both solutions are inert, that is, have lost their enzymic activity. Thus the reason why pancreatic substance is partially destroyed in the stomach is because the electrically positive pepsin discharges the electrically negative pancreatic substance. But in order to be completely discharged and rendered inactive, the pancreatic particles must meet an equal number of pepsin particles, just as a given quantity of tenth-normal sodium hydroxide requires an equal quantity of tenth-normal hydrochloric acid for complete neutralization.

Just as a weaker solution of hydrochloric acid will not completely neutralize an equal quantity of tenth-normal sodium hydroxide, so an excess of pancreatic substance will not be completely destroyed by pepsin. The following experiment will make this point clear.

Set up a series of tubes, each containing  $\frac{1}{2}$  c.c. of a colloidal solution of pancreatic substance. To the same tubes add respectively, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6 c.c. of a colloidal solution of pepsin. Shake and incubate. Meanwhile, set up another series of tubes, each tube containing 2 c.c. of soluble starch solution. Now, to the starch tubes add  $\frac{1}{2}$  c.c. of the successive pepsin-pancreatic substance mixtures. Thus we have a series of tubes, each tube containing 2 c.c. of soluble starch solution, plus  $\frac{1}{2}$  c.c. of pepsin-pancreatic solution, the quantity of pepsin varying in each tube.

When the tubes have incubated for several hours, they are titrated with Fehling's solution to determine the quantity of sugar. It will be found that the quantity of sugar is greatest in that tube containing the smallest quantity of pepsin, and least in that tube containing the largest quantity of pepsin, thus indicating that a given quantity and strength solution of pepsin is only completely discharged by the same quantity and strength solution of pancreatic substance; and that if there is an excess of pancreatic substance, the excess remains undischarged. Consequently, it follows that

if sufficient pancreatic substance is given by mouth—sufficient to discharge the pepsin present in the stomach plus an excess—the excess passes uninjured and active into the duodenum.

Clinically, we have found this to be the case. If pancreatic substance is given in large enough dosage—from 75 to 90 grains daily—sufficient will reach the duodenum in an active state to effect the serum level of enzymes. However, practically, this is a very wasteful and unscientific manner in which to give pancreatic substance, as only a small part of the dose given reaches the blood in an active state. Then, too, most patients bitterly complain when required to take such large doses, as pancreatin is an exceedingly nauseating substance which often produces gastric irritation. When taken in the dry form, whether in the form of the powder suspended in water, the pill or capsule, the dry substance must first be put into solution before it can be absorbed. This requires time and it is during this time that it comes under the prolonged action of pepsin. When given in capsules the material is more pleasant to take; however, the regular gelatine capsules dissolve at once in the stomach, thus liberating the pancreatic substance which is discharged by the pepsin as it passes into solution. There is no essential difference between taking pancreatic substance in the form of the powder suspended in water, or taking it in the regular gelatine capsule.

Gelatine capsules can be hardened by exposing them to formaldehyde gas (glutol capsules). However, the time required for a capsule to pass through the stomach varies so greatly in different individuals that it is impossible to harden a capsule to the "just right" degree which will carry the material through the stomach in every instance, and then promptly break up in the upper bowel. It has been our experience that capsules either are hardened too little, in which case they break up in the stomach, or they are hardened too much, when they pass intact through the entire gastro-intestinal tract. After many attempts we have found it impossible to process a capsule to the correct degree of hardness so that it will always break up in the upper bowel.

Enteric coated pills likewise have been found unsatisfactory. It is impossible to apply an enteric coating which will protect the pill contents against the stomach secretions for varying periods—from 15 minutes to 4 hours—and then promptly break up in the upper bowel. We have many times recovered enteric coated pills from the feces. Because pills are pressed tightly in the process of manufacture, they break up very slowly, many only partially or not at all. We have recovered pills from the feces even when the enteric coating had first been removed. Another disadvantage is that the pressure used in making the pill seems to have an inactivating effect upon the enzymes.

Clinically, we have found that the pancreatic enzymes are best given in the form of a 50 per cent glycerin extract of the whole pancreas. The enzymes are soluble in glycerin and Haidenhain has found that a glycerin extract will remain active for 20 years (3). Because the pancreatic enzymes find their field of action in the blood stream and not in the bowel, it is not necessary that they pass into the duodenum. When

administered in glycerin, all three pancreatic enzymes (because they are already in solution in glycerin, which is itself a product of digestion and is therefore not attacked by the gastric juice) are immediately absorbed into the blood stream. After many trials with all other forms, we are convinced that a 50 per cent glycerin extract of the whole, fresh pancreas is therapeutically the most efficient, and scientifically the *only exact* form in which to administer the pancreatic enzymes. A quantity of glycerin extract equal to 5 grains of an active dry powder, after each meal, preferably given in a gelatine globule, has been found to be clinically effective in cases exhibiting the highest degree of hypofunction (minus 4). That pancreatic substance is effective, even when given by pill, is evidenced by the report of Sansum who contacted 280 patients who came under the classification of "indigestion" (of pancreatic origin) underweight and allergy (2). The cases of allergy comprised urticaria, eczema, angio-neuritic oedema, allergic indigestion, allergic rhinitis, allergic migraine, joint allergy, hay fever, and bronchial asthma. Under treatment with pancreatic substance 129 of 152 instances of allergy or 85% improved; 23 or 15% did not improve; and 9 did not follow the plan outlined. Of the 143 who followed the plan 129 or 90% improved, while 14 or 10% did not improve.

In our own series of 100 cases we encountered approximately similar results. The problem of truly interpreting the results of treatment is made difficult by the fact that many cases of allergy are complicated by the presence of secondary diseases. Asthma, for example, is very often accompanied by chronic bronchitis and varying degrees of emphysema; and these complicating anomalies must be taken into consideration in any evaluation of results of treatment. It is our distinct impression that results are always excellent if too much permanent damage has not already taken place when treatment is commenced.

The serum level of enzymes cannot be made to go above a concentration of 0.2 by the test which we have suggested. When given in excessive dosage, pancreatic substance is completely absorbed and stored in the active state, principally in the spleen, from which it is gradually liberated in such concentration as to maintain the normal serum level. Even when 200 grains are taken at one time, the substance is completely absorbed, none of it appearing in the urine and feces. The absorption and fate of pancreatic substance when taken by mouth will be fully discussed in a later paper. Apparently, the enzymes are not toxic when given in large doses; nor do they injure the kidneys, as we have never encountered a case in which the urine showed signs of irritation.

### CONCLUSIONS

1. "Indigestion," secondary to pancreatic hypofunction is a fairly common cause of digestive disturbances.

2. Food allergy may be caused by a decrease in the concentration of serum enzymes, which permits whole, unracemized proteins to reach the body cells, where, because they cannot be used as food, they exert their own physiological action which is essentially that of irritation.

3. The administration of pancreatic substance in the form of a glycerin extract of the whole gland by

mouth, is therapeutically justified and clinically effective.

4. Patients who are allergic to foodstuffs and in whom too much permanent damage has not resulted when treatment is commenced, usually improve promptly when given an active glycerin extract of pancreatic substance.

5. Allergy to foodstuffs can be diagnosed and treatment controlled by a simple test which we have described elsewhere.

This work was encouraged by a grant from Fairchild Bros. and Foster of New York, who also made available for clinical use generous quantities of Holadin, a highly active extract of whole pancreas.

## Histidine in the Treatment of Peptic Ulcer: a Preliminary Report\*

By

JOHN T. EADS, M.D.  
PHILADELPHIA, PENNSYLVANIA

THE injection treatment of peptic ulcer has been popular for several years, perhaps in an effort to find some shortcut to a permanent cure thereby avoiding the drawn out dietary and alkaline regime so often the despair of the patient and physician alike. While both orthodox medical and surgical treatment at times fail to achieve the desired result, the final analysis of cures effected compares favorably thus far with the newer modes of therapy.

A number of methods of the injection treatment have been used. To mention a few, C. R. Jones has used insulin. Glaessner uses injections of pepsin. Cunba reports favorable results with "synodal." Van Kleeck and others have used sodium citrate and sodium chloride intravenously. Favorable results have been reported by practically all of the various methods in use today. Only a few, however, have had sufficiently long periods of observation for any accurate estimation of their real value.

Quite a few foreign authors have used preparations of amino acids in the treatment of peptic ulcers. Most of this work has followed the experimentation of A. G. Weiss and E. Aron of Strassburg. These authors repeated the experiments of F. C. Mann and produced jejunal ulcers in dogs by shunting the gastric contents directly from the stomach into the jejunum. They, as did Mann and others, found that exposure of these experimentally produced ulcers to normal duodenal contents resulted in their rather prompt healing. When the duodenal contents were withdrawn and gastric juice again permitted to course over the area the ulcers were re-activated. Weiss and Aron experimented with various amino acid preparations and found that certain of these were effective in healing these experimentally produced ulcers. They concluded that a preparation of histidine was the most effective in this respect.

Histidine is an amino acid produced by protein digestion and is supposedly essential for cell life. The actual mechanism of the action of this amino acid in the healing of these ulcers is by no means clear. There

may be some explanation in its essential rôle as a factor necessary to cell integrity and repair. It also may be a factor in causing a secretion rich in the protective and acid combining mucin.

Most of the clinical use of this treatment of peptic ulcers has been reported by foreign investigators. Weiss and Aron, Blum, J. Lenormand, George Hessel, L. Bogendorfer and Ernest Bulmer have all reported its use in small series of peptic ulcers in humans. The reports are for the most part concerned with immediate results, the follow-up on many of the cases being insufficient.

However, for the most part these authors report favorably on this method of treatment. It appears that immediate clinical improvement resulted in the majority of their cases with X-ray changes indicating healing and in many instances complete disappearance of the characteristic ulcer deformity. Reduction in the gastric acidity was also reported by some and in no instance were any unfavorable reactions noted. Gastric ulcers responded better than duodenal as a rule.

In this country, at present, there have been very few reports on the usage of this form of treatment. Vilini and McLaughlin report favorably on its use both as to clinical results and in the reduction of the acidity of the gastric secretion.

The method of treatment was practically the same with each author—a 4% solution of histidine hydrochloride was used. It was given in daily injections of 5 c.c. either subcutaneously or intramuscularly, the intramuscular route being preferred. From the experimental evidence the best results were obtained when the average course of treatment extended over a 21 to 24 day period. Bulmer and Bogendorfer report the largest series of cases treated, the intramuscular route being used and a daily dosage of 5 c.c. of the histidine solution given for periods of approximately 24 days. No unfavorable complications were observed. Good results were reported. Bulmer reported 58% symptomatic cures with disappearance of abnormal X-ray findings, 19% clinical improvements with no radiological changes and 23% failures in his series of 52 cases. A large number of these were gastric ulcers.

\*From the Medical Department, Jefferson Hospital, Philadelphia. The preparation of Histidine solution used in this series of treatments is Larostidin supplied by Hoffmann-LaRoche, Inc., Nutley, N. J. Submitted August 1, 1935.

Case 1. A typical ulcer history for one year. The film at the left shows a gastric ulcer of the lesser curvature. The one at the right shows its disappearance after 24 injections of histidine. Relief obtained after the sixth injection—no diet or medication. No recurrence after six months.

### METHOD OF STUDY

Since October, 1934, we have treated 35 cases of peptic ulcer with histidine injections. Practically all cases have received a minimum dosage of 24 daily intramuscular injections of a 4% solution of histidine hydrochloride. Several cases have received as many as 36 injections. Only those cases definitely diagnosed peptic ulcer both clinically and from an X-ray point of view were selected. For purposes of record a careful history in each case was taken. The patient's weight, complete blood count, gastric analysis, pulse, blood pressure and roentgen findings were recorded before treatment was instituted. In addition, each patient was given an intradermal test, using 1/20 c.c. of the histidine solution, before the proposed course of injections were started. At various times during the treatment the gastric acidity curve was determined. No special diet or medication was followed except in some instances, where hospitalized, patients were given occasional doses of alkalis or told to omit such articles from their diets known to cause them trouble. None of the patients was confined to bed and the majority was permitted to continue usual occupations.

The number of cases observed during this particular study is not a large one, but it compares favorably with the series reported by other authors. Bulmer reports on 52 cases, Bogendorfer on 30 cases, Hessel on 22 cases, Weiss, Aron and Lenormand on several smaller series, Volini and McLaughlin on a series of 21 patients.

The follow-up of this series of 35 cases consists of a six-month observation period. Naturally, this is too short a period of observation to determine the permanency of results, but for the most part the same can be said of all the other reported series of cases similarly treated.

This report is, then, in the nature of a preliminary one, and the work is to continue with a subsequent report on a larger series of cases as to more or less immediate results together with a reasonable period of follow-up observation.

### DESCRIPTION OF CASES

1. In this series there were 35 cases of peptic ulcer, of which 30 were duodenal and 5 gastric in type, the percentage of gastric ulcers being generally less than in those series of cases reported abroad. There were 32 males and 3 females in this series. The oldest patient was 59 years of age, the youngest 23 and the average age 41 years.

2. The average duration of symptoms for the entire group was  $7\frac{1}{2}$  years, the longest history being 12 years and the shortest 2 months.

3. 24 of these patients had been on some other form of ulcer treatment prior to the histidine treatment. 11 had received no treatment. The results in those patients already treated had been generally unfavorable.

4. 26 of this series of 35 cases presented a gastric hyperacidity prior to the institution of the treatment. 7 gave practically normal acid figures and in 2 cases there were low acid figures.

Case 1

5. There were 8 cases who presented some degree of obstruction with a varying degree of gastric retention.

6. There were 3 ulcers in which some gross hemorrhage had taken place.

7. 2 cases had been subjected to previous operative procedures (gastro-enterostomies), one with a reactivation of the duodenal ulcer, the other diagnosed as a marginal ulcer.

8. Pain or discomfort with or without direct relationship to meals was the most common complaint in each case.

### ANALYSIS OF IMMEDIATE RESULTS

1. There were no noticeable local or systemic reactions.

2. There was no appreciable change in the blood pressure or pulse rate determination after each injection.

3. The intradermal test was positive in 7 cases out of 28 in which it was used. This may be of some significance in that it was positive in those cases showing the best results.

4. The blood counts were generally unaffected by the treatments.

5. 16 patients exhibited a gain in weight during the course of treatment. 13 cases remained fairly stationary and 6 showed a loss in weight. The greatest gain was 21 pounds, the lowest gain 2 pounds and the average gain in the 15 cases was  $5\frac{1}{2}$  pounds. A gain in weight often began early in the treatment.

6. In this series of cases the gastric acid curve remained generally unaffected except in 5 cases. In these 5 cases in which a rather marked hyperacidity was present some reduction was noted, but not to normal figures. A total of 118 gastric analyses were done on this series of cases. An ordinary tea and toast meal was used with the location of the tube always the same and with the test meal always at the same time of day. These findings with regard to lack of acid reduction are at variance with some of those reported by other investigators, notably Volini and McLaughlin.

7. In the majority of cases in which improvement was noted it occurred relatively early in the course of treatment, usually after the fifth injection. The improvement symptomatically consisted in relief of discomfort, a gain in appetite and weight and a tolerance for a more normal dietary.

8. No improvement was noted in the patients presenting signs of an obstructive lesion causing gastric retention, even after a full course of injections were given and in some instances after 36 or more injections.

Case 2. A 10 year history of ulcer, repeatedly studied over that period and so diagnosed. Had been on medical treatment with very little benefit. The films at the top illustrate the deformed duodenal cap before the histidine was given. Those below show the change in appearance after treatment. Symptomatic relief obtained after 5 injections and continued. X-ray evidence of improvement after 10 injections.

Case 3. A two year history of ulcer with hemorrhage at times. From left to right films show an ulcer of the lesser curvature. In the last film the ulcer has practically disappeared after 15 injections of histidine. Patient operated because of hemorrhage. Scar found at site of previous ulcer. No diet or medication. No recurrence after 4 months.

Case 4

9. The X-ray findings were variable. There was a disappearance of radiological evidence of ulcer in 6 cases. In 8 other cases there was definite improvement in the X-ray findings. In the remaining patients there was little or no change noted, even several months after the series was completed. In the accompanying illustration of the X-ray films in 6 cases, the change in the characteristic deformity readily can be recognized. Disappearance of radiological signs was rapid in several cases. The illustrations show the radiological findings before and after the course of treatment.

10. There was distinct improvement both clinically and roentgenologically in both the patients upon whom operations previously had been performed.

#### CLASSIFICATION OF IMMEDIATE RESULTS

6 cases or 17.1% showed clinical and X-ray evidence of immediate healing.

8 cases or 22.8% showed evidence of clinical and X-ray improvement.

9 cases or 25.7% showed evidence of amelioration of their symptoms but no X-ray change.

12 cases or 34.3% were unimproved at the completion of the course of treatment.

These immediate results are not as favorable as other authors have reported. Most of the other investigators have had a larger percentage of gastric ulcers; these appear to respond better than duodenal. The average duration of symptoms in this series is longer than it is in the histories of other cases reported. These factors may to some extent influence the picture.

#### DISCUSSION

Thirty-five cases of peptic ulcer were treated with intramuscular injections of a 4% solution of histidine hydrochloride, averaging a series of 24 injections with no local or systemic reaction.

Six of these cases (17.1%) showed immediate clinical and X-ray evidence of cures. Of these 6 cases, 3 were gastric ulcers and 3 were duodenal. The average history of symptoms in these 6 cases was 2½ years—much less than the average of the entire group. Symptomatic relief of distressing complaints was early—usually after the first three or four injections. The

Case 4. A typical one year history of duodenal ulcer. Film at the left shows the deformity of the duodenum. At the right can be seen the duodenum filled normally after 24 injections of histidine—no diet or medication. Relief of symptoms after 4 injections. No return of symptoms after 6 months.

gain in weight in these cases was the most marked. None of these patients was restricted as to diet or placed on medication. Four of these 6 cases demonstrated a positive intradermal reaction. None of them, after a period of observation of 6 months or more, has shown any recurrence. Five of these cases showed some decline in the acid curve but not to normal figures. All of these cases presented a disappearance of the characteristic deformities seen at X-ray.

Eight cases (22.8%) presented definite clinical and X-ray improvement, not so rapidly as the first group, but still it was definite. There were 6 duodenal ulcers and 2 gastric ulcers in this group. A gain in weight was shown by 6 of these cases, 2 showed no gain. Three presented positive intradermal reactions. Five began to show improvement after the tenth injection, 2 after the fifteenth and the remaining one after the twenty-third injection. Five of these cases were on no dietary restrictions, 3 were advised regarding elimination of tobacco, coffee, alcohol, et cetera and one had alkalies at times, but not regularly. The average history of duration of symptoms in this group was 4½ years.

Nine cases (25.7%) showed some clinical improvement, but no X-ray change at all. The symptomatic improvement was much slower than it was in the other two groups and not until eighteen or more injections had been given was any improvement noted. These were all duodenal ulcers with an average history of six years. There were some dietary restrictions imposed in 3 cases with little or no medication given.

Twelve cases (34.3%) were unimproved after the completion of twenty-four injections. Three of these unimproved cases were given further injections—2 carried to 30 injections and 1 to 36 with no improvement noted. At times experiments were made with a fairly rigid dietary schedule and alkalies were given in 7 cases with no appreciable change in the symptoms. Seven of this group were classified as obstructive lesions of a varying degree and were not improved at all. In 3 of these the symptoms appeared aggravated by the injections and 4 showed a weight loss. Three of the obstructive cases were subsequently operated upon, with one fatality due to pulmonary infarct.

Case 5

Case 5. A three months history of duodenal ulcer. Film at left shows duodenal deformity. The one on the right shows a normal duodenal cap after treatment with histidine. Symptomatic relief obtained after the third injection. A gain of 20 lbs. in weight—no diet or medication. No recurrence after 6 months.

Case 6

It might be mentioned that of these 12 cases showing no immediate improvement, 3 subsequently appeared to show definite improvement a week or so after the completion of injections, after being placed on a strict orthodox medical regime, where before the injections, such a treatment had been of no value. This suggests the possibility of some delayed benefit. The duration of symptoms in this group was the longest. These were for the most part those ulcers the most resistant to the forms of treatment and complicated by some obstructive phenomena in 7 cases.

#### SUMMARY

1. Peptic ulcers, non-obstructive in type with comparatively short histories, appear to respond best to

Case 6. A duodenal ulcer history of three years duration. The films show the deformed duodenum and its return to a normal appearance after 24 injections of histidine. Symptomatic relief obtained after the 15th injection.

histidine injection treatment. Gastric ulcers appear to show a more rapid improvement than do duodenal.

2. There may be value in its use in those re-activated ulcers previously operated upon and in marginal ulcers, or in those cases in which further surgery is contra-indicated. More cases of this type will have to be studied.

3. If proven to be of value after a proper observation period, the histidine treatment's chief benefit would appear to be in its elimination of dietary and medication regimes together with rather prompt and early improvement of symptomatology with no disagreeable local or systemic reactions.

4. While this treatment appears of value, it can be seen from this preliminary report and from other cases reported that there has not been a large enough number of ulcers so treated with a period of follow-up observation of length sufficient to draw definite conclusions as to the permanency of apparently beneficial results.

## ABSTRACTS

GARRETT, B. C.

"Congenital Hypertrophic Pyloric Stenosis." *South. Med. Jour.*, 28:450-452, May, 1935.

In this disease, there is a spasticity as well as a hypertrophy of the pyloric muscle fibers. The disease generally appears between the second and fourth weeks, predominates in breast-fed babies, is eight times as frequent in males and in most cases affects the first baby. The signs and symptoms include projectile vomiting, visible peristalsis, palpable pyloric tumor, loss of weight and scanty stools during the first few weeks of life. The combination of a palpable pyloric tumor and visible gastric peristaltic waves is almost pathognomonic. The author believes that X-ray examination is a safe procedure and attaches importance to the presence of a blunt rounded pyloric end of the stomach and a 60-80% gastric retention.

The cases that respond to atropine or belladonna medication are those in which the spastic element predominates. Most cases, however, require surgical treatment, the Ramstedt-Fredet operation is a most satisfactory one, the expected mortality being from 2 to 4%. It is emphasized that the operation is not a true emergency one and that there should be adequate preoperative care consisting of parenteral fluids, whole blood, atropine, gr. 1/500 A.C., phenobarbital, gr. 1/8 to gr. 1/4, thick cereal feedings, and gastric lavage before surgery and occasionally before feedings. Post-operative care consists in keeping the baby warm, beginning fluids by mouth in 2 to 4 hours after the operation, hypodermoclysis where indicated, early resump-

tion of thick cereal feedings, atropine, and breast milk, and adequate general pediatric care. The operative technique is described and mention is made that subsequent laparotomies have shown a normal pylorus in many instances. Recurrence or latent complications are described as rare. A table showing nine points in the differential diagnosis of pyloric stenosis and pylorospasm is included in the paper.

CONE, ROBERT E.

"Sigmoid Diverticulitis and Urinary Tract Infection: Case Reports." *South. Med. Jour.*, 28:535-536, June, 1935.

Although sigmoid diverticulosis is relatively common, its etiological relationship to urinary tract infection has been seldom reported. In practically all of these cases, the route was by direct extension from inflamed diverticula. The author presents three cases of *B. Coli* urinary tract infection which were coincident with and apparently the result of sigmoid diverticulitis. In each instance, there was prompt relief or marked improvement after successful treatment of the diverticulitis. While the route of infection may be ascending or by the lymphatics, the author favors the hematogenous route as most likely but admits that the rarity of cortical renal infection is difficult to explain. He suggests that the possibility of the intestine being the focus should be considered in all cases of stubborn recurrent urinary tract infections due to *B. Coli*. Gastro-intestinal X-ray will be of considerable aid in making the diagnosis.

J. Duffy Hancock, Louisville.

## SECTION VI—*Abdominal Surgery*

### Bleeding Gastric and Duodenal Ulcers\*

By

D. PHILIP MacGUIRE, A.B., M.D., F.A.C.S.†  
NEW YORK CITY, NEW YORK

**A** LONG with perforation, hemorrhage is an extremely serious complication of gastric and duodenal ulcers.

Clinically, ulcers may be classified as follows: (1) *exulceratio simplex* of Dieulafoy, the follicular erosions of Cruveilhier, and also the punctuate erosions of Brinton; (2) the acute round, simple or peptic ulcer whose base is formed by the *muscularis mucosa*; (3) the callous ulcer whose base is covered with granulations and whose margins show the results of long-standing reactive inflammation with the walls correspondingly thickened; frequently, the base ulcerates through the *muscularis mucosa* with a tendency to perforate and adhere to the neighboring viscera; (4) the type that the Continental surgeons term 'ulcer gastritis or duodenitis' which is, at times, almost phlegmonous in character. We invariably associate an invasion of bacteria, usually the streptococci, with both the third and fourth varieties.

The occurrence of hemorrhage varies from approximately 25% to 30% in duodenal, and 20% in gastric ulcers (1). Von Bergman, whose view is shared by the highest English authorities, concluded that the mortality, under medical management, was 5% in an analysis of 2,000 cases of bleeding ulcers. Hurst (2), of Guy's Hospital, London, reported a mortality of 2½% which is even less than that of von Bergman. On the other hand, Finsterer (3 and 4) gave a mortality of 25% under medical management, with 50% having very massive hemorrhages. A mortality of 25% was reported by Chiesman among the cases admitted to St. Thomas Hospital of London for gross hematemesis and melena.

In the writer's opinion, these hemorrhages should be classified into four grades: (1) when there is a small hemorrhage or repeated small hemorrhages by bowel; (2) in which, the patient vomits blood repeatedly in small quantities, in addition to small amounts of blood by bowel; (3) a rather continuous vomiting of small quantities of blood each time, possibly accompanied by some bleeding into the bowel which is persistent and alarming to the patient, himself; and (4) the so-called massive hemorrhagic variety, in which, the patient suffers primarily from serious epigastric distress before hemorrhage ensues. In those cases of duodenal and gastric ulcers that are being treated, and

cases of marginal ulcer that are suspected, there need be little conjecture as to the sources of the bleeding.

Hemorrhages may also be classified according to the blood and hemoglobin count. In the first and second grades, the red blood count is above two million and the hemoglobin 50 per cent. In the massive and serious forms, the red blood count is less than two million and the hemoglobin is less than 40 per cent. The systolic blood pressure is above 80 in the first and second, and less than 80 in the third and fourth grades. When in doubt, it should be remembered that bleeding occurs in the following liver conditions, viz.: portal cirrhosis, spirochaetosis icterohemorrhagica, obstructive hepatic jaundice, malignant tumors of the liver, hypertrophic biliary cirrhosis, hydatid disease, acute necrosis, portal cirrhosis, carcinoma of the common duct, haemochromatosis, primary carcinoma of the gall-bladder, calculi of the external biliary system, and cholecystitis. Special emphasis should be given to the congenital obliteration of the bile ducts and latent cirrhosis of Rolleston because of the possibility of the same infection, causing the ulcer, might also bring about the cirrhotic change in the liver.

Hemorrhages may also occur from splenic diseases such as: Vaquez's disease, polycythemia, von Jaksch's disease, Gaucher's disease, and, most important of all, Banti's disease (splenic anaemia) when the hemorrhage is so profuse and alarming. Rolleston believed that the enormously distended vasa brevia ruptured into the stomach as a result of torsion of the splenic vein. This was due to the great bulk of the organ which resulted in massive hemorrhages. Hemorrhage may also be encountered in acute and chronic leukemias.

Hemorrhage may also occur in Meckel's diverticulum with aberrant gastric tissue in its wall, ulcerations of the small intestines, and, of most importance, in serious pathological changes in the appendix.

According to Gray, in his Textbook of Anatomy, the gastro-duodenal artery is a short but large branch of the hepatic which descends near the pylorus behind the first portion of the duodenum. At the lower border of the duodenum, it is divided into two branches, the gastro-epiploica-dextra and pancreatice duodenalis superior. This is in close relationship with the common duct, anterior to the portal vein.

In the first, second, and third grades of ulcers of a single bleeding, the medical treatment of hemorrhage consists of the administration of a hypodermic of mor-

Submitted April 11, 1935.

phine (gr. 1/6), and atropine (gr. one one-hundredth) which should be repeated in order that the patient may enjoy rest and quiet. Small quantities of ice water, about 200 to 300 c.c., each, of chilled ferric chloride (1-1,000) and also silver nitrate solutions (1-1,000), glucose solutions up to 50%, and adrenalin solutions may be introduced through a Levine or similar tube. If the stomach is distended with blood, a suction should be applied with a syringe or an evacuator in order to permit the gastric walls to contract.

Dr. Frank Smithies (5), Chicago, advised the following medical treatment for bleeding ulcers. Repeated doses of morphine are to be administered which should be given intravenously in shocked patients. He prefers the Thomas Bogg method of clotting and estimating of blood clotting time. In cases of vomiting, bleeding, and gastric distension, he advocates a thorough lavage with normal saline solution at 110° F., as suggested by the late Dr. Rodman. After a preliminary emptying by lavage, nothing should be given by mouth. For more than twenty years, Dr. Smithies has employed as a nutrient enema the following: 8 ounces of normal salt solution, 50 c.c. of syrup of glucose, and 50 c.c. of 50% alcohol, administered by the Murphy drip at body temperature which is given four times within 24 hours. He also advises the administration of fluids intravenously and per rectum to keep up the fluid reserve. In cases where bleeding continues up to 36 hours, he advocates operative procedure. Both Hurst (2a) and Smithies (5) prescribe the immobility of the patient by keeping him quiet in bed, reassuring him, and administering sufficient morphine and atropine (one 1/100 gr.) or morphine alone, to keep him drowsy. Whole blood transfusions of cross-grouped blood are advocated by Smithies for control of continued seepage or "non-spurter" bleeding (5b). Some Internists have advised the use of foods and liquids by mouth but both Hurst and Smithies disagree with this treatment.

Dr. Lester Unger, the transfusionist of our hospital who also advocates massive transfusions in these cases, has so thoroughly convinced the writer of the advisability of this method that he has consistently applied it in all such cases, in which, he routinely administered 1,000 c.c. of whole blood by transfusion with marked success. If necessary, this amount is repeated three times in cases of massive hemorrhages. In the desperate ones, Dr. Unger believes that, after severe bleeding, a chemical change takes place at the site of the hemorrhage causing imperfect clotting to occur which has an unfavorable effect on checking the bleeding. Consequently, in these desperate cases, arrangements should be made for three donors instead of the usual one. If the hemorrhage continues after the administration of the usual medical treatment together with the series of massive blood transfusions advocated by Dr. Unger, it is generally conceded that all conservative measures have been exhausted and operative procedures must be considered.

Hurst (2b) states: "I believe that the only indication for operation, in the acute stage, is the persistence or recurrence of severe hemorrhage whilst the patient is still fasting, especially in individuals past middle life with a long history pointing to the presence of a chronic ulcer and with arteries so degenerated that they are unlikely to contract sufficiently for satisfactory plugging by thrombosis."

In operative cases of hemorrhage, particularly the third and fourth grades, the procedure usually consists of two stages. In the first stage, under local anesthesia supplanted by cyclopropane, ethylene, or gas-oxygen, surgical intervention should be confined to the source of the bleeding. In the hemorrhagic ulcers of the duodenum, the three vessels that we should bear in mind are the right branches of the coronary or gastric, and the pyloric branches of the hepatic artery in the bleeding gastric ulcers and the gastro-duodenalis, a branch of the hepatic.

A complete excision should be made through the healthy tissues, even to a transgastric approach, in the gastric ulcers; if necessary, ligating the "bleeders" with mattress sutures controlling the gastric or pyloric branches. It may be necessary to cut through the gastro-hepatic omentum in order to mobilize the gastric area. After mobilization of the gastric area, an incision is made 1 c.m. distal to the pyloric ring. It is brought transversely across the duodenum, holding the superior and inferior angles taut by stay sutures according to the von Haberer technique. The incision should be sufficiently extensive so that the ulcer may be excised by a cautery of low heat. The base of the ulcer should be scarified according to von Haberer's technique and the bleeding kept under control. Then, the resected edges of the ulcer should be sutured together. The exclusion operations of von Eiselberg through the pyloric ring, or Devine of Melbourne, above the incisura, require too much time in patients whose lives virtually hang on a thread. In the before-mentioned operative procedure, the time factor involves the necessity for furnishing a jejunal anastomosis. Again, unfortunately, it leaves the acid producing pyloric antrum intact.

In the Author's opinion, there is no question but that the operating surgeon has been unable to find the offending lesion in many cases and has encountered a general oozing condition which might have been due to extrinsic causes and not ulcers. In such cases, the gastric or duodenal area mucous surfaces resemble the appearance of a wet blotter. Faulty diagnosis was often due to an imperfect work-up.

In the third or fourth grouping that the writer has made, the condition to be dealt with is far more serious than the ulcer. This is a streptococcus invasion of the blood vessels, with all its attendant pathology, which reduces them to almost a gelatinous state obliging the surgeon to explore quite a distance to find an artery sufficiently healthy to clamp-off.

Out of every seven cases of massive hemorrhages, three are fatal according to Aitken (6) and 10 to 11% of the moderately severe ones.

In those cases, not reacting favorably to medical treatment and massive whole blood transfusions (3 if necessary), operative intervention is indicated. If the bleeding continues in a persistent hemorrhage from a posterior duodenal ulcer before a posterior duodenal approach has been made, it is advisable for the operating surgeon to pass his left index finger into the foramen of Winslow and attempt to control the hemorrhage by applying pressure so that he may orient himself. The writer has found that, by inserting his left index finger through this foramen and extending it under the gastro-hepatic omentum above the first portion of the duodenum, and making an incision in the omentum so that a rubber catheter may be passed through by

elevating the ends of the catheter caught by a Kelly clamp, the bleeding, in this area, may be controlled in most cases, except in those exceptional ones, in which, a collateral anastomosis exists with the gastro-epiploica-dextra artery. There is little danger of injuring the common duct since the Author has found it to be a very resistant structure. In experiments on the cadaver, his efforts to tear it after suturing in a rubber drainage tube were of no avail. Having controlled the hemorrhage, the next step is to make the posterior duodenal exposure and ligate the cause of the bleeding.

Some authorities have cautioned against transfusions in amounts greater than 250 to 300 c.c.. They believed that it increased the systolic pressure to such an extent, even up to normal or above, that further bleeding would be encouraged since tarry stools are sometimes seen even after a blood transfusion of 500 c.c. This is only a temporary condition and the blood added in large amounts is very beneficial to the patient. There has often been some question, in the Author's mind, as to whether blood transfusions in small amounts are really beneficial in serious cases since the patient is usually disturbed by the preparations for the procedure as is evidenced by the perspiration and the look of anxiety that appears on his face. Small amounts of transfused blood hardly compensate for this nervous state. Dr. Unger disproved the before-mentioned theory and further claims that the systolic pressure declines following repeated transfusions of whole blood, never coming up to normal, and is usually 10° to 20° below it.

Dealing with patients who are already mortally ill, it is not surprising that a mild, or even, severe alkalosis develops from a combination of alkalosis, due to the Sippy regime, a chloride formation of 2 gm. instead of 5 gm. according to Wildman, and a hemorrhage with intense vomiting. When the acid gastric secretion occurs in normal function, chlorine ions are withdrawn from the blood bearing an excess base which, combining with  $\text{CO}_2$ , increases the bicarbonate reserve of the blood. The base chlorine balance in the blood is re-established by the absorption of chlorides and water from the gastric juice in the ileum and colon. Alkalosis may result from any abnormality which prevents the absorption of the chlorides in the small intestine.

In the ulcer cases, particularly in the presence of an obstruction, there is a loss of gastric juice, which contains hydrochloric acid, due to the vomiting. This depletes the chlorine ion content of the blood.

The normal blood chloride level and blood volume may be maintained for a while by the withdrawal of tissue chloride and fluid which is actually responsible for dehydration. When this supply of tissue chloride has been exhausted, a hypochloremia develops which liberates the originally combined chloride base so that it unites with the  $\text{CO}_2$  which increases the bicarbonate content. Then, the urine becomes alkaline because of the markedly diminished chloride excretion and the presence of an excess of base ions. The occurrence of alkalosis in ulcers is evidenced by a low chloride level, a high  $\text{CO}_2$  combining power of the plasma, a marked increase in the non-protein and urea nitrogen, and an alkaline reaction of the urine.

The imperativeness for the recognition of this complication is evident. The benefit to the patient, derived from the transfusions, will be augmented when this

affection is cured by the intravenous injection of 5% glucose and saline solutions.

In these ulcer cases complicated by obstruction and vomiting, the Author firmly believes that many of the fatalities were mainly due to alkalosis and not to the hemorrhage.

A re-emphasis has been recently made by Dr. Wright\* who states: "that preclinical and even severe scurvy is frequently present but unrecognized in adults. Vitamin C is omitted from the diet for various reasons some of which include: poverty, individual dislike for the foods containing Vitamin C, faddist diets, and last but of considerable importance, diets imposed by the medical profession in the therapy of gastric and duodenal ulcers, colitis, and certain other conditions."

Using a standard capillary fragility test, previously described by Dr. Wright (7), it has been made possible to demonstrate that the capillary fragility is definitely increased in a moderate percentage of patients who have been on ulcer or colitis diets deficient in Vitamin C. At first, this is present without gross evidence of scurvy but is later accompanied by frank hemorrhage from the gums, intestines, and subcutaneously. Thus, such diets have been shown to definitely increase the tendency to hemorrhage.

This syndrome can be quickly cured by the use of crystalline Vitamin C (cevitamic acid) either orally or intravenously. The oral dosage should be from 60 to 100 m.m. given daily in divided doses. The amount, given intravenously, is 100 m.m. dissolved in 5 c.c. of normal sterile saline solution or distilled water. In a series of acute ulcer and colitis cases, this substance has been well tolerated when taken by mouth. In several instances, severe intestinal hemorrhage, ascribed to colitis, has been entirely cleared-up by simply adding this substance to the diet. Therefore, it is suggested that cevitamic acid should be included in all diets deficient in Vitamin G, particularly, in those conditions frequently associated with oozing or frank hemorrhage. It is candidly admitted that the use of this substance will not effect hemorrhages which are dependent on the erosion of large blood vessels. However, it may have a very definite influence on bleeding associated with changes in the smaller blood vessels.

Cases have been seen, in which, it is impossible to arrest the hemorrhages by the administration of repeated blood transfusions and the application of glucose and saline solutions. In order to build-up these cases to the proper condition for exploratory operation, the writer recommends repeated intravenous injections of liver extract from ampules (5 c.c.), the active and anti-anaemic principles, of which, are equivalent to 100 grammes of fresh liver. He also recommends the intravenous injection of glucose solution up to 50 per cent. The liver extract raises the hemoglobin and red blood cell count and both solutions are invaluable for the elimination of the hemorrhage. Further experiments with these injections will be reported at a later date.

Regarding the operation of choice for cases of ulcer in the vicinity of the pyloric ring, a modification of the Billroth No. 1 procedure, advocated and practiced by von Haberer in nearly 2,000 cases, is becoming very popular at the present time. There should be no devia-

\*Personal communication to the Author by Dr. Irving S. Wright of New York City, N. Y.

tion from this technique since he has perfected it to a high degree of efficiency.

The Hoffmeister-Finsterer type of operation is advised to deal with ulcers higher up in the lesser, or in the greater curvature or body of the stomach. We are all well aware that the higher the resection is made, the greater is the corresponding increase in the mortality in these cases.

In cases of the non-resectable type of posterior hemorrhagic duodenal ulcers, in which, it is impossible to cover the base of the ulcers by suture, the only hope of alleviation is by neutralizing the gastric acidity by a gastrojejunostomy as advocated by Balfour (8 and 9), who reports such cases of his cured to as high as 85 per cent, or, preferably, a gastrectomy, in which, the percentage of cure is 10% higher or better. During the period of operation, the mouth should be kept scrupulously clean in order to avoid the danger of parotitis. Hurst (2c) recommends 15 ounces of normal saline solution via rectum every 6 hours. Both Hurst and Smithies agree that it is necessary to wash out the stomach in cases of continuous hemorrhage.

After the patient has recovered and is in good condition, the second stage of the operative procedure should be performed which should aim at preventing a recurrence of the ulcer.

### CONCLUSIONS

From the surgical standpoint, the most important step in dealing with serious and persistent bleeding ulcers is to confine the operator's efforts to the arrest of the hemorrhage since the second stage of the operation eliminates the cause.

## ABSTRACTS

MCNEALY, R. W. AND LICHTENSTEIN, M. E.

*Evolution and Present Technique of Gastrojejunostomy. S., G. and O., Vol. 60, No. 5, May, 1935, pp. 1003-1015.*

In a complete review of the history of gastrojejunostomy the authors show how experimental work in the laboratory has contributed to our present knowledge in that branch of surgery, and how trial and error in actual clinical surgery have contributed far more. The stoma of the efferent limb of the first gastrojejunostomy performed by Billroth was found to be obstructed because of a mechanical defect. Shortly thereafter many modifications of the operation were suggested. Woelfler, who had performed the first gastrojejunostomy in 1881, suggested stenosing the stoma of the afferent loop by suture, or removing the

No surgeon should consider operating on cases of acute ulcer complicated with massive hemorrhages, which are often primary, when the patient is in actual shock since most of the patients die on the operating table as a result of the low systolic pressure, hemoglobin and blood count.

Errors are seldom made in dealing with gastric bleeding ulcers, but this, unfortunately, is not the case in the duodenal variety. Small or already healed ulcers that appear on the anterior or superior surface of the duodenum are excised, following which, a gastro-enterostomy is performed. When the patient starts to bleed again several days following the operation, which the operator may ascribe to a marginal or gastrojejunal ulcer occurring post-operatively, he suddenly realizes his lack of foresight for not making a more thorough exploration of the area.

Von Haberer, whose technique is generally used on the Continent, incises the duodenum, transversely, clear across the anterior duodenal wall with a wire loop cautery. Exploration of the posterior duodenal wall can then be safely made with either a diagnostic lamp or the operator's finger since ulcers on the anterior or superior surface of the duodenum have seldom been known to cause a severe hemorrhage. The Deaver-Judd exploratory longitudinal duodenal incision is often used in this country.

Extreme care should be exercised when handling a cautery so as not to injure the pancreatic capsules. It should never be held at right angles, but flat to the surface being cauterized.

afferent limb entirely and suturing it to the afferent limb at a point beyond the anastomosis. That principle was later expounded by Roux in relation to posterior gastrojejunostomy. In 1885 the feasibility of performing posterior gastrojejunostomy through an avascular area in the transverse mesocolon was proposed from Billroth's clinic.

The posterior operation grew in favor and attracted the attention of many surgeons. It received a further stimulus by Peterson, who showed that it was possible to anastomose the jejunum to the stomach close to the duodenojejunal flexure without much tension. That obviated the necessity of a proximal loop, and made it unnecessary to perform the Y operation of Woelfler or Roux.

Among the factors contributing to the failure of those early operations, infection and its sequellae were outstand-

ing. Various devices were proposed to make an aseptic anastomosis possible; among them was the elastic band of McGraw, the heavy silk ligature of Postnikow and Podrez, the angiotribe of Souligoux, and the use of caustics by others. Failure of such cases was due to the closing of the stoma sometime after operation. In order to split the margins of the stoma and keep it open, various devices were proposed, among them were the decalcified bone plates by Senn in 1888, raw hide plates by Robinson in 1890, the button by Murphy in 1892, the bone-bobbin by Mayo-Robson in 1893, and in 1900 the perforated silver plates by Crede.

Physiologically the stomach has been divided into two large divisions, namely: the secreting portion, and the motile, grinding portion. The former is the cardia, fundus and body of the stomach, while the latter is the antrum and pylorus. Experimentally it has been found that the stoma of a gastrojejunostomy functions best when it is neither in the antral portion of the stomach, nor too high on the body. Considerable discussion about the exact position the stoma should occupy has brought some degree of general agreement. The location of the stoma in the small intestine should be on the antimesenteric side close to the ligament of Treitz. The lowest portion of the stomach will be found somewhere on the greater curvature between a point one and one-half inches proximal to the pylorus, and another point two inches from the mid-line. This lowest point in the stomach usually lies to the left of the mid-colic artery, but occasionally is to the right of it. There is no general agreement about the direction of the long axis of the stoma in the stomach. If the anastomosis can be made without kinking or twisting the small bowel, it will probably function satisfactorily. Moynihan stated that "just as there is no natural direction of the jejunum, so there is no best line for the anastomosis." Occasional variations in the anatomy of the stomach, duodenojejunal angle and transverse mesocolon will influence the exact location of the site of anastomosis.

Herniation of viscera from the greater sac into the lesser sac may be guarded against by suturing the edge of the hole in the mesocolon to the stomach, or to the line of anastomosis between the stomach and jejunum.

Increasing experience has shown that the use of absorbable suture material is probably most satisfactory. It is important that the sero-muscular suture include the submucosa also.

The Authors feel that the lock stitch is not satisfactorily hemostatic, if post-operative hemorrhage is to be consistently avoided.

Before the operation has been concluded a careful inspection and survey should be made to establish: (1) the correct arrangement of the anastomosis, (2) the absence of twists or kinks, and (3) the patency of the stoma.

Four figures and a large bibliography accompany the article.

CURRY, F. S., AND BARGEN, J. A.

*Studies on Absorption and Excretion in Segments of the Colon in Man. Surgery, Gynecology and Obstetrics, Vol. 60, No. 3, March, 1935, pp. 667-674.*

The authors studied the absorption and excretion of certain substances by the distal segment of bowel in a number of colostomized patients. The distal segment of the colon was cleansed until practically sterile. The test substance was instilled through a rubber catheter, and after a period of time the residue was recovered by irrigating the segment with 1000 cubic centimeters of water. This residue was then analyzed.

It was found that when sucrose was instilled into the bowel it was promptly absorbed and excreted by the kid-

neys. Following the removal of the sucrose from the bowel, urinary excretion of sucrose abruptly ceased.

When arsenic in the form of a solution of neoarsphenamine was instilled into the bowel in quantities of 0.6 gram it was excreted by the kidneys, and also by the bowel above the colostomy.

When glucose solutions were instilled into the bowel it was absorbed in each instance. In non-diabetic individuals the blood sugar value remained unchanged, while in patients with diabetes the blood sugar values were definitely elevated.

Methylene blue and atropine, when instilled into the distal segment of the colon, are absorbed.

It was found that methylene blue, when administered orally, was not excreted by the distal segment of the colon. Glucose and sucrose, when given intravenously, are not excreted by the distal segment of the colon. Arsenic given orally may be recovered in part from the distal segment of the colon.

Eight tables and a bibliography accompany the article.

ERNEST J. OESTERLIN, M.D., AND ROBERT W. BLUMENTHAL, Milwaukee, Wis.

*Spindle Cell Sarcoma of the Pancreas. (From the Pathologic Laboratory of the Milwaukee Hospital).*

Sarcoma of the pancreas is very rare. Gruber could not find one in 20,302 autopsies and Remo Segré mentions only two in 11,492 postmortem examinations. Notwithstanding the small number reported the authors state most of them cannot stand criticism.

Three types are described: Round cell, giant cell, and spindle cell sarcoma but Marxer found that many of the reported pancreas sarcomata are either lymphosarcomata, or metastatic tumors or not true blastomata but of inflammatory origin.

Litten's case which is quoted so often as the first described sarcoma of the pancreas was really a lymphosarcoma. The spindle cell sarcoma is the only type withstanding criticism and but only a few of these are to be found in the literature covering a period from 1890 to 1930.

The authors describe a case of spindle cell sarcoma of the pancreas admitted to the hospital for the first time in March, 1932, after several years of slowly progressing weakness. Six months previously he had a severe chill with fever and vomiting which anomalies recurred irregularly over the next three months. Following this he felt better for three months, gained 30 pounds in weight and returned to work. He again had fever, chills and vomiting preceding his return to the hospital. His abdomen then was rounded and no tumors or tender areas were observed. "The liver was 1 cm. below the costal margin; spleen not palpable."

*Laboratory findings:* Basal metabolic rate + 20%, blood Wassermann negative; blood culture negative; blood sugar 196 mg., non-protein nitrogen 38.7 mgms.; blood in feces, benzidine positive; guaiac and Rolland tests negative; electrocardiogram showed slight evidence of coronary sclerosis; r.b.c. 5,650,000; w.b.c. 18,300.

On the second admission (May 12) urobilinogen (1-8) was found in the urine but the test was negative five days later—then became positive again; three days later, just after operation, it was present 1-2, and increased gradually 1 to 100 June 1st. Then it came down 1 to 40 until he died June 4th. Bile pigment was constantly found in the urine. The highest temperature while in the hospital was 104° F., pulse rate 108, respiration 22. The urinary sugar ranged from negative to 4+.

*The exploratory operation* (May 20) revealed a greatly distended gall bladder, an enlarged but not nodular pan-

creas and an enlarged liver with rounded edges and irregular areas.

*Postmortem examination:* Anatomic diagnosis: Pleomorphic spindle cell sarcoma of the pancreas. Its head was the size of a large grapefruit containing many cryptic cavities. The parenchyma was replaced by fibrous tissue which showed microscopically irregular whorls of pleomorphic cells with the coarse mature connective tissue fibres; spindle shaped cells predominated. There were occasional giant cells and scattered necrotic areas invaded by neutrophils. The spleen weighed 370 gm. There was acute splenitis. The liver weighed 2130 gm. and contained multiple abscesses; culture of the pus showing *B. coli*. Microscopic examination showed necrotic areas invaded by neutrophils. The periportal connective tissue and the bile ducts were much increased. The liver cells showed fatty degeneration.

The authors note the probability that the sarcoma of the head of the pancreas developed on a preexisting fibrosis.

EDWARDS, H. C.

*Diverticula of the Duodenum.* S., G., and O., Vol. 60, No. 5, May, 1935, pp. 946-965.

Duodenal diverticula are classified by the Author as acquired hernial (or primary) type, those secondary to ulcer, traction diverticula and anomalous forms.

Of the author's five specimens, four are single and were found in relation to the ampulla of Vater (perivaterien). In the fifth, two diverticula were present, arising from the transverse part of the duodenum. A typical primary duodenal diverticulum is a thin walled sac opening into the bowel by a wide mouth. It rarely exceeds the size of a golf ball, and is rounded in shape as opposed to the finger-like congenital type of diverticulum.

The average age of the cases reviewed was 51.9; the oldest being 73, the youngest 31. Females are more often affected than males.

The diverticula were found most frequently in the second part of the duodenum, and were rarest in the first part.

The Author feels that the great frequency of diverticula about the ampulla of Vater is due to the weakness of the duodenal wall at that point. The common bile duct and the pancreatic duct of Wirsung pass obliquely through the duodenal wall for about one-half an inch. Along the course of those ducts there is a deficiency in the longitudinal musculature of the bowel. Deficiency of the muscular layer along the course of the blood vessels is not so marked. Increased intra-duodenal pressure resulting from obstruction, or, more often, from incoordination of contractions, results in a herniation through the weaker point, or points. The Author feels that a possible pre-disposing cause of increased pressure may be constriction of the transverse portion of the duodenum by the superior mesenteric vessels, or a sharp angulation at the duodeno-jejunal juncture as is found in most cases of visceroptosis.

Diverticula which develop upon old ulcers may be identified by the presence of the small scar, usually at the mouth of the diverticulum. They are found most frequently in the first part of the duodenum. The contraction of the dense scar tissue shortens and puckers the wall of the duodenum causing the ballooning out of the adjacent part.

Traction from an old adherent gall bladder, or common bile duct, may produce traction diverticula.

Pseudo-diverticula may result from perforation of duodenal ulcers into the peritoneal cavity. One case of diverti-

culum associated with a new growth has been described.

Twelve figures and a complete bibliography accompany the article.

FINNEY, J. M. T., JR., AND MOHR, CHARLES F.

"Coronary Occlusion Simulating an Acute Abdominal Emergency." *Am. Jour. Surg. (New Series)* 28:629-639, June, 1935.

Three cases of coronary occlusion presenting purely abdominal symptoms are presented. While cases of this kind are rare, proper differentiation is most important since surgery, such a necessity in acute abdominal conditions, becomes a tragedy in this group. The usual criteria of the location of the pain, irregularity of heart action, drop in blood pressure, and electrocardiogram are often of little aid. All the pain may be referred to the abdomen, the irregularity of heart action may not show itself for some time, the drop in blood pressure may either be deferred or may have occurred before the patient was seen by his physician, and electrocardiographs are not likely to be diagnostic immediately. Other signs of cardiac failure are also often rather late in their manifestations.

A carefully taken present and past history is of extreme importance. The longer the history and the more severe and frequent the pain, the less likely is it to be cardiac. Males are four times more subject to coronary occlusion than are females. So far as age is concerned, the heart is more likely the offender after 50. In regard to the past history, the following points would rather incline to coronary occlusion: pre-cardiac discomfort, sense of constriction in the chest, appearance of pain after activity, tachycardia and irregularity of heart action, and dyspnea. While the abdominal pain in occlusion is often confusing, it is not so prone to radiate as in gall-bladder disease and the point of maximum tenderness is more usually found close to the midline. In spite of these differential points, the possibility of the disease must be borne in mind in order to recognize its presence.

JELKS, EDWARD.

"Some Points in the Early Diagnosis of Gastro-Intestinal Cancer." *South. Med. Jour.*, 28:446-450, May, 1935.

Altho the recent decrease in mortality of cancer of the stomach is attributable not so much to improvement in surgical technique as to earlier diagnosis, there is still too much delay in the recognition of malignancy of the gastrointestinal tract. Emaciation, tumor, obstruction with persistent vomiting, and severe hemorrhage occurring in a person in the cancer age are indications of incurable malignancy rather than early operable lesions. There are, however, seven rather early findings. They are alternating diarrhea and constipation, recurrent attacks of vomiting long before complete obstruction occurs, indefinite indigestion which may or may not be related to ingestion of food, discomfort from distention in epigastrium or lower abdomen, anorexia, anemia manifested by paleness or dizziness, and unexplainable weakness. Briefly, any change in the gastro-intestinal life of an individual over 30 years of age may be an early sign of cancer and in those instances the burden of proof against cancer rests on the physician. Sigmoidoscopic examination of all patients with hemorrhoids and X-ray study and examination of the stool for both gross and occult blood in all patients with gastro-intestinal complaints are recommended.

## SECTION VIII—*Editorial*

NOTE: The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Gastroenterological Association is in no way responsible for editorial expressions.

### ON AN ADEQUATE CONCEPTION OF THE ETIOLOGY AND THE SIGNIFICANCE OF PEPTIC ULCER (GASTRIC AND DUODENAL)

IN 1917, writing upon the necessity for a broad conception of the cause of peptic ulcer as bearing upon its clinical management, we made the following statement: (1) "We cannot expect ever to establish a single, definite cause of gastric ulcer"; "likewise, it would appear that we have no basis for regarding gastric ulcer as a distinct disease entity," and "facts strongly suggest that peptic ulcer presents aspects indicating its being a self-limited 'disease.'"

In that particular communication, we proposed a mode of ulcer therapy which had, at least, the merit of attempting to be in line with known physiologic and pathologic departures from the normal where peptic ulcer was present.

In 1923 (2), the writer reaffirmed his position and amplified the mode of management which, after nearly six years' trial under careful control, had proved certainly not less efficacious than the "rule-of-thumb" treatment in vogue (chiefly over-alkalinization). In 1927 (3) and in communications subsequent to that year, the significance of known facts (physiological, experimental, chemical and clinical) was emphasized as they concerned treatment, not alone of gastric ulcer but also of the duodenal lesion. Schematic representations of what we considered mural concomitants of the peptic, gastric or duodenal, lesion, were exhibited and evidence was adduced to prove that by our "physiologic rest regime"—the *non-interference with natural healing*—a higher percentage of lesions went on to favorable clinical outcome than occurred when medical, "drug treatment," was pushed. Fuller data in this respect were submitted in 1932 (4) when we considered before the Section on Gastroenterology and Proctology of the American Association at New Orleans the limited clinical usefulness of so-called "gastric mucin" as an agent in ulcer therapy.

Today, after more than twenty years of a type of clinical experience which has been carried on in close proximity to observations at the operating table, the physiologic, pathologic, chemical, roentgen laboratories and in the postmortem room—we feel that an adequate concept of gastric or of duodenal ulcer lies in considering these lesions not disease, *de novo*, but in fact *complications appearing when certain mural anomalies*

*occur and when these so progress as to interfere with the normal nutrition or life of tissue from those zones, lumenward.* The consequences are the development of areas of faulty structure which readily are digested whenever any proteolytic agent comes into contact with them.

Such agents or combinations capable of causing local gastric or duodenal proteolysis are:

(a) *HCl plus pepsin plus "devitalized" tissue.*

(b) *Pancreatic juice (with or without bile) plus "devitalized" tissue.*

(c) *Certain bacteria possessed of ereptic characteristics which may be carried to visceral walls and there, when conditions are favorable, attack devitalized tissue (quite likely, such bacteria are those to which former investigators attributed great significance in ulcer production, particularly when, by blood or lymph streams, the organisms were transported from distant so-called "foci of infection" to places of lodgement in the walls of the stomach or the duodenum; where the bacteria remained viable, these "infectious emboli" primarily caused areas of mural infarction).*

(d) *In the presence of mural, circulatory disturbances of a degree sufficient to result in local tissue death or lack of normal defence, the lytic action upon such altered tissue of the peptid-splitting enzyme present in normal blood-serum (5).*

(e) *Potent capillary—or arteriole—spasms (in degree and character similar to those capable of bringing about marked circulatory disturbances or even "trophic" ulceration in severe grades of such affections as Raynaud's syndrome and allied disorders) where, locally in the visceral walls, superficially or deeply, areas of defenseless tissue appear upon which any of the already mentioned agents or mechanisms subsequently may cause proteolysis. Particularly important is this conception of one mode of ulcer production since (1) Reeves' micro-anatomic injection investigations demonstrated how scant are the arterial-capillary anastomoses in the very regions where ulcer commonly develops; (2) since Goto, Durante and others have produced ulcer readily by adrenalectomy and by interfering with normal innervation to the visceral blood vessels; and (3) since Schiff, and more recently, Cushing, have produced or called attention to peptic ulcers occurring where certain portions of the brain or the spinal cord are the *loci* of injury or disease. Of by no means trivial significance is the weight in ulcer etiology of disturbed innervation, with regards not just alterations in the quantity and kind of digestive secretion but more definitely in the production of mural circulatory defects of a grade capable of*

ending in structural anomalies. Further, fatigue or emotional upsets, of themselves, are being more widely recognized as responsible for actual organic damage in the stomach or the duodenal wall: these abnormal mental and psychic states are capable of setting moving a mechanism whose end-consequences are large or small areas of tissue death or lack of normal defense. Such chain of events may include increased adrenal secretion, potent and prolonged capillary or arteriole spasm leading to structural damage, alterations in duration and kind of digestive secretion, muscle "spasms" or disarrangement of normal peristalsis—in sequence or in degree—gravely interfering with normal, mural, blood distribution. Indeed, this aspect of the etiology of peptic ulcer now is being admitted so widely that today few considerations of the affection's management fail to specify the lowering of the patient's nervous, mental or psychic level, the lessening of the individual's "drive" in business, home, sports. Etiologic factors arising from the emotional make-up of ulcer subjects received scant attention when we stressed them in 1917.

(f) *Arteriosclerosis*, whether or not associated with arterial hypertension, undoubtedly is responsible for initiating certain peptic ulcers. Usually, such sclerosis is that which early involves the capillary bed and extends from there, heartward, to larger and eventually to major blood vessels. Detection of such type of sclerosis is difficult unless, at operation or at autopsy, one has available for study the excised ulcer or a segment of visceral wall. In such specimens, one has little difficulty in demonstrating, minute, multiple (usually eventually coalescing) or large, solitary areas of true apoplexy. Tissue death is prompt in the hemorrhagic zone and later, provided the bleeding is not actually fatal, gradually it includes all the tissue lumenward from the particular vessel involved.

Study of the walls of the stomach or of the duodenum of many individuals particularly persons who are very active, physically and mentally, reveals numerous areas where scar tissue has replaced zones of apoplexy but where, however, no submucosal or mucosal damage took place (as evidenced by peptic ulcer) because the ruptured arteries were not those which supplied those parts. Examination of other specimens (particularly in instances where, as an initial lesion, there appears an acute, perforating, "round" ulcer such as described by Craveilhier—"punched out and non-inflammatory") demonstrates apoplexy in major arteries lying just beneath the serosa. In these circumstances, within a period so brief as an hour, lumenward tissue death, hemorrhage and necrosis occur. The necrosed tissue promptly is digested, by any proteolytic agent present (commonly the normally secreted HCl and pepsin), through the entire visceral wall: the classic form of ulcer results. Usually it is fatal. It is folly to think that any non-surgical mode of treatment could have been of value in this type of ulcer: indeed, all too often, the promptest operative procedures are of no avail.

Craveilhier's type of ulcer, illustrates in an *acute and complete degree* the mechanism of all ulcer production or recurrence. In the chronic lesion, successive areas of tissue-proteolysis occur (the clinical "relapse") wherever devitalized structure arises when any of the causes mentioned becomes active. Quickly or slowly, the ulcer-area becomes larger, scar tissue re-

places normal mural architecture, deformity supervenes (obstructive in about 19% of instances), crater-like lesions may be seen (especially in the stomach where a thick wall admits of considerable "burrowing"; less commonly in the relatively thin duodenum); larger arteries may be opened or proteolysis "digests" gross mural structure and then appear such dramatic "complications" as massive hemorrhage or "acute" perforation of a chronic affection (histologically considered only, inasmuch as in a time sense the "chronicity" may include but a few weeks or months).

(g) *Congenitally*, from birth may be present anomalies of circulatory distribution or at times, the visceral wall (more frequently in the stomach than in the duodenum) may include "tissue rests"—as those pancreatic rests described by the late Dr. Warthin. In such circumstances, the structural fault may be exhibited in infancy. Just so soon as the viscera are put to digestive stress, demands are thrown upon the circulatory mechanism, the normal secretions are elaborated and neuro-motor activity required, the defective architecture permits mural necrosis; proteolysis—"digestion"—follows and, in the infant or the very young, long before emotional "keying-up" or physical or mental "drive" has opportunity to develop, peptic ulcer symptoms and signs occur, not rarely as initial hemorrhage or perforation. Here, indeed, is the clean-cut occurrence of gastric or duodenal ulcer from intramural defects and long before "hyperacidity," "corrosion" (a term dating back to Celsus, later to be revived by Müller) or "the impact of the acid chyme upon the alkaline-bathed duodenal mucosa" have opportunity even to be regarded seriously as etiologic factors in ulcer production. Doubtless, more careful study of the structural, mural defects of the stomachs and the duodenums of the new born or of infants would prove most illuminating in respect to elucidating the significance of mural anomalies as later they occur more or less regularly in the adult viscera, whether such common birth defects are or are not complicated by the clinical symptoms or the outright appearance of peptic ulcer.

(h) It is not improper and certainly not valueless, here to consider so-called "*gastritis*" or "*duodenitis*" with regard to its bearing upon the etiology of peptic ulcer. Not rarely, such lesions precisely mimic the clinical picture of gastric or of duodenal ulcer: in fact, all too often, despite the absence of positive X-ray evidence, gastritis or duodenitis long is treated medically as ulcer and, in instances where symptoms persist despite carefully planned and long-maintained "ulcer" regimens, surgical intervention takes place: of course, no ulcer is demonstrated. However, in our experience, even though no localized "peptic" lesion is found, such surgical intervention (or, where untoward complications prove fatal and autopsy is secured) by no means is worthless if one looks upon the laparotomy as "exploratory" not just in the sense of proving that ulcer is or is not present. The "exploration" should be carried far beyond the search for ulcer or for extra-alimentary canal pathology.

In these "*gastritis*" or "*duodenitis*" patients, our observations have shown that by inspection, palpation, and particularly by transillumination of the stomach and the duodenum by an appropriate electric light, often it is possible to demonstrate the following: (1)

localized or general thickening of the visceral wall, (2) local or general areas of vascular engorgement or of anemia, (3) "stiffening" of segments—or, indeed, the entire stomach or duodenal wall; especially is this pronounced in the so-called "ulcer-bearing" areas; (4) the irregular scattering in the deeper (*i.e.* towards the serosal surface) layers of the wall of more or less definite plaques or zones of induration which feel scar-like compared with the normal mural softness and elasticity. These, upon transillumination, actually are definitely, or poorly circumscribed patches of induration due to vascular engorgement or scar formation: in fact, certain of these areas may extend to the serosa and then are comparable with the scarred "soldier spots" seen in certain hearts or aortas; (5) should the viscera be incised (as in the case of transgastric incision for posterior wall ulcer or search for such), the mucous membrane frequently is very thick, oedematous, congested; islands of such tissue are present amid areas of normally appearing membrane. While these islands may even bleed on handling or upon brushing firmly with a cotton applicator, no true ulceration is demonstrable: the mucosa, even tho very evidently abnormal, not yet has lost its protective vitality and acid and pepsin or other proteolytic agents are incapable of "digesting" it. The mucosal disturbance evidently arises from circulatory or even sluggish inflammatory processes lying deep (serosa-ward) in the visceral wall.

(i) Ingenious and painstaking as have been the *experimental methods* whereby have been produced peptic ulcer (duodenal and gastric, tho by far more numerous the former), the following facts must be recognized when interpreting the real significance of these artificially produced ulcers: (1) few ulcers, indeed, have been produced experimentally in animals in which "spontaneously" arising ulcers—as seen in the human—are of common occurrence; (2) in the production of experimental ulcer in animals, quite uniformly, the technique of production has upset the normal circulatory, secretory, nervous or even the anatomic relations of the parts involved; (3) even the most assiduous and careful experimenter has found great difficulty in producing the "chronic" ulcer, the type *spontaneously* developing in humans; (4) study of the stomachs or the duodenums of animals in which, experimentally, ulcers have arisen do not disclose such mural areas of defective circulation, infection, thickening, scar formation or neuro-muscular anomalies commonly observed in humans in whom peptic ulcer arises without such abnormal anatomic, secretory, nervous or muscular sequence as experimentation demands before ulcers are produced or maintained; (5) most recent investigations upon animals, would indicate that in such animals—subjects who rarely, if ever, develop the spontaneously appearing peptic ulcer of man (few monkeys, have been the subjects of experimentation: monkeys, structurally if not dietetically, are nearest akin to man)—some chemical "humoral" agent, regulates in a yet unknown way, the initiation, the duration and, perhaps, the quantity and "strength" of the output of gastric juice and probably the duodenal digestive content. In other words, this form of mechanism during the digestive process, in experimental animals, at least, controls beginning of digestion, the qualitative or quantitative values of the digestive juices and, not yet wholly proved but suspected, the

neuro-motor activity. If this concept be correct, much that is concerned with digestion (and absorption) from the time food is taken into the mouth is self-regulated in accordance with the kind and quantity of pabulum by successive "humoral" (a term generally understood in effect, but actually one which hides our ignorance of actual facts) sequences beginning even before food really is ingested and exhibiting itself in orderly fashion from the mouth down even to include happenings in the colon. Disorganization of these normal "humoral" sequences, may, of themselves, lead to quantitative secretory and motor anomalies in the digestive (and, probably, the absorptive) function. While the chief result of interference with these normal sequences may come through psycho-neural pathways, the manifestations of this activity account for changes from the normal in quantity and quality of digestive juices, duration in which food being digested remains in the stomach, or duodenum or jejunum, and, doubtless, variations in the rate of absorption. Whatever may be the provable variations from the normal so far as digestion is concerned, the *result* of the abnormalities is an interference with the normal "humoral" sequences which, in proper circumstances, make the digestive process an auto-regulatory mechanism. In the experimental production of ulcer, undoubtedly, much of this psycho-neural interference with digestive sequences of an "humoral" character is lost. Further, in the normal life of the average animal used as an experimental subject, such psycho-mural processes doubtless rarely are active and what, in a way, may be an etiologic cause of spontaneously arising peptic ulcer, never becomes operative—hence, again, one finds here the lack of a mechanism which lack seriously interferes with the comparison of experimentally produced ulcer with that appearing without recognized gross existing cause, in man.

#### SUMMARY

Careful histo-anatomic, clinical, pathologic and chemical studies, correlated from the time when peptic ulcer first attracted the attention of clinicians to the present day, indicate that the lesion arises "spontaneously" in the human family and in no other groups of living creatures.

Investigations point to *various agents or circumstances* as being etiologic factors but the *basic mechanism* of ulcer production (gastric and duodenal) evidently consists in disturbances in normal, mural, arterial blood circulation. Such disturbances occur almost universally in the walls of the stomach or the duodenum but only when they prevent free arterial blood-flow to a segment—large or small—*which includes the mucosa*, does ulcer follow: then, tissue, dead or lacking some yet unknown protective attribute, undergoes proteolyses and the peptic lesion appears.

The proteolytic agents are numerous but commonly consist of nothing other than normal digestive juices digesting defenseless tissue after the fashion in which they would attack protein as it occurs as part of a meal in the *lumen* of the viscus. Proteolytic agents other than normal digestive secretions have been listed and commented upon. The extent of proteolysis—and, hence, the size of the initial ulcer—is limited by the quantity of defenseless tissue available. Recrudes-

cences occur on a basis similar to the appearance of the initial "peptic" lesion. Thus, it follows, that in extent, persistence, severity and clinical attributes (hemorrhage, obstruction, deformity, perforation) the lesion is more or less "self limited."

In the walls of stomachs and duodenums where the proteolytic process has not involved the mucous membrane and, hence, no ulcer has occurred, usually can be demonstrated by histo-pathologic changes at microscopy and grossly by sight, palpation and transillumination, areas of congestion, tissue-lysis, scar production, deformity, in all respects resembling what occurs in true peptic ulcer, with the exception, however, that mucosal destruction has not developed and given rise to so-called "peptic" ulcer. The mural affection has healed and has been confined wholly to the wall. The older the individual, usually the greater is the number of these mural lesions—"scars"—which can be ob-

served. However, age is not a requisite for the appearance of such changes: in infancy, childhood and youth where local circulatory, neural, muscular or intra-mural localized infections or traumata have occurred, similar tissue defects can be demonstrated; at times they include the mucosa and are the fore-runners of peptic ulcer.

*Seriously and broadly considered, peptic ulcer is not a disease, sui generis. It is a complication of a prior mural defect due to many agents acting to produce arterial, circulatory defects. Whether or not these defects involve the mucosa and then are followed by the ulcer complication is accidental. Evidence is available which proves that the large majority of the human family experiences these mural defects but that such never include the mucosa and, hence, the large majority of the human family never develops peptic ulcer.*

Frank Smithies.

## SECTION IX—Book Reviews

(This section is open to contributions from any medical reader, whether a member of the Editorial Council or not).

*The Patient and the Weather, Vol. 2, Autonomic Dysintegration*, by William F. Petersen, M.D., with the assistance of Margaret E. Milliken, S.M. Published by Edwards Brothers, Inc., Ann Arbor, Michigan, 1934. 530 pages, 8½x11¼, price \$6.50.

FOR many reasons, this is a very interesting volume. In the first place, it is the most beautiful example we have seen of the new method of reproducing a type-written manuscript. The result is so satisfactory that it is to be hoped that in the future more books will be produced in this economical way. It would make possible the publication of many highly technical monographs which for economic reasons cannot now be printed in the usual way.

This is the second of a series of four volumes. The writer's thesis is that most diseases of the body are influenced by the weather. Wisely he admits, on the first page, that "other interpretations are possible and indeed probable. Seldom is one environmental factor alone responsible in a mechanism so complex as the human body. We deal with a constellation of events—but in this constellation of events the meteorological environment is probably the most important."

Dr. Petersen frequently uses the term "autonomic dysintegration" which may perhaps prove useful in the future. It may be an apt way of describing what takes place in many now poorly understood diseases. There is much evidence also in favor of the idea that many distressing upsets in health appear when they do because the patient is passing through a certain phase of one of many cycles which normally take place in the body chemistry. These cycles seem to be much more marked in females than in males. It is an impressive thing to go into a laboratory such as Slonaker's at Stanford or Richter's at Johns Hopkins where the movements of scores of white rats are being recorded every hour of the day and to see the remarkable peri-

odic variations in the activity of the females. Similar cycles of various kinds have been found in women, and it does seem reasonable to suppose that an attack of migraine or paroxysmal tachycardia or an epileptic seizure should coincide with some phase of one of these cycles of metabolism.

It has been known for ages and it has been shown scientifically by Rowntree and others that in some persons painful attacks of arthritis come with certain changes in weather, and it seems reasonable to suppose that careful study would show that other diseases are similarly influenced. Most openminded physicians are likely to feel receptive to such a thesis, and they would be interested to see what could be done in the way of proving it. Unfortunately, it has not been easy in the past to correlate arthritic pains with any particular meteorologic change. The impression the reviewer has had is that the body answers to some change in its surroundings which are not yet being detected or measured by any meteorologic instrument.

Even a cursory inspection of the volume before us will show that Dr. Petersen has attacked his problem with tremendous energy and perseverance. He has gathered and graphed an enormous mass of data, and one wonders how any one man could have read so widely and done so much research in so many fields. The cost also of the blood chemical work done must have been tremendous. For instance, on page 462, one finds 17 curves plotted one above the other, besides six meteorological records. The experiment was carried on daily from the 20th of April until the 15th of July on a patient with arthritis. Anyone who has ever attempted to carry out such a study knows what a time-consuming and costly job it is, and how large a force of laboratory helpers it requires.

Unfortunately, we fear the reader will feel rather appalled at the plethora of material. Certainly the reviewer feels that it would be impossible for him to ap-

praise the value of the volume or to form a safe opinion of the correctness of the author's theorizing unless he could spend several weeks analyzing the curves and studying the text. The reviewer's feeling is that the author would have created a much better impression and would have had many more readers and much more examination and discussion of his views if he had not offered so much material and had not claimed so much for so many diseases. It seems also as if he should have, in each case, briefly pointed out what the graphs show or prove. The reviewer fears also that in many cases the experiment was too short to prove much. Dr. Petersen presents scores of short charts showing that an attack of this or that occurred coincidentally with some meteorological event, but the reader must wonder if it would do this several times running, and would it fail to do so with the opposite type of weather?

We all tend to remember our hits and to forget the misses, and nowhere is this tendency more dangerous than in a work like this.

Another thing that throws doubt on the value of the book and makes it less easily read is the inclusion of many subjects which one does not expect to find here. For instance, it is hard to see what eclampsia and premature delivery have to do with weather. It is possible, as Dr. Petersen says, on page 204, that the weather precipitates attacks when the individual is conditioned by certain meteorological conditions, but it seems to the reviewer that a wise man would not dilute his best arguments by including a lot of weak and unlikely and unconfirmed theories. He who expects to have his writings read, especially in these busy days, must be brief, and must leave out everything that is not pertinent to his subject.

The reviewer has the feeling that Dr. Petersen's book is a wonderful quarry in which one might profitably dig. A better salesman would have taken out of this quarry his most beautiful bits of marble and placed them in logical order and clearly labelled in a small booth by the wayside where every passerby could see them with ease. It is one of the tragedies of this world that some of the hardest workers in science, men sometimes with unusual and original minds, and an enormous knowledge of the literature, fail to get a hearing or to influence the work of their fellows, simply because they write up their results so poorly or so unsystematically, or so vaguely, or so verbosely, or with such an admixture of chaff that other men throw up their hands in despair and say, "He is doubtless a genius and there is probably much in his writings which is of value, but I haven't the time now to search through his papers to see what is there." Such a man ought to stop every little while and get a trained editor to sit down with him for a week or two to put his writings into easily understandable form. He should get some one to show him where he is leaving out large gaps in his descriptions of work done, or gaps in his reasoning, to interpret him to the public, and to keep him from filling his papers with material which, although of interest and perhaps well enough written, does not belong where it is, and only brings confusion and boredom to the reader.

In spite of anything unfavorable that may be said of the plethora of data in this book, this reviewer has been sufficiently interested by it to hope that Dr. Petersen will supplement it with a shorter essay, based on his great work, and having as its purpose evaluation and interpretation.

Walter Alvarez, Rochester, Minn.

#### *Preview of Dr. B. B. Vincent Lyon's "Atlas"*

IN the Scientific Exhibit at the recent meeting of the American Medical Association we saw one demonstration which should be brought to the attention of our readers who are interested in the very difficult field of microscopy—and its interpretation—of material recovered by duodenal drainage of the biliary tract. We learned that from that exhibit soon there will be available an "Atlas" compiled by no less an authority than Dr. B. B. Vincent Lyon, himself.

This "Atlas" will be purely clinical in motive and scope. Over many years, Dr. Lyon, carefully and assiduously has made photomicrographs of characteristic and unusual cellular, crystalline, infectious, parasitic, etc., sediments and has correlated them with clinical and pathologic data. The scope of the work is tremendous. Practically every known gall-bladder and biliary tract condition has been covered. Most faithful photomicrography has been done. The advance sheets of this work reveal a series of actual photographs of the greatest interest and value. The accompanying descriptive text has been written by Dr. Lyon from the data in his own and others' archives; it presents a mass of really authoritative information compressed into an extremely brief space.

According to the schedule now set, Dr. Lyon's "Atlas" will not be available for distribution for about three months because of the immense amount of work required to make and mount the microphotographs (each is an "original") and to group and bind them in logical clinical sequence. What such a "different" Atlas can be sold for, of course, is problematical. In any event, the number of Atlases issued of necessity will have to be limited, since each volume is almost entirely hand-work. It is to be hoped that the cost per volume can be kept as low as twenty-five dollars: certainly, at such low price, it is our opinion that the books which become available, eagerly will be spoken for by clinicians who wish to do biliary tract drainages scientifically and purposefully. Even at double the mentioned price (no profit can accrue to the Author at such charge) the proposed Atlas will pay the purchaser big dividends on the investment.

Our profession could benefit greatly from the type of publication proposed by Dr. Lyon: what all of us need is not text-heavy books, largely constructed as "compilations" and illustrated by pictures as familiar to us as are those in the "Jack-and-Jill" books of our childhood. We need before us those facts, observations and data upon which important clinicians actually depend in their day-by-day diagnostic and therapeutic efforts.

Frank Smithies, Chicago.

## SECTION XII—"The Clinic"

### Typical and Atypical Terminal Ileitis

By

A. GALAMBOS, M.D.\*

and

W. MITTELMANN, M.D.

NEW YORK CITY, NEW YORK

**T**ERMINAL ileitis" or "regional ileitis" designates a condition described in 1932 by Crohn, Ginzburg and Oppenheimer as a "non-specific granulomatous inflammation of the terminal ileum."

The disease is a well defined ulcerative enteritis, in the greatest majority of the cases restricted to an average extension of about ten inches of the terminal portion of the ileum. This process is followed by a disproportionately marked chronic inflammation or connective tissue reaction in the covering submucosa, muscularis and serosa, producing a striking thickening of the wall of the gut, with a subsequent narrowing of the lumen, which results in stenotic or even in obstructive symptoms. The involvement of the serosa leads at times to ascites, more often however to an adhesion formation between the ileal coils, or between the small and large intestines as well as between the intestines and abdominal wall. The very marked tendency to a characteristic fistula formation, producing communicating fistulous tracts among the organs involved, viz.: the ileum, colon, abdominal wall, retroperitoneal tissue, should be emphasized.

The granulomatous infection secondarily involves the mesenteric glands. The thickened, strikingly infiltrated mesentery acts like a retroperitoneal mass, fixating and inhibiting the free peristaltic movement of the thickened ileum, huddling it into a mass, producing the manifestations of an apparent adhesion, when, often there is no peritoneal adhesion actu-

ally present. It is instrumental in producing outside of adhesions, secondary break-downs of the tissues, suppuration, retro-and intra-peritoneal abscesses and fistula formation.

The underlying pathology may lead to a palpatory finding of an indefinite resistance, or of a large inflammatory tumor in the area involved.

The macroscopical appearance and the microscopical histological findings in the resected specimen are uniform and pathognomonic, often only *per exclusionem*.

The X-ray examination reveals more details and characteristic hints than does the physical examination. In well defined cases, the diseased area is marked by a large filling defect, with a typical "string-sign," representing the direct visualization of the stenosed lumen of the terminal ileal coils. Fistulous tracts may similarly give a resemblance to the string-like appearance on the films.

The main points in the history of the case are: the age of the patient, the protracted course of the disease, diarrhea, undefined pain, occasional fever, slight leukocytosis, secondary anemia, tendency toward fistula formation, failure of previous appendectomies to improve the condition.

It is interesting to note that practically all the patients who came under observation were young adults. The question arises as to the fate of these patients as they arrive at old age. If we disregard the quite improbable outcome of a complete resorption, except probably in its earliest stage, one is forced to the conclusion, that all these patients die before reaching old age.

*Early recognition* of the condition is urged, because early diagnosis followed by adequate surgery (resection), leads, as a rule, to a cure, while a failure to recognize the disease results in chronic marasmus, leading eventually to a fatal outcome.

*Incorrect diagnosis*—as the history of most of the cases proves—often leads to unnecessary appendectomies, failing to afford any relief to the patient's condition, in fact, often preparing the way to a secondary fistula formation.

One of the causes responsible for the failure to recognize the ailment, in our opinion is due to the fact, that the X-ray examination of the ileocecal region is performed routinely, six hours after the barium intake, . . . at a time when the terminal ileal coils in that particular area are as a rule empty already. The X-ray examination will reach no conclusion, and "negative findings" will be reported.

Instead of the routine X-ray examination with a fixed standard time of six or twenty-four hours, it would be more correct to have an X-ray study instituted using varying time intervals, and varying technic, dictated by the individual needs of the case. As an instance in both of my cases the routine six hour examination produced diagnostically irrelevant pictures. In the first case, the films taken two and three hours after the barium intake, in the second case the thirty-six hour pictures proved to be most decisive and diagnostically most important. As a rule, the two, three or four hour exposures will prove to be of the greatest value.

\*Formerly Associate in Medicine, Royal Hungarian University of Sciences, Budapest.  
Submitted March 30, 1935.

The disease does not seem to be extremely rare. Crohn reported in his first series in 1932 about 14 cases; two years later the number of cases referred to was 42. Kantor mentions six cases in his paper. We ourselves diagnosed terminal ileitis in the last ten months, three times. Two of this series already underwent an operation and the operative and pathological findings proved the correctness of the diagnosis.

In all of our cases diagnosis has been made pre-operatively, in fact, in the first case strong suspicion has been expressed for this diagnosis, even before the X-ray examination has been performed.

### CASE REPORTS

Case 1, refers to a 42 year old white female, first seen at my office the 13th of March, 1934. She had diarrhea, of 15 years' duration. Her disease had a slow onset, and a slow progress. She had 3-4-5 mushy bowel-movements daily, without a noticeable admixture of pus, mucus or blood. She had no tenesmus, but she noticed an occasional periumbilical griping pain during defecation.

There was a more marked loss of weight during the last two years. She was beset by chills and fever (to 102 F.), of a few days' duration, once in every few months. Her general feeling during the intervals was quite satisfactory. Her doctor diagnosed these febrile attacks as "grippe." Her loss of

where appendectomy has been performed. Patient remarks, that according to her surgeon's description the appendix removed has been found normal, but he noticed during operation certain unusual puzzling anomalies over the small intestines. The latter looked "swollen," like "sausages," or, resembling typhoid intestines. Between the appendix and sigmoid, retroperitoneal abscesses were found. They were opened and drained. Patient left the hospital after three weeks, and felt all right for the next three months, when the surgeon had to open the abdominal wall and drained externally an intestinal fistula. Patient felt generally comfortable as long as the fistula drained freely, but, as soon as it became blocked up, symptoms appeared. The surgeon had to intervene four more times to reconstitute and assure free drainage.

Her history was otherwise irrelevant.

On physical examination the abdomen showed spontaneous tenderness, which increased either upon touch or on examination even through the vagina or rectum. In the right lower quadrant there was a large indefinite mass palpable. The extreme sensitiveness of the abdomen decreased the following day, after the fistulous tract—incidentally just blocked—opened spontaneously, and drained pus again, freely. Presence of post-operative scar and fistulous tracts completes the findings over the abdominal wall.

Urine contained traces of albumen, with a negative findings in the centrifuged sediment. Feces gave slightly positive reaction for occult bleeding (Weber test). Hemoglobin was 58%. White blood count was 15,500, with 88% polynuclear, 7% large mononuclear cell, and 5% lymphocytes. The temperature on the first day of examination, when the fistulous tract failed to drain, was 102° F. The following day, after it broke open, temperature dropped to normal, pain subsided, white blood count fell to 14,000, with 72% polynuclear, 8% large mononuclear cells, and with 20% lymphocytes. The discharge consisted of a copious, odorless, thin and purulent material.

On account of this unusual history and physical findings, strong suspicion has been expressed as to the possibility of a terminal ileitis, and the subsequent X-ray examination served to substantiate this *a priori* diagnosis.

The X-ray examination of the gastrointestinal tract revealed the stomach, duodenum, jejunum and colon to be normal. All the pathology present was confined to the ileum.

The right lower quadrant of the abdomen was grossly characterized by a large filling defect of the ileal coils. The "string-sign" (Crane-Kantor) was demonstrated on all the films. It was interesting to note that the very last portion of the ileum in a length of 1-

Fig. 1. Case 1. Terminal Ileitis. Typical case. Two hour film. Note the "string-sign" (arrow) and the "filling defect" in the ileocecal area. (Other parts of the G.I.T. are visualized by previous Ba. intake).

weight during the last 6 months was between 20 and 25 lbs.

On the 29th of July, 1933, patient was suddenly taken severely ill, with chills, fever and periumbilical pain and was rushed to a Brooklyn hospital,

Fig. 2. Case 1. On both the upper and lower films, the "string-sign" and the "filling defect" manifest marked similarity to the picture of the previous figure. "String-sign" (arrow) proved at operation to be the direct visualization of a narrowed ileal lumen and not an ileocecal fistula. All other pictures are nearly identical.

1½ inches was visualized as fairly normal. The proximal loops were not visibly distended. The 6 and 24 hour pictures were "negative," i.e. no visualization of the terminal ileal coils, nor of the proximal loops was demonstrated, evidencing the absence of an ileal obstruction. Films taken 2 and 3 hours after the barium meal proved to be the most convincing, visualizing the narrowed intestinal lumen ("string-sign"), with an otherwise failing filling of the other ileal loops (Stierlin's sign).

On re-operation, a sixty (60) inch portion of the terminal ileum, the cecum and two-thirds of the ascending colon have been removed, and an anastomosis between the ileum and the middle of the transverse colon instituted. The removed small intestine's wall was very thick, and its lumen greatly narrowed. No abscess was found at that time. The external fistula led into the ileum, four

inches above that valve of Bauhin. The string-sign proved to be a narrowed ileal lumen, and not an ileocecal fistula.

Patient made an uneventful recovery, and is today, ten months after the heroic operation, in perfect health.

Case 2, a female, white, aged 45, who was referred to me by Dr. Bela Mittelman, on the first of December, 1934.

Her symptoms started eight years ago, with pain in the right lower quadrant of the abdomen. An operation for appendectomy in 1931 failed to relieve her suffering of years' duration. According to the description of the patient, the surgeon upon opening the abdomen was puzzled by certain unusual adhesion around the small intestines and the ascending colon. In the following year (1932) patient suffered from severe "heart-burn" during a period of two months. Then she was seized by severe abdominal pain, which after a few days' duration terminated with a gastric hemorrhage and melena, the latter allegedly present for two months. Patient, thereafter, has been taken to a leading hospital for a thorough examination, including an X-ray study of the gastro-intestinal tract. During a stay of eleven days no peptic ulcer has been found, and no definite diagnosis has been stated. Ulcer diet (Sippy's), and ulcer treatment, instituted several times always proved of no avail, in fact, the patient felt worse under strict regime.

Subsequent condition of the patient in the following period until six months ago was satisfactory. In September, 1934, she was seized by severe abdominal pain, necessitating her confinement to bed for a week or so. Ever since patient never felt quite well. She was losing weight in the last six months between 20 or 25 lbs. She felt a burning sensation in the throat, bad taste in the mouth, had anorexia, occasional vomiting, diarrhea, or a tendency thereto, with two or three mushy stools daily.

Physical examination was irrelevant, except for a moderately tender resistance felt in the cecal region.

Gastric analysis revealed complete achylia gastrica.

X-ray examination of the gall-bladder showed normal shape and function of that organ.

X-ray examination of the gastro-intestinal tract revealed normal stomach, duodenum, jejunum and colon. No signs of a chronic peptic ulcer has been detected. The pathology found referred solely to the ileocecal region. The ileal coils huddled into a mass, in the right iliac fossa, showed upon repeated examination, even on the 36 hour films, the picture of a permanent visualization, nearly identical on all the films. A very marked motor delay, pointing to the presence of an obstructive process

Fig. 3. Case 2. Atypical terminal ileitis.

Left upper. Nine hour film, taken in prone position. Terminal ileum and cecum huddled in one mass (arrow). No separate coils visualized.

Right upper. Nine hour film, taken in prone position. Upon the application of compression to the ileocecal region, some of the terminal ileal loops are separately visualized as definitely dilated (arrow).

Left lower. Thirty-six hour film, taken in prone position. Note the marked kink and angulation of the cecum (arrow) and a certain irregularity in the outline of the cecum and ascending colon. Terminal ileum is still barium filled.

Right lower. Thirty-six hour film, taken in prone position. After cleaning enema a partial barium retention in the terminal ileum is still noticeable. Note the hazy, still definite separate visualization of some of the narrowed lumen of the terminal ileum (arrow).

at or around the ileocecal juncture was demonstrated.

Compression applied to the right iliac fossa, with the patient in recumbent position, failed to separate the ileal coils, and it was only occasionally possible to recognize some of the loops as markedly dilated, among the majority of the hazily visualized and pathologically narrowed ileal coils.

The cecum showed certain irregularities of its haustration and there was a definite kink and angulation of the deformed, fixated, angulated and hyperdescendent cecum visible.

We made the diagnosis of *terminal ileitis with a superadded incomplete ob-*

*struction through adhesional bands around the ileocecal juncture.*

The operation performed proved the presence of a terminal ileitis involving the last ten inches of that gut with a striking infiltration of the mesenteric glands. Adhesions as assumed were present in the form of isolated cord-like bands, constricting but not strangulating some of the loops of the terminal ileum. Some adhesions extended between the cecum and the wall of the lower abdomen.

The mesenteric fat tissue exuberantly invaded, nearly completely covered the entire portion of the involved terminal ileum. The latter, in an extension of about ten inches, looked heavy, red-

dened, darker, thickened, sausage-like, in sharp contrast to the adjoining normal ileum.

The heavily infiltrated glands coalesced into solid masses as one would find them in Hodgkins disease or in typhoid fever. The thickened and shortened mesentery fixated and nearly immobilized the terminal ileum.

Patient made an uneventful recovery and left the hospital two weeks after the operation, in good health.

Excerpts from the report of the pathologist (Dr. A. Shifrin):

"Gross specimen consists of a resected portion of ileum, measuring 25 cm. in length. . . . . At a distance of approximately 6 cm. of the proximal end the *valvulae conniventes* are distorted. The next 7 cm. are occupied by a lesion which is stellate in appearance, showing superficial and deep furrows in the mucosa. The latter is markedly edematous, thickened and indurated. It is not stony hard. The impression is that the mucosal surface is intact. The edges of this area are not indurated. There has apparently been stenosis at the site of stellate scarring. . . . . A second area with a very slight induration is found 9 cm. from the distal end. The mucosal surface is ulcerated, granular and slightly indurated. At a distance of 2½ cm. from the distal end there is a mucosal polyp which is delicate, reddened and measures 1 cm. by 0.3 cm. . . . .

*Microscopic study:*

. . . . . In places the mucosal epithelium is necrotic and ulcerated. The surface is in these places delimited by the exposed submucosal stroma. The latter is highly cellular, consisting mainly of plasma and roundcells. Polynuclear leukocytes are present but not in large number. There is edema. Numerous young fibroblasts and prominent reticulum cells are seen. This cellular infiltration in the main is well marked in the superficial portions of the mucosa, but it penetrates distinctly into the submucosa and even in places to the interstices of the muscularis. . . . . The submucosa shows aggregations of lymphocytes into follicles. Secondary lymph follicle-formation and reticulum cell hyperplasia is also observed. There is a striking hypertrophy of the smooth muscle tissue both in the mucosal and internal and external layers. Fibrosis is present but not marked. In places the cellular infiltration of the mucosal stroma has given a polypoid appearance to the mucosa.

It is of note to observe the absence of (1) caseous necrosis, (2) giant cell reaction of either the foreign body or Langhans' type of cells, (3) epithelioid tubercle formation, (4) mononuclear changes within the lymph follicles or hyperplastic inflammatory areas.

Diagnosis: subacute and chronic ulcerative regional ileitis."

## FOR PEPTIC ULCER A REVOLUTIONARY TREATMENT

## The Practice « of Dietetics »

By L. H. Newburgh, M.D.,  
Professor of Clinical Investigation, Medical School  
University of Michigan;  
and Frances Mackinnon,  
A.B., Dietitian, Diet Therapy Clinic, University Hospital,  
and Instructor, Dept. of Hygiene and Public Health,  
University of Michigan.

### Comments of reviewers—

"This is a very complete and scientific text and reference book on dietetics. The book will be of greatest value to the physician, the dietitian, and the medical student."

*The Forecast*

"In this book the place of dietetics and diet therapy in medical therapeutics is discussed in a manner that gives the reader a clear picture of its importance, and, at the same time, impresses him with the need for a sane point of view in its practice."

*Practical Home Economics*

"This book contains all the material necessary for the practice of dietetics. It is both didactic and practical. Dr. Newburgh writes as he practices; so direct, clear, and yet scientific that even the student or busy practitioner can understand."

*Long Island Medical Journal*

## DISCUSSION

The first case shows a clear-cut, a typical instance of terminal ileitis. The history and the physical examination alone nearly assured the diagnosis, which has been completed by the characteristic X-ray findings and proven by surgery and the pathological examination of the resected specimen.

The second case, in contrast to this represents an *atypical appearance of terminal ileitis*. In this case, the history was by no means typical, it was probably more indicative of an obscure case of a milder sprue than of terminal ileitis. As we have seen, the physical examination proved likewise insufficient to substantiate the diagnosis. A careful X-ray study was necessary properly to diagnose the case. This showed a 36 hour retention in the terminal ileal coils. Motor power insufficiency in itself can not be considered pathognostic for regional ileitis. This can rather be encountered in any disease or condition causing stenosis or obstruction strictly distal from visualized gut.

The following may give an approximate idea what lesions might have come into question from the view point of a differential diagnosis: post-operative adhesions; appendicular and peri-appendicular abscesses; chronic appendicitis with adhesions, kink, angulation; right lower quadrant pathology: tubo-ovarian tumor, cyst, inflammation, abscess; tuberculosis: of the ileum, cecum and peritoneum; lues: gummata or glands; actinomycosis; carcinoma, primary or rarely metastatic; sarcoma; lymphosarcoma; benign tumors: lipoma, fibroma, myxoma; lymph gland enlargements: Hodgekins' disease, leukemia, or rarely: lymphogranulomatosis, reticulosis, foreign body granuloma; carcinoid, mucocoele or lymphoma of the appendix; congenital Jackson's membrane; Meckel's diverticular tumor, cyst, inflammation or strangulation through its rudimentary ligamentous band; localized idiopathic dilation of the ileum; multiple diverticula of the cecum with concretion; accumulated foreign bodies swallowed by the insane and at last terminal ileitis.

Our reasons for arriving at the diagnosis, as aforementioned, are the following:

We assumed the presence of adhesive bands for the following reasons: (1) the cecal angulation as evidenced on the film; (2) failure to

separate and individually clearly visualize the terminal ileal coils (which would point to the probability of the presence of adhesions among these loops); (3) the findings of adhesions during the previous appendectomy; (4) the well known tendency of terminal ileitis to develop postoperative adhesions.

If only such adhesions were present, then, the proximal loops would be all compensatorily dilated. The case not being so, we had to assume the presence of additional factors.

We assumed the presence of terminal ileitis on account of the following facts: (1) the process seemed to be strictly localized to the terminal ileum; (2) presence of adhesions, characteristic of this condition; (3) presence of both dilated and narrowed loops; the latter proving the intraluminal stenosis in the terminal ileum—a direct visualization of the narrowed lumen—loops of the former were pre-stenotic compensatory dilations. The visualization of the stenosed lumen, in the case of terminal ileitis, where the filling defect or the local hypermotility of the diseased gut (Stierlins' phenomenon) is the rule, would definitely point to the fact, that the motility of the diseased stenotic loops is impaired by some mechanical obstacle encountered at its distal edge. *Narrowed lumen proves intraluminal stenosis; its visualization points to the presence of some motor disturbance due to certain organic obstruction distal to the point*; (4) the visualization of the separated loops—whenver feasible—is not sharp because of the overlapping of the loops and the small barium content in the narrowed lumen, with a simultaneous heavy fibrotic thickening of the intestinal wall, and the presence of non-opaque adhesions; (5) absence of most of the typical symptoms of the diseases enumerated above; (6) relative frequency of the terminal ileitis; (7) data referring to the patient's age, to the protracted course of the disease, lack of cachexia, diarrhea, etc.

Though it seems to be fairly safe to assume that the terminal ileitis existed primarily, and the adhesions developed thereafter, the assumption of the reversed mechanism seems, however, not perfectly excluded. A congenital adhesion, like the remnants of a Meckel's diverticulum, may produce kink or strangulation, thereby circulatory and motor power disturbances, causing chronic irrita-

tions of the tissues in some of the intestinal loops. Like a chronic, un-specific granuloma may develop as a result of a chronic irritation due to the presence of a foreign body, or a specific granuloma may develop as a result of a chronic irritation brought on by bacterial or toxic agents as in tuberculosis, lues or actinomycosis, likewise, a primary adhesion with all its chronic irritative effect might occasionally produce a non-specific granuloma in the appearance of a non-specific terminal ileitis.

The chronic obstruction at the ileocecal juncture was not a complete one. In such instance the paralytic dilation of the hypertrophied small intestinal coils produces the well known picture of the multiple fluid levels with the gas bubbles thereon, and proximal thereto the small intestinal loops present the picture of the step-ladder or herring-bone appearance, on the X-ray films, which were all absent here.

The 36 hour delay as was observed in this case is unusual and atypical in terminal ileitis. Crohn, also Goldfarb, found the ileal coils on the 6 hour films usually empty. And that is the rule.

One should not lose sight of the fact that the content in the ileum is still liquid, and as a rule, it does not require much compensatory hypertrophy of the proximal loops to overcome the mechanical obstacle produced by the narrowed lumen in the terminal ileal coils. For that reason there may be no motor delay in the ileum as evidenced on the X-ray films. If there is any—as there was in our second case—there must be some additional factor responsible for this phenomenon, as was proven in this case by the adhesion around the ileocecal juncture.

Lastly, it should be recalled that an ileal retention rarely may find its explanation by the presence of either a pyloric stenosis, or a cecal regurgitation (Jordan) without an anatomical obstruction at the ileocecal region.

### CONCLUSIONS

Two cases of terminal ileitis are reported, a typical and an atypical one. In both cases pre-operative diagnosis was made.

In the atypical case a 36 hour delay was demonstrated in the terminal ileum, due to the complicating effect of adhesions around the ileocecal juncture.

Both cases recovered after a successful resection of the diseased area.

Failure to recognize the ailment early, is partly due to a faulty or unsatisfactory "routine" X-ray technic.

Early diagnosis is urged because a correct diagnosis followed by appropriate surgery offers an unusually good prognosis, with a permanent cure, while a failure to diagnose the case means chronic marasmus, with perhaps a fatal outcome.

## TILDEN has Kept Faith with Physicians

## ELIXIR MALTOPEPSINE (Tilden)

IN conditions involving gastric and intestinal upsets, as a dietary aid, and as a palatable vehicle for prescriptions carrying Iodides, Salicylates, Nux Vomica, etc., physicians have prescribed MALTOPEPSINE (Tilden) for a good many years.

MALTOPEPSINE (Tilden) includes DIOSCOREIN, LACTIC ACID, DIAS-TASE and PEPSIN, with acidic and other ingredients, combined in a manner exclusive with Tilden.

An elegantly flavored fluid, MALTOPEPSINE (Tilden) may be used freely.

Physicians have established the prescription specialties of Tilden, one after another, by nearly a century of practical experience.

Correspondence from physicians is respectfully solicited.

## Insulin-Glucose Therapy in Coronary Thrombosis

By

GERALD J. KOHNE, M.D.

DECATUR, INDIANA

THE following case is reported to emphasize the benefits of insulin-glucose treatment in coronary disease.

### CASE REPORT

The patient, 73 years old, male, has suffered for 8 years from sub-acute, combined degeneration of the spinal cord, during which time he has continually taken liver therapy in high dosage. For many years he has also had a severe pyuria due to a resistant chronic pyelonephritis.

His gastric analysis gave the following results: Material mucoid; total acid 5°, free HCl 0°; blood: none. At first he had a blood picture characteristic of pernicious anemia, but, since he has faithfully followed

Submitted July 1, 1935.

the liver therapy, no further anemia of any kind has been present. Locomotion, gait and balance were partially interfered with by the cord changes but the latter never progressed to a complete paralysis. His blood pressure always has been low, 100 to 138/65 to 80. The radial arteries have been noticeably sclerosed for years; the aorta prominent in chest films, the heart normal in size and shape.

Early in October, 1934, while raking leaves from his lawn, he felt a sudden pain over the sternum, this was referred to the left shoulder. For several weeks he regarded this a "neuritis" and did nothing about it. The patient consulted me on Nov. 12, 1934; a diagnosis of coronary thrombosis seemed justifiable. No friction

sound was heard but the electrocardiogram made at this time showed a definite "coronary" T wave in leads I and II (Fig. 1).

He was given 50 c.c. of 50 per cent glucose intravenously daily for 9 days, each dose containing 5 units of insulin. Quite marked general improvement occurred and there was considerable decrease in the amount of cardiac pain.

After keeping the patient in bed for 8 weeks, and contributing theobromine sodium salicylate Gr. V., after each meal, he appeared to be well again. At this time another electrocardiogram was made, and it will be noted that the T wave in lead II had become positive (Fig. 2). The man was permitted to be out of bed and gradually to resume his customary light duties. He has remained comfortable since.

#### SUMMARY

An instance is reported in which it is believed that the use of an insulin-glucose solution, given intravenously, greatly hastened improvement of an affection diagnosed (from history, physical examination and electrocardiographic studies) as coronary thrombosis.

## SECTION I—*Clinical Medicine: Diseases of Digestion*

### Acute Pancreatitis: a Clinical and Pathological Study, with Personal Observations

By

ALBERT LE SAGE, M.D., F.R.C.P. (Canada)\*

and

JEAN R. A. LE SAGE, B.A., M.D.†

MONTREAL, CANADA

**E**VEN at a casual glance, one cannot but be struck by the singular situation occupied by the pancreas in the abdomen. Indeed, this organ seems to covenant indissoluble alliances with the surrounding organs. It is connected with the general circulation by the blood vessels by which it is abundantly irrigated: the aorta, the pancreatic or duodenal artery, the splenic vessels and the portal system. It is encompassed by a vast network of lymphatic vessels with a centrepetal direction, and is accompanied by a mass of ganglions disseminated here and there, thus keeping it in close relations with the digestive tract, the appendix, the gall-bladder, and most of the organs located within the large cavity of the epiploön.

The head of the pancreas is set in the internal curvature of the duodenum, the second part of which receives the common duct with its orifice, the Vater ampulla provided with the sphincter of Oddi.

Its posterior surface rests on the spine against the third lumbar vertebrae, in the neighborhood of the solar plexus. It is a tubulo-alveolar gland with two secretions:

(a) *An external secretion* comprising ferments of which one, trypsin, has the action of breaking down the albumins whereas other ferments saponify fats such as lipase or, like amylase, convert the starches into maltose. Trypsin and lipase play the leading rôle in the question.

(b) *An internal secretion* originating from the Islets of Langerhans: insulin.

These elementary observations upon anatomy and physiology are useful to bear in mind.

#### ETIOLOGY

To simplify this *exposé*, let us admit that acute pancreatitis will be studied according to two forms: the septic, and the aseptic.

##### I. THE SEPTIC PANCREATITIS:

We shall deal briefly with the chapter of the septic form, as most authors point out the presence of well

known bacteria in more than half of the cases (those of peripancreatitis, or the pancreatitis with suppuration). All infectious diseases may give birth to acute pancreatitis: the organisms are carried by the blood vessels or the lymphatics, in other cases by the biliary tract, the duodenum, the neighboring organs, or may be the bacteria contained in the pancreas itself.

Fig. 1. Relations of the pancreas with the neighboring organs. The vascular system is easily recognized: the aorta in the center; above and at the left, the hepatic artery, the hepatic duct, the gastro-epiploic and pancreatico-duodenal arteries. At the bottom: the mesenteric artery, the duodenum, spleen and the kidneys. (Sobotta)

Let us mention some of the causes and ways of access to the pancreas:

1. The lymphatic system;
2. The blood stream;
3. The biliary tract, the duodenum, from which the septic secretions penetrate into the pancreatic ducts;

\*Professor of Clinical Medicine, U-niversity of Montreal.

†Chief Gastro-Enterologist, St. Luke's Hospital, Montreal.

Submitted July 29, 1935.

Fig. 2

4. Contamination due to a focal infection of the neighboring organs;
5. The increase of bacterial virulence (intracanalicular or intraglandular).

The arterial and canalicular theories are generally admitted by the majority of authors, but the theory of the lymphatic origin often is questioned. Some authors assert that the lymphatic system plays no rôle in the affections of the pancreas; whereas others, on the contrary, relying upon serious experimental research, claim to have succeeded in demonstrating the importance and frequency of this origin in relation with acute pancreatitis.

Both groups of oppositionists quote very illustrative experiences as a basis for their opinions.

Still, we believe in the rôle of the lymphatic "paths" of access of the infection in acute pancreatitis, because of the most intimate connections between the liver, the gallbladder and the duodenum, even the caecum, and the pancreas; moreover one should not entirely place reliance upon the experimental methods upon animals as applying to human pathology.

## II. THE ASEPTIC PANCREATITIS:

In order to facilitate their study, a subdivision is necessary:

### (A) The acute idiopathic pancreatitis:

1. The pancreatitis with oedema;
2. The pancreatitis with hemorrhage;
3. The gangrenous pancreatitis.

### (B) Acute pancreatitis with cancer;

### (C) Acute traumatic pancreatitis (?)

This division embraces most of the cases, with their various agents:

1. The mechanical origin (due to a stagnation in the bile ducts);
2. The chemical origin, due: (a) either to an over-

Fig. 2. Of the pancreas showing: 1, the alveoli; 2, the intra-lobular ducts; 3, the interlobular ducts; 4, the intra-lobular vessels and the nerves. (William Hinton, "Chronic Pancreatitis as a Clinical Entity," in Surgery, Gyn. & Obst.)

activity of the pancreatic ferments mixed with bile, or (b) to duodenal secretions or focal degeneration of the biliary and pancreatic ducts; (c) or due to autodigestion;

### 3. The degeneration of the pancreas:

- (a) Secondary to a malignant tumor;
- (b) Secondary to a vascular rupture, viz: due to an hemorrhage by stasis, arteritis, etc.
- (c) Secondary to a general intoxication;

### 4. Secondary to a traumatism (including the operative shock).

## PATHOGENESIS

According to what mechanism do these different forms of acute pancreatitis appear?

1. *The mechanical origin:* would be due either (A) to a stagnation in the biliary tract or (B) to the penetration of the duodenal secretion into the pancreatic ducts through an inadequacy of the ampulla of Vater, or by a retrograde path through the *ductus Santorini*, deprived of its sphincter.

(A) *The stagnation of the bile in the ducts* may take place either because of a gall-stone lying in the ampulla of Vater, or on account of an hyperacidity of the duodenal secretion with stasis producing a contracture of the sphincter of Oddi, which theory is well grounded on experimental and clinical facts in both cases. According to some authors, we are concerned with an abnormal elevation of the intracanalicular pressure followed by a flow of bile into the pancreas.

The pathogenesis of pancreatitis in the case of an obstruction caused by gall-stones in the ampulla of Vater, rests not so much on the intra-canalicular pressure as on the intermixing of the biliary and pancreatic secretions, giving rise to chemical transformations and to a true auto-digestion soon followed by an hemorrhage and necrosis of the organ. Normally the gland itself cannot be destroyed by the pancreatic ferments

Fig. 3

Fig. 3. A descriptive schema showing several anatomical causes of Acute Pancreatitis: 1, the duodenal pathway to the Wirsung duct; 2, through the Santorini duct; 3, through the biliary ducts; 4, the arterial system; 5, infarct following a thrombosis of the portal vein; 6, a traumatism; 7, a duodenal ulcer infecting the pancreas through the lymphatic system. (Schmieden and Sebening)

Fig. 4

as has been abundantly proven by experimental and even clinical research. It has been our privilege to observe an unusual case, where a tumor compressing the Wirsung duct in the very neighborhood of the ampulla of Vater had caused the accumulation of a large quantity of pure pancreatic secretion without the least trace of bile. The pancreas was atrophied, but no steatonecrosis or infarct was found.

Such are the following twin typical observations:

1. *Pancreatitis with oedema*.\*

Case 1. A woman, aged 50, complained of digestive troubles for the last three years with epigastric pains. During the last six weeks aggravation of the pain with vesperal fever ( $39^{\circ}$  C) is observed. Pulse: 140. Upon examination a pain is found with a muscular "defense" in the right epigastric quadrant with an irradiation to the left hypochondrium. Leucocytosis: 11,800, later, 18,000, with 82.5% polynuclear cells.

A diagnosis of acute pancreatitis is made. Upon laparotomy, a yellowish liquid flows from the cavity. Gall-stones are found and the pancreas is enlarged, soft, bleeding copiously. Drainage. Recovery.

Case 2. *Pancreatitis with oedema* (Prof. A. LeSage, Montreal; unpublished): Mrs. V. T., aged 41, complains for two days about an epigastric pain radiating to the right and to the left hypochondria, the right radiation reaching the collar-bone, the shoulder and the back. Several anterior attacks. This time, the pain is so acute that she can hardly breathe. The maximum distress is localized in the epigastrium.

Upon examination, the Murphy sign is positive with phrenic irradiation, the gall-bladder being easy to delimit,

\*Irvin Abel. *Am. Annals of Surg.*, Oct., 1926.

Fig. 4. Secondary infection of the head of the pancreas, following an injection of the ileocecal ganglions. (Braithwaith)

having the shape of a pear, in the epigastrium with a local resistance and a swelling. No stools were available; no gas passed for two days. The face is drawn. The pulse is slightly perceptible, slow at 55. A blood count shows: r.b.c.'s.: 2,000,934; w.b.c.'s.: 15,625; polys: 80%.

In the presence of this severe condition, of most acute pain, we diagnosed *hydropic cholecystitis*, probably with gall-stones followed by a pancreatitis, because of the pain, of its acuteness, its localization, its irradiation to the left as far as the back, and chiefly because of the severeness of the general condition, realizing in brief, a true solar plexus syndrome. Upon operation, the gall-bladder is found congested, much enlarged, containing calculi, and the pancreas exhibits oedema and congestion extending to the entire mesocolon. Drainage. Recovery. The patient, admitted on the 14th of January, 1928, left the hospital on the 17th of February.

This rare clinical observation comes in support of experimental researches published elsewhere.

(B) As much can be said about the spasm of the sphincter of Oddi. Many experimental researches of which those published by Brocq and Morel, from Paris, Flexner in the United States, and Archibald of Montreal, confirm this theory. The latter has succeeded in obtaining an acute pancreatitis with necrosis after injecting in the gall-bladder glyco-sodium taurocolates. Such is the consequence of stasis in the bile ducts that the intermixing of both pancreatic and biliary secretions, followed by a reactivation of trypsin, that finally is produced a brutal attack on the pancreatic gland; thence, an interlobular oedema, a congestion of the vessels, then a rupture, then hemorrhage and a necrosis.

The reactivated pancreatic ferments make irruption out of the gland and soon give rise, under the impulse of the activation of the lipase, to those well-known "candle-spots," known as *steato-necrosis*.

What are the substances activating these two ferments: *trypsin* and *lipase*?

According to the majority of authors who have repeated the experiments of Delezenne, the kinases (en-

Fig. 5

Fig. 5. Relations between the lymphatic vessels of the gall-bladder and the head of the pancreas. (Bartels)

Fig. 6

terokinases or cytokinases) combined with the action of the calcium chloride of the blood, contribute to activate both these ferments, especially trypsin. The transmission of this activation would, in certain cases, give rise to an autochthonous kinase resulting in, (according to Delezenne), a phenomenon of auto-catalysis. In view of preventing this reactivation, this author advises an alkaline lavage of the stomach and the use of fluorate or oxalate of sodium.

However, let us add that a *period of digestion is indispensable before there occurs a pancreatitis with a hemorrhage*, such as an injection of bile into the pancreatic duct, this observation having been well shown in 1913 by Brocq and Morel (1). We shall establish further how clearly this fact is fully confirmed by clinical observations, the attack appearing two or three hours after a copious meal.

**Other causes:** Amongst other causes should be investigated the following ones: cholecystectomy with a compensating dilatation of the biliary ducts associated with a spasm of the sphincter of Oddi, intestinal parasites, of which a typical case, found upon autopsy, is further reported. On the other hand, gastric hyperacidity, leucocytosis, the nervous shock due to an irritation of the solar plexus, either following a compression, or following a painstaking operation, traumatism, contusions, may well be considered eventual causes of pancreatitis, notwithstanding conflicting experiences. Heart disease, prolonged vascular stasis with thrombophlebitis and infarcts are fairly frequent causes of pancreatitis with hemorrhage.

Age, sex, race, pregnancy, obesity, alcoholism, pyloro-duodenal ulcers, appendicitis, range amongst less frequent causes of this affection.

To conclude, perhaps the following order of frequency might be rightly adopted with respect the etiology of acute pancreatitis:

(a) The biliary tract diseases; (b) Duodenal ulcer and stasis; (c) Infarcts; (d) Intoxication; (e) Vascular stasis; (f) Intestinal occlusions; (g) Traumatism: contusion and surgical traumatism; (h) Parasites and all other causes.

Fig. 6. Relations of the lymphatic vessels of the pancreas in man with the territory of the lymphatic ganglions: C: Cardia; Sp.: Spleen. (Bartels), Arch. Anat. of Phys., 1904-06.

## SYMPTOMATOLOGY

1. *Pain* is the capital sign in acute pancreatitis. It is a sudden, violent, tenacious pain, resisting even morphine, reaching from the first its full acuteness. If persistent, it soon becomes intolerable, the location being usually epigastric and supra-umbilical, but sometimes it is hardly possible to localize it with precision. It irradiates chiefly to the left hypochondrium and to the back, oftentimes to the right quadrant and towards the shoulder; in other cases towards the iliac fossa.

The time of pain usually is two or three hours after a copious meal or after abundant libations. The state of digestion plays an important rôle, the clinical and the experimental medicine being in full accord on this point.

2. *Vomiting* is contemporary with the pain, sometimes preceding it; frequently it is very abundant, tinged with blood, but rarely of the fecal type.

3. *The interruption of the bowel movement and the passage of flatus* are inconsistent; they are not so complete as in cases of intestinal occlusion, yielding to an hypertonic sodium chloride enema.

4. *The abdominal signs* are of great importance. Tympanitis with meteorism without local spasm or muscular resistance will be noticed although local tenderness and possible supra-umbilical or epigastric contracture will be revealed chiefly in the pancreatitis

Fig. 7

Fig. 7. Post-mortem injection of the ileo-cecal ganglions and the flowing back of the liquid into the caecum and the head of the pancreas. (Braithwaith, Brit. Med. Journ., 1923)

Fig. 8

Fig. 8. Further aspect of the relation between the lymphatic vessels of the pancreas in man and the territory of the lymphatic ganglia. (Bartels) S: Stomach; Sp. Spleen; C. Cardia; L. Pyloric ganglion.

with oedema. Pain may be induced upon a deep pressure in the pancreatico-duodenal region, whereas; in a few cases a tumefaction is felt.

Apart from the pain element, the investigator will be rewarded in studying the *history of the preceding attacks* ("crisis"), which will be discovered to have occurred in the majority of patients. Such are characterized by more or less frequent *indigestion coinciding with the eating of copious meals*, stopping abruptly, but resembling altogether the later crisis but the last one—that indicative of the acute pancreatitis—is far more severe than prior ones.

5. The *pulse* is feeble and quick, the temperature normal or subnormal, with an impressive "dissoia" with the pulse.

*Polypnea* is observed; *oliguria* is much pronounced with or without glycosuria.

6. *Glycosuria* is considered of great importance for prognosis. If it persists and increases, the prognosis is grave; if it decreases rapidly, the prognosis becomes rather favorable. Its interpretation lies in the fact that a total infiltration of the glandular parenchyma is prevalent when glycosuria is exhibited.

7. *Hyperglycemia* is closely related to glycosuria; a permanent hyperglycemia, "en plateau," during the first 24 hours usually is followed by death, a decreasing hyperglycemia offers a more favorable prognosis. In certain cases, it is advisable to perform, when possible, the tolerance type of blood sugar estimations in order to discover whether or not the pancreatitis associated with oedema is progressing towards a pancreatitis with hemorrhage. According to Bernhard, a test of glucose tolerance has reliable significance when performed as follows:

1. An initial estimation of the glycosuria and the glycemia;
2. Ingestion of 50 grms. of glucose in 200 c.c. of water;
3. A second estimation of glucose after 45 minutes;
4. A third measure of glycemia two hours later.

#### RESULTS:

1. A *constant hyperglycemia* is found (0. gr. 153 to 0. gr. 178 instead of 0. gr. 102) in acute pancreatitis without glycosuria;

2. A *glycemia* three times higher than normal (0. gr. 292 to 0. gr. 310 instead of 0. gr. 163) after 45 minutes;

3. The hyperglycemia-maximum is reached after

45 minutes in acute pancreatitis, whereas it appears two hours after the ingestion, with the diabetic and is characterized by a slowly rising curve.

In certain cases this method would allow us to follow the progress of an acute oedema of the pancreas towards a pancreatitis with hemorrhage.

8. *Radiography* at times has revealed the enlargement of the duodenum with compression of the bulb and a local stasis of the barium caused by pressure of the viscus by the enlarged pancreas.

9. *The test of diastasia* (1) is highly praised by the English and American schools. A thorough study of its value has also been pursued in France and in Rumania. Its presence in excess in the urine would indicate an undoubted acute pancreatitis. Normally, its index oscillates between 6 and 30 units. In acute pancreatitis, it often reaches 100, 200, and as far as 400 units. Great importance is being attached to this observation, and to the number of units as already quoted, with respect confirming a clinical diagnosis of acute pancreatitis. Still, a confusion exists concerning the mechanism of the phenomenon. Two different methods have been reported by us on this subject, a laboratory one, and an ambulatory one, to which we refer the reader for more details (1) (2).

10. *The blood count* has special characteristics: a drop in the number of the red blood corpuscles, quickly followed by a polyglobulia; a hyperleucocytosis ranging from 15,000 to 42,000 in certain cases, with an average of 25,000 in cases of pancreatitis with suppuration. We have personally observed two patients where the leucocytosis exceeded 15,000. Owing to an hypercholesterolemia, the blood-serum may resemble milk.

Other symptoms which have received well deserved consideration are:

1. *The Halstead sign*: that is, patches of cyanosis in the supra-umbilical region—a sort of local, hemorrhagic purpura;

2. *The Mayo-Robson sign*: a pain localized in the left, posterior, costo-lumbar region, corresponding to the location of the tail of the pancreas;

3. *Loewi's pupillary sign* or mydriasis by adrenalin: two drops of a 1 to 1000 solution are applied to

It takes about 40 minutes (including the 30 minutes' incubation) to perform the urinary diastase test, and, as no elaborate apparatus is required, the technique and time spent in its performance are both within the reasonable limits allowed by the preliminary preparations for operation on an acute abdominal condition.

In the present series, suitably graduated burettes for the saline and starch solution, and a pipette for dilutions were used in each case. However, in the absence of these facilities, it was found that a "diagnostic" reading could be obtained in a much simpler manner as follows. A one in 25 dilution of urine was prepared by adding one cubic centimetre of urine to 24 cubic centimetres of saline solution, one cubic centimetre and five cubic centimetres or ten cubic centimetre graduated syringes being used. One cubic centimetre of this diluted urine was now added to a small glass tube fitted with a stopper, for example, a Wassermann tube, and two cubic centimetres of 0.1% starch solution added. The tube was then placed in a vest pocket and the time noted. In about five minutes a small quantity was extracted and tested with a drop of iodine. If a blue colour resulted, the tube was "incubated" for a further five minutes and again tested, and so on until a test revealed a brown or reddish-brown colour, but not blue. This represented the end point, and meant that it attained within 30 minutes

there were at least  $\frac{1}{2} = 50$  units present. The test was thus

often reduced by 15 or 20 minutes. Although a quantitative estimation was not made, a significant increase in urinary diastase was established.

Fig. 9

Fig. 9. Congestion of the pyloric territory following an injection of the caecal and appendicular ganglions. (Braithwaith)

A living ascaride was found in the pancreatic duct, the head of the parasite was located in the tail of the pancreas.

**OBSERVATION II.** *Illustrating a retention of the pancreatic liquid in the Wirsung duct, with integrity of the pancreas* (Prof. A. LeSage and Pierre Masson). Mr. L., age 42, a house-painter, is admitted in the hospital on December 19th, 1933, for digestive troubles having started a month before, consisting of a tenacious *diarrhea* (10 stools per day, sometimes 20). A burning sensation felt at the epigastrium, accompanied by frequent regurgitations, belching and alimentary vomiting. Colicky pains are also complained of, located in the epigastrium. In 1930-31-32, the patient has complained of frequent indigestion associated with chills.

*General condition:* pallor, undernourishment, emaciation. The sensation of a foreign body or of a tumor complained of by the patient with a pain in the left hypochondrium towards the back. *Upon examination,* does not reveal more than a resistant epigastrium without a true muscular rigidity. The other regions show no tenderness whatever, but the pain complained of in the epigastrium, *radiates to the left and to the back, whereas local pressure determines another pain definitely localized in the dorso-lumbar regions.*

The examination of the stools showed the presence of neutral fats, of undigested muscular fibres without traces of starches. The Koch B. was not found. The blood-count, done repeatedly, showed a leucocytosis fluctuating from 10,000 to 18,000. No sugar in the urine specimens.

The character of the pain, the signs of an obvious pancreatic insufficiency with leucocytosis, had inclined us to the making of a diagnosis of a subacute lesion of the pancreas. The impression of a tumor made us think it was due to a cancerous lesion.

The autopsy revealed the presence of a tumor of non-cancerous nature, lying at a little distance from the ampulla of Vater, causing a compression of the Wirsung duct, which was in turn enormously dilated by large quantities of a *pure pancreatic liquid* imprisoned above the tumor. No bile was found in the liquid. The pancreas

the eye-conjunctiva and repeated after five minutes. The positiveness of the sign consists in a mydriasis half an hour later;

4. Other accessory signs will just be mentioned: the milky appearance of the blood-serum, jaundice, blood in the stools;

5. The *general condition* accompanying the signs especially mentioned is of outstanding significance. The constitutional condition is most impressive; usually it rapidly becomes adverse: a real condition of shock, with an anxious, drawn expression, a pale, livid complexion, a "pinched" nose, excavated eyes, cold perspiration, chilled and asphyxiated extremities; in brief, a state a severe collapse, although with it the patient keeps conscious..

#### PERSONAL OBSERVATIONS

**OBSERVATION I.** *Ascarides in the Wirsung duct.* A case concerning a man, aged 50, operated six hours after the outset of the disease, after a diagnosis of probable acute pancreatitis. A crucial pain in the epigastrium radiating towards the left hypochondrium and to the back, the patient being in a state of collapse. Upon laparotomy, bloody and serous liquid is found in the peritoneal cavity. The pancreas has a deep red color with hemorrhages and infarction. Death occurred 14 hours later. The autopsy revealed the lesions of hemorrhage and of steatonecrosis.

Fig. 10

Fig. 10. Presence of calculi in the ampulla of Vater, showing the anatomical types of calculi, their various localizations, the local obstruction and the eventual flowing back of bile from the biliary ducts or the duodenum into the pancreatic ducts. (Schmieden and Sebening)

Fig. 11

itself was more or less atrophied, with no traces of infarct or steatonecrosis. Neither were found any subacute lesions of the pancreas, but a plain stasis notwithstanding clean signs of an insufficiency had been verified in the stool analyses.

**OBSERVATION III.** (Prof. A. LeSage), *demonstrating some post-operative pancreatic accidents.* A man, age 52, is operated for a constant pain in the lower right abdominal quadrant and in the gall-bladder region. Upon laparotomy, lesions of perivisceritis between the duodenum and the gall-bladder, plus peri-cecal membranes are found. Three days after the operation, an epigastric pain appears, the acuteness of which becomes more and more pronounced. The medical treatment is followed by a slight improvement. The crisis soon re-appears, more severe, so that the patient dies during the night. The autopsy shows a pancreatitis with hemorrhage and necrosis.

We came to the conclusion that the painstaking surgical manipulations had caused a shock due to various draggings upon the solar plexus during the operation.

**OBSERVATION IV.** *Acute pancreatitis with hemorrhage* (From Gosset and Mondor). A female, 45, complaining of digestive trouble. The abdominal pains are unbearable during the night. Severe signs of a general intoxication, becoming aggravated every hour. The abdomen is swollen, tympanic, tender more than painful. Nothing is revealed by the palpation. No stools, no gas are passed. No contracture or "defense," but a resistance.

*Operation:* cholecystitis, lesions of steatonecrosis scattered over all the omentum; necrosis with hemorrhage. Hematoma located in the head of the pancreas, the former bulging forward into the stomach: a bloody serosity in the "arrière-cavité." An enormous calculus is in the gall-

Fig. 11. An aspect of the sub-meso-colic lesions of this patient. Shores of bullous oedema, surrounded by vascular colic arcades. Some elements (in clusters) are shown smaller, transparent, at the left of the mesenteric artery. (R. Couvelaire, "Acute Oedema of the Pancreas" a thesis. Paris, 1933, p. 85).

bladder. Temp. 38°; pulse 39°. Recovery after four months.

**OBSERVATION V.** *Cholecystitis with gallstones. Pancreatitis with secondary hemorrhage* (Prof. A. LeSage). A female, overweight, age 75, is admitted with a long standing history. For a year, she complained about repeated "indigestion" following large meals. The last spell was registered in December, 1933, when a sudden, very acute pain was felt in the epigastrium radiating around the waist and towards the right shoulder, necessitating an injection of morphine. Soon after appeared a jaundice with uncoloured stools. Temp. 103° F. Pulse: 110. A lull of 4 days, then there was a return of the accidents: a more acute pain in the epigastrium, with the same radiations and tenderness on palpation. There was local resistance, but the abdomen was not found retracted; there was no "defense musculaire." Bilious vomiting occurred. The general condition became more severe, and the patient was admitted in the hospital for an emergency operation.

*Operation:* a sero-bilious liquid was abundantly found in the peritoneal cavity with lesions of chronic cholecystitis and gallstones, the gall-bladder itself being hidden behind the network of adhesions. Owing to the age of the patient and the painstaking operation, a drain was placed and the operation quickly finished.

The following days, the disease takes a happy turn, but later the general condition again became aggravated. Blood leaked through the drain *following lavages*; the pulse was arrhythmic, and at times appeared a crisis of complete arrhythmia with cyanosis of the extremities and a deep alteration of the facial expression. The abdomen became more and more swollen. No stools or gas were passed notwithstanding the hypertonic salt enemas. The blood urea increased and the patient succumbed with all the signs of an internal hemorrhage.

Fig. 12

Fig. 12. Incision of the gastro-colic ligament, giving access to the pancreas and the cavity, where are produced and accumulate the serous and bloody liquids. (Schmieden and Sebening, in Surg. Gyn. and Obs., June, 1928, No. 6, p. 743)

Fig. 13

The *autopsy* was refused. There is no doubt, however, about the post-operative evolution of this case: a pancreatitis with necrosis and hemorrhage. The progress of the pancreatitis of biliary origin was carried on even after the operation, in accordance with several similar observations where proof had been possible. The autopsy is lacking, it is true, but it seems that the clinical signs are sufficient to teach us a lesson.

**OBSERVATION VI.** *Illustrating pancreatitis with suppuration. Cholecystitis with gall-stones and suppuration. Acute pancreatitis. Steatonecrosis* (Prof. A. LeSage). A female, age 53, was admitted to Notre-Dame hospital for a crisis consisting of paroxysmal pains alternating with long intervals of apparent good health.

Upon examination, the liver was found enlarged, the gallbladder painful, with phrenic radiations to the sub-clavicular regions and to the right shoulder. There was slight jaundice. Altho painful, the epigastrium was easily examined. It is elastic and only lightly swollen. There was constipation with uncolored stools. On the first days of Oct., 1933, the patient complained of a more severe spell than before. The pain, very acute, compelled her to be confined to bed. Morphine had but a temporary effect. The pain radiated definitely to the left and to the lumbar region. The tenderness was pronounced without a true contracture. The two lower abdominal quadrants are soule. Vomiting soon appears, first biliary, then bloody, without any effort. Temp. 102° F. Leucocytes: 25,000.

The clinical diagnosis was: Cholecystitis with gallstones—acute pancreatitis with suppuration. As the general condition was low, we endeavored to stimulate the patient in view of an impending operation.

Death occurred on the 12th of October, 1933.

*Autopsy:* (Prof. P. Masson) after a median incision of the abdomen, an adhesion extending from the anterior abdominal wall to the liver was detected, involving more precisely the gallbladder. Dissection revealed that the gall-

Fig. 13. Necrosis of the pancreas caused by the presence of an ascaris in the canal of Wirsung. (Schmieden and Sebening).

bladder, hidden behind a mass of local peritonitis, is drowned in yellow and green pus. From the larger abdominal cavity, 100 c.c. of dark liquid were recovered. The liver and gallbladder were drawn upwards, when suddenly a stream of very turbid liquid flowed out of the Winslow foramen. During this dissection, the gallbladder, most friable, was ruptured and gave a tablespoonful of pus, containing two dark green calculi, the size of a cherry-stone. From the gallbladder to the hepatic pedicle were found columns of thick pus; this process extended to all of the sub-peritoneal fat, the anterior region of pancreas, and the mesenteric pedicle. These yellowish frenums were covered with scattered white, opaque lesions of steatonecrosis. The liver was about the normal weight: 1,450 grams, very soft and congested. The *histological examination* showed cholangitic abscesses with innumerable bacterial colonies, in the sinusoids; also a variety of lesions of the parenchyma: anisocytosis, irregularity in the size of the nuclei, direct and mitotic divisions, cells showing a biliary retention (intra-cellular) and necrotic foci. Such are characteristics for intense toxi-infectious lesions.

The pancreas showed ancient lesions of the parenchyma consisting in the development of numerous microcysts containing an albuminous substance derived from the acini. It exhibits no suppuration, the latter being isolated from the fatty zones.

The fat tissue behind, chiefly pancreatic, covered purulent fistulas, the pus being entirely necrotic and surrounding or outlining nuclei of steatonecrosis.

**OBSERVATION VII.** *Cancer of the pancreas with glycosuria* (Prof. LeSage). Mrs. T., age 65, was admitted to Notre-Dame Hospital for persistent pains in the epigastrium radiating variously to the left or to the right, but appearing to have a maximum of acuteness in the dorso-lumbar regions, all of which have seemingly occurred formerly but have been aggravated since an automobile accident in August, 1934. During the collision, the patient was thrown to the back of the seat, and later showed marked distress in the pancreatico-duodenal quadrant.

Upon examination, the gallbladder was found painful and associated with phrenic and supra-clavicular radiations; another point was found in the epigastric region with radiations to the left hemithorax, a maximum point being detected on the two dorso-lumbar vertebrae. No other pain was recorded. B. W. negative. Spinal fluid: normal. Blood cholesterin: 1 gr. 84. Glycemia: 1 gr. 92. Urea: 0. gr. 74 and 0. gr. 35. The blood-count: Red cells: 4,300,000. White cells: 4,500. Hemoglobin: 75%.

Bleeding time: 3 minutes; coagulation time: 6 minutes;

Fig. 14. Pancreatitis with hemorrhage; a necrotic form involving the tail of the pancreas with a calculus in the ampulla of Vater. (Brocq, quoted by Mondor)

Fig. 15

in the urine, traces of albumin and urobilin; no acetone; no blood acidosis.

Pancreas: non-emulsified fats were found in the stools with numerous undigested meat fibres.

An X-ray examination showed the presence of calculi in the gall-bladder.

Twice glucose was found in good quantity in the urines.

On account of this complicated syndrome, we diagnosed: Cholelithiasis with a pancreatic insufficiency and subacute pancreatitis involving the body and the tail of the pancreas.

Operation: a dark bile is found in the gall-bladder with a small calculus. Cholecystostomy.

In the liver, 4 or 5 nodules the size of a chestnut are found, one of which was situated on the front edge of the liver, in the very neighborhoods of the anterior ligament of the liver. It was umbilicated, pinkish, rather hard.

In the pancreas, a mass as big as a chicken's egg was found in the head, behind the pylorus, which was intact but bulging forwards; there was a very indurated pancreas. Obviously, we had to do with an epithelioma with hepatic metastases. The patient eventually died from a neoplastic cachexia.

**OBSERVATION VIII.** For diagnostic purposes, to show that a latent duodenal ulcer may suddenly manifest itself like an acute pancreatitis (Dr. Jean LeSage, obs. 10,440). An old man, age 70, was admitted to the medical ward St. Luke's Hospital on July the 22nd, 1933, in a state of undernourishment, with a generalized but light jaundice. This jaundice had appeared very recently. Fifteen days ago there appeared vague digestive troubles: an epigastric sensation of heaviness, an indefinite pain in the two lower abdominal quadrants, belching, constipation, and suddenly, a syndrome of icterus with retention, pale stools, voluminous, very fatty. The appetite remained good.

Fig. 15. Acute hemorrhagic pancreatitis. Touches of fat-necrosis on the gastro-colic ligament, cut vertically.

Antecedents: no painful spells detected, no rhythm in the pain, no hematemesis or melena. Pronounced alcoholism is confessed, but luetic infection is denied.

The laboratory examinations suggested a partial confirmation of the previous diagnosis of chronic pancreatitis with probable cancer of the head of pancreas; this was strongly suggested to us by the patient's poor general condition, a very resistant pancreatico-duodenal region and a positive Murphy's sign (Chiray and Pavel). The total quantity of fats and meat fibres in the stool was high; the biliary pigments were reduced to traces. No parasites or occult blood were found. The Wassermann was negative in the blood and in the spinal fluid. Repeated duodenal intubations at fortnight intervals seemed to help the jaundice to retrogress and to produce a reappearance of the bile pigments in the stools; still, bile "B" did not appear once, whereas the examination of bile fractions, "A" and "C", showed very low concentration of pigments, biliary salts and cholesterin. Unexpectedly, two months after admission our patient was taken with lypothymia, severe epigastric pain, soon followed by very abundant melena. Death occurred a few hours later.

Upon autopsy, a large posterior duodenal ulcer was found; it had perforated into the pancreas, having ruptured the pancreatico-duodenal artery; also there was a chronic pancreatitis; a diffuse hepatic degeneration . . . but no cancer.

#### DIAGNOSIS

What diseases might be confused with acute pancreatitis? We propose to review the principal ones, in the order of their frequency, and keeping for the

Fig. 16. 1, biliary calculus in the cystic duct; 2, calculi in the hepatic ducts; 3, intra-hepatic lithiasis; 4, dilated crypts filled with purulent secretion and calculi; 5, inflammatory thickening; 6, a frequent localization of cystic stenosis before its inosculation with the common duct; 7, calculi of the common duct above the ampulla of Vater.

Fig. 17. Islands of fat-necrosis on the great omentum (Mondor).

last those requiring the more delicate differential diagnosis.

1. *Acute gastritis*, which is often preceded by certain sympathetic or motor troubles, such as a tenacious cephalalgia, palpitation, fainting, a sensation of gastric or intestinal distress, a respiratory embarrassment or an epigastric distention. In this affection, uneasiness, more than pain, is complained about, the uneasiness persisting several hours and even days. Alkaline or bilious vomiting terminates the attack, whereas, in acute pancreatitis, the attack reaches at once its "acme." No "period of incubation" is noticeable as in the acute gastritis.

2. *The gastric crisis of tabes* are occasionally confused with acute pancreatitis, as they often burst out of a sudden, with a transfixing pain, unyielding to morphine, followed by acid or even bloody vomiting; but such a spell will last a few hours, then often disappearing abruptly after an intravenous injection of atropine. A few signs of organicity may lead to the diagnosis, such as a positive Argyll-Robertson pupil, the absence of the patellar reflex, a positive Rhomberg, etc.

3. *A gastric or duodenal ulcer* might suggest the possibility of a pancreatitis. In favor of an ulcer however we have the periodic pains at regular hours, two or three hours after each meal and the fact that they are relieved by food or alkalies. No abdominal distention is found. In the case of a perforation, one can be guided by the classical diagnostic tripod: (a) A sudden, atrocious pain; (b) a parietal resistance localized to the supra-umbilical region accompanied by epigastric tympanism; (c) a few dyspeptic antecedents. An error in diagnosis will not influence the final decision which is one of surgical intervention.

4. *Acute appendicitis* is associated with a number of well proven clues: a dull pain in the lower, right, abdominal quadrant, often hidden behind the mask of an indigestion, accompanied by vomiting, constipation, or gas occlusion, muscular resistance, "ventre de bois." No pain irradiation except possibly to the corresponding leg. Usually, the pain is relieved by morphine.

Collapse and cyanosis occur in the case of a generalized peritonitis only. Hyperleucocytosis. Here also, no hesitation should hold back an emergency operation.

5. *The torsions or twistings* of the bowels are accompanied by paroxysmic pains, interrupted by short "lulls." The gas and stool occlusions, the meteorism, should rapidly decide on surgical intervention.

Moreover, in such cases we are now approaching the disconcerting grounds of intestinal obstruction, where invagination, "volvulus," stenosis with frenum and intestinal infarct are to be found closely associated.

The diagnosis rests upon the appreciation of the symptoms, seldom easy to ascertain, the doubt about which soon disappear however after an early operation.

6. Let us briefly mention: the *intestinal infarct*, with or without mesenteric thrombosis, which is revealed more

by the signs of an intestinal hemorrhage than by those of a shock;

The *iliac agony*, with the signs of an obstruction of the small intestine, early vomiting soon becoming fecal and associated with oliguria;

The *acute gastro-duodenal dilatation* recognizable by the profuse and easy vomiting, the filiform pulse, a total atony of the intestine and hiccoughs. It is a dramatic accident, sometimes post-operative; the prognosis always is severe.

7. Pancreatitis could hardly be confused with a *nephritic colicky pain*, as in this affection the pain is lumbar and the irradiations tend towards the inguinal regions, the thigh or the genital organs.

8. To the *hepatic colicky like pain* should be given a greater significance because of its frequency, its dorsal and clavicular irradiations. No shock nor collapse here is to be found, whereas the previous history of the case will bring forth several clues.

On the other hand, the hepatic colic like pain often is associated with lesions of acute pancreatitis. It is undoubtedly in such cases that the association of the symptoms will incline the physician to hold in suspense a final diagnosis of pancreatitis, as he is already hypnotized by the characters of the colicky pain.

Would it be superfluous to suggest that the following simple axiom be borne in mind to stigmatize this important chapter of medical pathology: the decision to carry through the diagnosis of an acute pancreatitis will most of the time depend upon the fact that one has thought of it and has acted promptly, keeping uninfluenced by a network of contradictory symptoms, which have made so true the well-known motto that "Il y a des malades plutôt que des maladies."

#### SUMMARY

This report might be briefly resumed in the following propositions:

1. *Acute pancreatitis* is more frequent than is usually believed, as it is often hidden behind the mask of the indigestions.

Fig. 18

2. Amongst the causes, let us enumerate in order of frequency:

- a. Gall-bladder and biliary duct diseases;
- b. Duodenal ulcer, and duodenal stasis;

Fig. 18. How the pus and blood issuing from the pancreas reaches the peritoneal cavity (Schmieden and Sebening).

- c. Infections;
- d. Intoxications;
- e. A vascular stasis;
- f. Intestinal obstruction;
- g. Traumatism: contusions and surgical trauma;
- h. Parasites and other causes.

3. *The pancreatic syndrome* progresses, as a rule, in the following manner; oedema, hemorrhage, necrosis, suppuration, the former relapsing, but spontaneously curable, although progressing towards the more severe form.

4. *The clinical symptoms* of difficult appreciation in the majority of cases, reach a higher acuteness in the oedematous form, which is curable, than in any others, often fatal. The pain and general condition must be our best guides in the estimation of the disease.

5. *The diagnosis* must be rapidly decided upon, because the emergency operation becomes a law, especially if a thorough investigation and a brief analysis of the various diseases or syndromes involving the organs situated in the vast hepato-gastro-pancreatico-duodenal territory has been carried through.

6. *Acute pancreatitis* should be more frequently thought of, the evolution being a deceptive and insidious one, and the prognosis, oftentimes fatal.

# Bacteriological Observations in Disease of the Biliary Tract

## A Comparison of Operative Findings with those of Non-Surgical Drainage of the Biliary Tract in 104 Cases\*

By

EILIF C. HANSEN, M.D.†

and

ANTONY YUREVICH, M.D.

NEW YORK CITY, NEW YORK

THE importance of obtaining reliable evidence with regard to infection of the biliary tract long has been recognized. Various attempts have been made to evaluate the rôle played by infection in disease of the biliary tract by bacteriological examination of specimens removed at operation.

Rosenow (1), in 1916, reported fifty-five per cent of positive cultures of specimens of "operative" bile. He also reported cultures of the cystic duct lymph nodes in which streptococci were obtained in sixty-three per cent; other organisms obtained were *B. coli*, *B. welchii*, *B. proteus*, and diphtheroids. There was a relatively high percentage of mixed infections in both series of cultures. More recent investigators, Drennen, Blalock, Johnson, Kelly, Judd, Mentzer and Parkhill, Illingworth, Wilkie, Branch, Williams and McLachlan, and Gordon, Taylor and Whitby, on the contrary have reported a predominance of cultures showing a single variety of organism. Drennen (2) in 1922, reported cultures of the fluid contents of operated gall-bladders in 100 cases, and found nineteen per cent to be positive, the predominating organisms being *B. coli* and staphylococci. Eighty-one per cent of the bile cultures were reported as sterile. Mixed cultures occurred in not more than five per cent of these cases.

Blalock (3), in 1924, reported 58% positive cultures in a series of 270 specimens of operative bile from the gall-bladder with 6% mixed cultures. *B. coli*, staphylococcus, and *B. typhosus* were the predominating organisms.

Johnson (4) of the Cleveland Clinic, in 1925, made a bacteriological study of the operative bile in 100 cases. He found it to be infected in thirty-two per cent of these. When infection was present a single variety of organism, usually staphylococcus or *B. coli* was found. Kelly (5), in 1926, reported the results of culture of the wall of the gall-bladder in 240 cases from the Clinic of Dr. Deaver. Forty-seven per cent of these cultures were positive. Practically all the infected cases showed a single variety of organism of which the staphylococcus, *B. coli*, and *B. typhosus* predominated. Judd, Mentzer, and Parkhill (6) in 1927, studied 200 operated cases and found the bile infected in fifteen per cent. The majority of cultures again

showed a single variety of organism of which the streptococcus and *B. coli* were most frequent. Among the organisms found by these investigators in the gall-bladder wall and in gall stones were the staphylococcus, streptococcus, *B. coli*, *B. welchii*, and *B. proteus*.

Illingworth (7), in 1927, reported bacteriological findings in cultures of the wall of the gall-bladder in 100 cases. The cultures were positive in 62% of cases, mixed cultures occurring in only 5%. The same investigators found pure cultures of *B. coli*, staphylococcus and streptococcus in 30% of 23 cases in which calculi were studied bacteriologically.

In 1927, A. L. Wilkie (8) of Montreal, working in Professor D. T. D. Wilkie's Clinic in Edinburgh, reported bacteriological studies of specimens of fluid contents and wall of the gall-bladder, and of the cystic duct lymph glands. He found that bile inhibited the growth of the streptococcus, and that for the same reason cultures of the entire wall of the gall-bladder frequently proved sterile, whereas those of the submucosa showed streptococci. Inasmuch as culturing the submucous coat was unreliable, because so frequently the specimen was contaminated, at Professor Wilkie's suggestion, cultures from the cystic duct lymph glands in all cases of cholecystitis were made. He found an astonishingly high percentage of positive cultures in the cystic duct lymph glands. In 43 out of 50 cases (86%) the cystic duct lymph gland yielded streptococcus in pure culture, one case showed *B. coli*, one case *B. welchii*, and only five cases proved sterile.

Nickel and Judd (9), of the Mayo Clinic, state that contrary to the experience of Wilkie, in their experience, bile did not inhibit the growth of organisms unless present in rather large amounts. Their series of 300 specimens of the wall of the gall-bladder yielded positive cultures in 50% of cases, the predominating organisms being streptococcus, a bacillus, and a staphylococcus.

Branch (10), in 1929, reported bacteriological studies in 210 cases of cholecystitis, culturing specimens of fluid contents, and wall of the gall-bladder, and gall stones. He found the bile infected in 19%, the wall in 25%, and the calculi in 29%. Mixed cultures occurred in 5% of cases. *B. coli*, staphylococcus, and streptococcus predominated.

Gordon-Taylor and Whitby (11), in 1930, reported 28% positive cultures in 50 cases in which cultural studies were made of gall stones at operation. All were pure cultures. These investigators also found

†Assistant Surgeon.

We wish to record our indebtedness to Dr. R. Franklin Carter, Dr. J. Russell Twiss, and Dr. Adele Sheplar through whose kindness the data used by us in this paper were made available. We are also grateful to Dr. Carl H. Greene for his valuable assistance.

Submitted July 8, 1935.

positive cultures in the wall of the gall-bladder in 82%, and in the fluid contents of the gall-bladder in 32% of cases. By making anaerobic cultures as well as aerobic ones they found in addition to the usual predominating *B. coli* and staphylococcus, a high incidence of *B. welchii*.

Williams and McLachlan (12), in the same year, performed similar studies. They found the wall of the gall-bladder infected in 51% of 84 cases. The fluid contents of the gall-bladder yielded 47% positive cultures in 81 cases. Pure cultures occurred in all but 7% of cases. Positive cultures were obtained in 56% of 43 cystic duct lymph nodes studied. The usual organisms found were the staphylococcus, *B. coli*, and streptococcus.

Whipple (13), in 1931, reported bacteriological studies in 178 cases of disease of the biliary tract. The various tissues studied yielded positive cultures in 60% of the cases. *B. coli*, staphylococcus, and streptococcus predominated. *B. typhosus* occurred in 4% of cases, and *B. welchii* in 3%.

In 1932, Magner and Hutcheson (14) reported positive cultures in 89% of specimens of the wall of the gall-bladder in 200 operative cases, and 33% positive cultures in 106 cases in which cultures were made of the fluid contents of the gall-bladder. The organisms which occurred most frequently were *B. coli*, streptococcus and staphylococcus.

In Rehfuess's (15) recent composite review of 2162 cases of cholecystitis studied bacteriologically following cholecystectomy, 45% of the cases yielded positive cultures from the wall of the gall-bladder, 29% from the fluid contents of the gall-bladder.

The wide variation in percentages reported by the various investigators may be explained by the fact that some series included more acute cases than others. Branch (10) found that in chronic cholecystitis the gall-bladder is infected in approximately 12% of the cases, whereas in acute cholecystitis the percentage rose to 75%. Nickel and Judd's (9) findings in this regard are in close agreement with those of Branch. Another factor may be the lack of uniformity in culture methods.

#### AUTHORS' INVESTIGATIONS

The present study, which was made in The Clinic for Diseases of the Liver and Biliary Tract of the New York Post-Graduate Hospital, includes 104 cases of chronic cholecystitis studied at operation. In these cases, cultures were made of the wall of the gall-bladder and fluid contents of the gall-bladder and of the cystic duct lymph node, and gall stones when present.

Bacteriological studies of the specimens removed at operation were made in the Department of Bacteriology under the direction of Dr. Adele Sheplar.

The methods used were as follows (16):

Specimens for culture were placed into previously labeled sterile test tubes by the surgeon at the time of operation. Gloves and sterile instruments were used in handling the specimens but no washing or searing of the gall-bladder wall or calculi was done. The test tubes were then immediately transferred to the bacteriologist who added the culture media. The gall-bladder was cultured in dextrose broth, the bile in dextrose broth and on blood agar plates as well. Aerobic cultures were the only ones made. Cultures were examined at the end of twenty-four hours. If no growth was present, they were reincubated and observed daily for four days. If a growth was present, the colonies were identified. Coliform colonies were

seeded in carbohydrate media in fermentation tubes for production of acid, gas, and determination of type. From the dextrose broth culture, Gram's stain was done on a film preparation. If streptococci were present, subcultures were made on blood agar plates to determine the action on blood and to complete the identification.

For the detection of typhoid bacilli, Endo medium was used as well as a tube of dextrose broth. If no typical colonies of *B. typhosus* were present, subcultures from the twenty-four hour broth cultures were made on Endo medium.

The results of the operative findings in the 104 operated patients as well as a comparison with the data reported by previous investigators are shown in the accompanying Tables I-V.

In our series all specimens were sterile in 67.3 per cent of cases (Table I). Positive cultures were ob-

| Cystic Duct Node      | 58                    | 13                       | 22.4                                         | 38                                                                |
| Gall Stones           | 26                    | 8                        | 30.7                                         | 24                                                                |

tained in 32.7% of cases. The organisms obtained were the following: streptococci 15.3% (*Streptococcus viridans* and *Streptococcus non-hemolyticus*), *Staphylococcus aureus* 2.9%, *B. coli* 9.6%, *B. typhosus* 3.8%, contaminating rods .9%, *B. welchii* and *proteus bacillus* 4.7%, and *ebertella* group .9%. Pure cultures of a single variety of organism occurred in 32 out of the 34 infected cases, 94.1% of the cases in which infection was present.

Cultures of the gall-bladder wall were made in 98 cases. The cultures were positive in 30% of the cases studied. The cultures yielded a single variety of organism in all but two cases, 93.1% of those infected. Streptococci and *B. coli* occurred most frequently. A comparison of these findings with those of other investigators, as shown in Table II, indicates a much smaller percentage of positive cultures in our series. Our low incidence of mixed cultures (2%) compares favorably with that of Kelly (5) Illingworth (7) and Williams and McLachlan (12). The frequency of occurrence of various types of organism found by us in the gall-bladder wall is considerably lower than that of other investigators.

A study of the *gall-bladder bile* obtained at operation was done in 100 cases (Table III). The bile was infected in twenty per cent. Pure cultures occurred in nineteen out of the twenty infected cases or 95%. *B. coli* and streptococci occurred most frequently. *B. typhosus* occurred in 4% of cases and contaminating rods in one case. Our findings are in agreement with those of Judd, Mentzer, and Parkhill (6) as regards frequency of occurrence of *B. coli* and streptococci.

Gall stones were cultured in 26 cases (Table IV). They yielded positive cultures in 31%. Mixed cultures occurred in only 4% of cases. *B. coli* and streptococci were found most frequently. *B. typhosus* occurred once. Judd, Mentzer and Parkhill (6), and Rosenow

(1) also reported *B. coli* and streptococci predominating in cultures of gall stones. In addition, Rosenow (1) found *B. typhosus* in 3% of cases and *B. Welchii* and *proteus bacillus* in 21%.

Cultures of cystic duct lymph nodes in 58 cases (Table V), yielded positive cultures in 22%. Pure cultures were obtained in all but one case in which

occurrence of infection in various parts of the biliary tract. 32.7% of the operative cases showed infection in at least one of the specimens cultured. When infection was present, it occurred in the gall-bladder wall in 85.2% of the infected cases, in the bile in 59%, in the cystic duct node in 38%, and in the calculi in 24% of infected cases.

\*\*\*\*Tissue not specified.

both *B. coli* and *Streptococcus viridans* were present. Organisms which were found most frequently were streptococci and *B. coli*. Staphylococcus and *B. typhosus* occurred occasionally. Rosenow's (1) percentage of positive cultures is much higher (88%) than ours. He too found streptococci and *B. coli* to occur most frequently.

A study of Table I shows the relative frequency of

Furthermore, the bacteriological study of operative specimens indicated that in 94% of the cases in which infection was present only a single variety of organism was found in cultures from all parts of the biliary tract.

Culture of specimens from the biliary tract of patients coming to operation, while interesting from the pathological standpoint, is manifestly of no value to

\*Predominating.

the clinician in making a pre-operative diagnosis. A number of investigators have, therefore, made extensive use of cultures of bile obtained by non-surgical biliary drainage to determine the presence or absence of infection in the biliary tract.

The usability of cultures obtained from the duodenal bile depends upon the fact that the normal duodenum in the fasting state is sterile. This has been stated by numerous investigators, notably MacNeal and Chace (17) who, in 1913, reported a series of cases subjected to non-surgical duodenal drainage. They concluded that: "The normal duodenal fluid during a fast is al-

bacteria (particularly the streptococcus, colon and typhoid groups) or an extensive infection exists noticeably through all the fractions, can we at present stress the significance of our cultural studies."

Piersol and Bockus (21) say that: "The diseased condition of the gall-bladder and bile ducts can be recognized by a microscopic and bacteriological study of the drainage bile which under pathological conditions shows alternations which are significant." Again quoting MacNeal and Chace (17): "It is possible with proper care to obtain a sample of intestinal juice through the duodenal tube sufficiently free from con-

\*Unidentified bacilli.

most free from living organisms." Twiss and Killian (18) reported a series of control cases in which cultures were made of the duodenal bile. The cultures were reported sterile in practically every case. Among others who have confirmed this fact are Cushing and Livingood (19), Kendall, Day, Walker and Haner (20), Piersol and Bockus (21), and Whipple (22). The latter author summarizes the results of these investigations as follows: "It has been established that in the normal person in the fasting state, the duodenum is collapsed, the little fluid content present is sterile."

The conclusions of practically all investigators in

tamination for bacteriological examination." Whipple (22) states: "That the bile thus obtained through the duodenal tube lends itself to bacteriological study would seem to be a valid surmise, and an organism thus obtained in pure culture might well be considered the etiological factor in the diseased biliary tract."

A. L. Garbat (25) in 1922, advocated the use of sterile duodenal drainage with culture of the bile for typhoid organisms as an additional and more reliable measure for the detection of bile typhoid carriers. Out of 39 duodenal cultures which showed typhoid bacteria, 82% occurred in pure culture. Garbat also reported

this field are that a carefully performed sterile duodenal drainage is of value in the diagnosis of biliary tract infection. This view point is held by Smithies (23), Lyon and Swalm (24), and many others. In a comprehensive review of non-surgical biliary drainage written in 1921, Smithies is quoted as follows: "Viable colon bacilli were returned by 75.4% of our patients; staphylococci, by 14.9%; streptococci by 5.26% and yeasts, *B. typhosus*, micrococci and unidentified organisms were found in 4.38%. It has seemed to us that only when one fraction of the segmented aspirates contains a predominant increase in a type or group of

(Table VI) 132 bile cultures which did not contain the typhoid bacillus. The items of interest in his figures are: (1) the high percentage of pure typhoid cultures (82%), and (2) the high percentage of sterile cultures (38%).

The only investigators who have reported the results of a bacterial study in detail are Lyon (24, 27), Garbat (25), Buttiaux (26), and Whipple (22). Lyon (24) in 1925, reported a study of 905 non-surgical biliary drainage cultures in 488 patients showing sterile cultures in 15% of cases. The organisms which occurred most frequently were *Staphylococcus aureus*,

*B. coli*, *Streptococcus hemolyticus* and non-hemolyticus.

The investigations of Buttiaux (26) included 50 cases having non-surgical biliary tract drainage (Table VI). He reported 42% sterile cultures. He diluted duodenal bile before plating because he found that freshly drained bile had bactericidal properties.

Correlated studies of both pre-operative bile and operative biliary tract specimens have been reported by Whipple (22) in 1921 and Lyon (27) in 1932. Whipple's series included 25 cases in which cultures of pre-operative drainage bile and cultures of gall-bladder bile, wall, and cystic duct node were obtained. He summarized his findings as follows: "In 50% of the cases, one or more varieties of bacteria found in the pre-operative duodenal bile were present in the gall-bladder bile or gall-bladder tissue at operation. In some of these, however, contaminations are suggested by the variety or type of organism. The presence of *B. subtilis*, *Streptococcus salivarius*, and *Micrococcus catarrhalis* may be regarded as contaminations in the duodenal cultures. On the other hand, the colon bacillus, the hemolytic streptococcus, and *Staphylococcus aureus*, especially if found in the bile following magnesium sulphate instillation, may be considered as

ing. All equipment requiring sterilization was previously autoclaved with the exception of the rubber tube which was boiled to preserve the rubber. Before passing the duodenal tube\*, we routinely passed sterile water through it collecting the washings in a sterile test tube for culture. This served as a check on the sterility of the tube. Our drainages were started at eight-thirty in the morning with a fasting stomach. Whenever possible two or three drainages were performed to serve as an accurate basis for proper interpretation of cultural findings.

A summary of our culture findings in these 222 biliary drainages is shown in Table VI as well as results of other investigators. In this series, 75% positive cultures were obtained and 25% sterile cultures. 56% of the positive cultures were mixed and only 19% showed but one strain of bacteria. The frequency of occurrence of various organisms is shown in Table VI. The predominating organisms were the streptococcus and staphylococcus. The following organisms occurred in 26% of the biliary drainages: *Micrococcus catarrhalis*, the Friedlander bacillus, contaminating rods, yeast, diphtheroids, and *B. pyocyaneus*.

| 1931. Buttiaux (26)           | 50                | 42      | 58       |         |            | 3-8     | 5-10    | 6-12                             | 1-2         |                       | 14      |

etiological factors and as probably present in the gall-bladder or common duct or both if "B" bile is obtained. Furthermore, it is the writer's impression from a study of these cases as well as some 150 cases in which the gall-bladder bile and tissue from the gall-bladder was cultured, that the colon bacillus is the most persistent of the bacteria found in the common duct." Lyon's (27) series of correlated studies consisted of 101 patients who were drained by non-surgical biliary drainage and later came to operation. Lyon states: "In the majority of the cases, the culture obtained at the operating table from the gall-bladder was identical with that recorded in the pre-operative drainage culture."

In 126 of our cases 222 non-surgical biliary drainages were done and cultures made of both the duodenal specimen of bile and the most concentrated specimen obtained after stimulation with magnesium sulphate solution or olive oil.

The method of performing the sterile drainage was that described by Twiss (28). The patient was first required to gargle or spray the throat with argyrol solution (1 dram of 10% argyrol in four ounces of sterile water). The duodenal tube was then passed and the bile collected in sterile bottles. Specimens of 2 c.c. of the various fractions of bile were collected in sterile test tubes and sent to the laboratory for plat-

A comparison of these findings with the operative findings previously reported (Table VII) shows that positive cultures were obtained much more frequently by duodenal drainage than at operation. On the other hand the percentage of cases in which a single variety of organism was found in pure culture was lower in the duodenal drainage than in the operative specimen. Furthermore, there was a different distribution of organisms found in the two series of specimens, for many more varieties of organisms were found in the duodenal drainage than in the operative specimens. These organisms may well be grouped into three categories: (1). Such organisms as *B. typhosus*, *B. coli*, *B. welchii*, and *B. proteus* which normally are not found in the upper gastro-intestinal tract, but which do invade the biliary tract. When found in the bile obtained by duodenal drainage, they afford presumptive evidence of infection of the bile or biliary tract. In typhoid carriers the bile obtained by biliary drainage is usually loaded with *B. typhosus*. Such a finding is pathogenic regardless of the presence of other or contaminating organisms. (2). Such organisms as the Friedlander bacillus, *Micrococcus catarrhalis*, pneumococcus, and yeast which are normal inhabitants of the buccal

\*Rehfsuss, Lyon, Levin, and Twiss tubes were used routinely. R. Buttiaux's French duodenal tube was tried and found to be reliable, but due to its fragility its use was abandoned.

cavity, the naso-pharynx, or stomach, but which are not found in cultures of the biliary tract at operation. When these organisms occur in cultures of the bile obtained by duodenal drainage they are presumptive

| Friedlander's Bacillus                      | 0                          | 0                                            | 4.0                                                   |

evidence of contamination of the latter. (3). Such organisms as streptococci and staphylococci which may infect the biliary tract, but which are also found as normal inhabitants of the buccal cavity, the naso-pharynx, or the stomach. These organisms when found in association with *Micrococcus catarrhalis*, the Friedlander bacillus, pneumococcus, and yeasts likewise are to be considered as contaminants, but when found in pure culture are more likely to indicate infection of the biliary tract. Multiple drainages are of value in determining the significance of such organisms.

The value of cultures of the bile obtained by duodenal drainage is best shown by a study of 48 cases in which pre-operative and operative cultures of bile were made. These results are shown in Table VIII. The percentage of sterile cultures in bile obtained by duodenal drainage was found to be 31; cultures of bile specimens from operated gall-bladders yielded sterile cultures in 73% of cases. In 31 % of the cases bile specimens both prior to operation and at operation were reported sterile. In 23%, the same organism was found in the bile, both before operation and at operation, making a total of 54% of cases in which there was agreement.

In 42% of cases, operative specimens of bile yielded sterile cultures, whereas cultures of bile obtained prior to operation by duodenal drainage contained organisms of various varieties. The organisms found included: *Staphylococcus albus*, *Staphylococcus aureus*, *Streptococcus non-hemolyticus*, *Streptococcus viridans*, *Micrococcus catarrhalis*, the Friedlander bacillus, *B. coli*, *B. proteus*, and yeasts. In 4% of cases the bile obtained by duodenal drainage as well as the bile at

operation yielded a bacterial growth but different organisms. *Duodenal drainage culture findings disagreed with culture findings at operation therefore in 46% of cases.* It is significant to note that when infection of the bile was shown by cultures of the bile taken at operation, positive cultures likewise had been obtained by duodenal drainage. On the other hand, in those cases in which bile at operation was sterile, positive cultures were obtained on duodenal drainage in 42% of cases.

## CONCLUSIONS

(1) The bacteriological examination of specimens removed from the biliary tract at operation furnishes the most accurate information regarding the presence of infection in the biliary tract. Infection was found to be present in 32.7% of the series of 104 cases.

(2) The gall-bladder wall was found to be the seat of infection more often than was the bile, the cystic duct node or calculi.

(3) When infection was found at operation, the organism was usually obtained in pure culture (95%). Streptococci and *B. coli* occurred most frequently. Staphylococcus, *B. typhosus*, *B. welchii* and *B. proteus* occurred less frequently.

(4) A much higher percentage of positive cultures was obtained in cultures of specimens of bile obtained by duodenal drainage than was found in operative specimens. Furthermore, when positive cultures occurred in the drainage bile there was a very high incidence of mixed cultures (75%). Many of these organisms may be regarded as contaminants. Our study of bile cultures both before and at operation in 48 cases showed agreement in 54% of cases, but 46% of the cases showed evidence of contamination of the specimens obtained by duodenal drainage.

(5) The present technique for the bacteriological study of bile obtained by duodenal drainage is unsatisfactory, because of the frequent occurrence in cultures of contaminating organisms from the naso-pharynx, the buccal cavity, or the stomach.

(6) A technique must be developed which will eliminate or reduce to a minimum the confusion due to

| At Operation                                                                              | 35           | 73      |
| Duodenal Drainage                                                                         | 15           | 31      |
| Both Specimens Sterile                                                                    | 15           | 31      |
| Same Organism found in both Specimens                                                     | 11           | 23      |
| Culture Findings Prior to Operation that Agree with Findings at Operation                 | 26           | 54      |
| Operative Specimens Sterile, Drainage Infected                                            | 20           | 42      |
| Both Specimens Infected, but with Different Organisms                                     | 2            | 4       |
| Drainage Sterile, Positive Culture at Operation                                           | 0            | 0       |
| Culture Findings Prior to Operation that were not in Agreement with Findings at Operation | 22           | 46      |

the presence of such contaminating organisms before cultures of bile obtained by duodenal drainage can be depended upon to supply reliable evidence of infection of the biliary tract.

## Calculating the Diagnostic Value of Gastric Analysis: A Study in the Methodology of Diagnosis\*

FRANCES R. VANZANT, M.D.\*\*

and

WALTER C. ALVAREZ, M.D.

ROCHESTER, MINNESOTA

**R**ECENTLY there came to The Mayo Clinic a physician with the story that he had been well all his life up to the week before, when, at the age of sixty years, he began to suffer with epigastric pain and indigestion. The roentgenologists saw a lesion which they thought was on the gastric side of the pyloric ring, and probably benign. Gastric analysis disclosed free acid of sixty units.

Now, what was to be done? With a short history at the age of sixty, the probability of the lesion's being a carcinoma was great, but just how great it was no one knew. The high acidity spoke for duodenal ulcer, but the report of the roentgenologist was against this. Summing up the several probabilities as best they could, the consultants who saw the man came to the conclusion that the likelihood of the lesion's being on the gastric side, and malignant, was too large for comfort, and since the probability of surviving an explora-

tory laparotomy performed by the surgeon chosen to do the work is better than 99 to 1, the patient cheerfully accepted the operation. Fortunately, the lesion proved to be a duodenal ulcer that could be excised, and when last heard from, the man was doing well.

This brief case report will serve to illustrate the main point that concerns us, and this is that when a man's very life hangs on the wisdom of a single decision, we physicians must often base it on a crude sort of mental arithmetic in which we balance probabilities, some in favor of one course and others against it. When one considers the fact that we only guess at the size of the several probabilities, and that few of us have any conception of the nature of the mathematics to be employed in combining them, the marvel is that diagnoses today are as correct as they often are.

In this paper we offer some figures which we believe will help in the solution of one of these problems, which arises every day in the practice of a gastroenterologist, and incidentally, we hope to contribute

\*This work was aided by a grant from the Josiah Macy, Jr., Foundation.

\*\*Now residing in Houston, Texas.

Submitted August 22, 1935.

something to the methodology of diagnosis as a whole. What we have done here is to calculate the probabilities that a patient at The Mayo Clinic, of a certain age and sex, and with a certain gastric acidity, (one hour after eating eight Sunshine brand arrowroot cookies and drinking 400 c.c. of water), has either a gastric carcinoma, a gastric ulcer, a duodenal ulcer, or one of a residual group of "other diseases" and neuroses.

We would have been better pleased if we could have observed the actual frequency with which the different diseases appear in men and women separately, at different ages, and with different gastric acidities, but this would have required analysis of thousands of records. For instance, we found on calculation that in order to secure a case of gastric carcinoma with hyperacidity among women aged from seventy to seventy-nine years, we would have had to search through the records of about 100,000 clinic patients. Naturally,

due not only to the relative incidences of the two diseases throughout the United States, but to other imponderable factors which bring to this clinic more patients with one disease than with another.

The sex of a patient also has an important influence on the probabilities under consideration because, in the United States, peptic ulcer and gastric carcinoma tend to appear from three to five times more frequently in men than in women.

Highly important also is the factor of age because, obviously, a young man is more likely to be suffering with duodenal ulcer than with gastric carcinoma while an old man is more likely to have a carcinoma. The next step, therefore, was to introduce this factor of age; the probabilities had to be calculated, and then used to modify those already computed.

If we had had a sufficient number of data we would have divided each of the eight main groups in Table 1

TABLE I

*Diagnoses made in the cases of 1052 patients who submitted to gastric analysis one after the other at The Mayo Clinic in the autumn of 1932*

| Disease           | Entire group |          |       |          | With free acid |          |       |          | Without free acid |          |       |          |
|-------------------|--------------|----------|-------|----------|----------------|----------|-------|----------|-------------------|----------|-------|----------|
|                   | Men          |          | Women |          | Men            |          | Women |          | Men               |          | Women |          |
|                   | No.          | Per cent | No.   | Per cent | No.            | Per cent | No.   | Per cent | No.               | Per cent | No.   | Per cent |
| Gastric carcinoma | 33           | 5.3      | 6     | 1.4      | 6              | 1.2      | 3     | 0.8      | 27                | 22.1     | 3     | 4.8      |
| Gastric ulcer     | 6            | 1.0      | 5     | 1.2      | 5              | 1.0      | 3     | 0.8      | 1                 | 0.8      | 2     | 3.2      |
| Duodenal ulcer    | 126          | 20.1     | 45    | 10.5     | 125            | 24.9     | 43    | 11.8     | 1                 | 0.8      | 2     | 3.2      |
| Other diseases    | 450          | 73.6     | 371   | 86.9     | 367            | 72.9     | 315   | 86.6     | 93                | 0.3      | 56    | 88.8     |
| Total             | 625          | 100.0    | 427   | 100.0    | 503            | 100.0    | 364   | 100.0    | 122               | 100.0    | 63    | 100.0    |

the gathering of so many cases is practically impossible. And hence it is that several of the probabilities which we needed in our calculations had to be derived indirectly, with the help of certain plausible assumptions based on the analysis of thousands of data which we have been gathering during the last five years.

We would emphasize again that in this analysis the relevant factors are four: (1) the fact that a patient came to The Mayo Clinic and submitted to gastric analysis after an Ewald meal of a certain type; (2) the sex of the patient; (3) his or her age, and (4) the degree of his or her gastric acidity.

We began by finding the percentage incidence, in our material, of patients with gastric carcinoma, gastric ulcer, duodenal ulcer, and a residual group of "other diseases" (see Table 1). We next calculated the probable incidence of the four types of disease in each decade of life (see table 3), and finally, we calculated the probable distribution of four grades of acidity in men and women, at different ages, affected with the four types of disease. The reader who is not interested in the details of these processes will probably want to skip the following section on method.

#### METHOD

The calculations which led to the construction of Figure 1, A and B, began with the making of Table 1, which shows the percentages of the men and women, examined during a certain period, in the gastric laboratory of The Mayo Clinic, who were found to be suffering with gastric cancer, benign gastric ulcer, duodenal ulcer, or one of a residual group of "other diseases."

From this table it will be seen that, given only the fact that a man is referred to the gastric laboratory of The Mayo Clinic, one can say, for instance, that the chances are twenty to one that his indigestion is due to a duodenal rather than to a gastric ulcer. This is

(four diseases and two sexes) into six groups according to the ages in decades of the patients, but as this was impossible, we had to assume that the age distributions in the case of each of the four different types of disease were the same as those already determined for hundreds of Mayo Clinic patients suffering with (a) duodenal ulcer, (b) gastric ulcer, and (c) gastric cancer. As was to be expected, the age distribution of the patients with "other" nongastric diseases was practically that of the run of clinic patients whose age distribution we knew (1). These four\* age distributions are given in Table 2.

To illustrate the arithmetic of the next step we will take as an example the first column in table 3. Beginning with the corresponding column in Table 2, we multiplied the first of the four percentage frequencies, which happens to be for carcinoma in men aged from twenty to twenty-nine years, by 5.3, which represents the percentage incidence (from Table 1) of gastric carcinoma in a hundred men of all ages coming to the gastric laboratory of The Mayo Clinic.

The next figure in Table 2 was multiplied by the next figure in Table 1, which represents the incidence of gastric ulcer, and so on. In this way, we obtained four numbers which were proportional to the probabilities of the incidence of the four types of disease in men, aged from twenty to twenty-nine years, who had submitted to gastric analysis at The Mayo Clinic. Since it would make no difference in the estimation of relative probabilities if each of these numbers were to be multiplied by a constant, we multiplied them by a factor which made their sum 100 and thereby reduced them to percentages. The procedure was then repeated

\*Actually there were eight distributions, but for the sake of brevity, we will not keep repeating that there were two sets of data, one for men and one for women, each treated separately.

until similar percentage probabilities were calculated for the other eleven age groups listed in Table 3.

We come now to the problem of introducing the last factor into the calculation, namely that of gastric acidity. Again we had to resort to indirect computation because our groups of cases were not large enough for repeated subdivision. What we needed were percentage distributions of gastric acidity for the two sexes, for each of six decades of life and for each of

of disease. We say three because no shift was needed for the residual group of "other diseases."

Each of the twenty-four acidity distributions (four disease groups and six decades) was then split arbitrarily into four zones representing achlorhydria, hypochlorhydria, euclorhydria, and hyperchlorhydria. To define the limits of euclorhydria, we marked off approximately the value of one standard deviation above and below the mean for acidity at middle age.

TABLE II

*Percentage distributions by ages for men and women with the four types of disease being studied\**

| Disease                              | Men<br>Age, years |       |       |       |       |       | Cases | Mean | S. D. |
|--------------------------------------|-------------------|-------|-------|-------|-------|-------|-------|------|-------|
|                                      | 20-29             | 30-39 | 40-49 | 50-59 | 60-69 | 70-79 |       |      |       |
| Gastric carcinoma                    | 2.0               | 12.6  | 31.7  | 35.5  | 15.1  | 2.8   | 1671  | 55.7 | 10.2  |
| Gastric ulcer                        | 6.7               | 21.7  | 33.5  | 25.8  | 9.5   | 1.7   | 393   | 46.2 | 11.4  |

\*In the cases of gastric carcinoma, gastric ulcer and "other diseases," smoothed values are given, computed from the normal curve based on the mean and S. D. The distribution of data from cases of duodenal ulcer is so skewed that the actual figures had to be used. We would have avoided a slight error by using actual figures in the case of carcinoma because this distribution is also slightly skewed. The actual figures are given for the sake of those who may wish to calculate their own Table VII

the four disease groups. We arrived at these figures as follows. In a previous study of several thousand persons (7) we constructed percentage distributions showing normal gastric acidity in the two sexes and in the several decades of life. In subsequent studies we found that, in our material, the percentage distributions of gastric acidity in the several diseases resemble closely those of normal persons except as they are shifted a certain distance to the right or left along the abscissal line representing acidity. There are also differences in the percentage incidence of achlorhydria. These deviations from normal are epitomized in Tables 4 and 5 (2, 6).

TABLE III

*Percentages of persons in each decade (submitting to gastric analysis) who were found to be suffering with one of several diseases, based on a study of 1052 patients with and without free gastric acid. The figures represent percentages of each age group*

| Disease           | Men<br>Age, years |       |       |       |       |       |
|-------------------|-------------------|-------|-------|-------|-------|-------|
|                   | 20-29             | 30-39 | 40-49 | 50-59 | 60-69 | 70-79 |
| Gastric carcinoma | 0.8               | 2.5   | 5.7   | 9.7   | 12.3  | 12.9  |
| Gastric ulcer     | 1.6               | 0.8   | 1.1   | 0.9   | 0.6   | 0.9   |
| Duodenal ulcer    | 29.4              | 22.5  | 19.7  | 18.1  | 18.7  | 68.9  |
| Other diseases    | 68.2              | 74.2  | 73.5  | 71.3  | 68.4  | 17.3  |
| Total             | 100.0             | 100.0 | 100.0 | 100.0 | 100.0 | 100.0 |
| Disease           | Women             |       |       |       |       |       |
|                   | 20-29             | 30-39 | 40-49 | 50-59 | 60-69 | 70-79 |
| Gastric carcinoma | 0.4               | 0.5   | 0.7   | 1.4   | 3.3   | 8.6   |
| Gastric ulcer     | 0.8               | 0.7   | 0.7   | 0.9   | 1.3   | 1.8   |
| Duodenal ulcer    | 16.7              | 11.7  | 9.6   | 10.0  | 12.4  | 17.9  |
| Other diseases    | 82.1              | 87.1  | 89.0  | 87.7  | 83.0  | 71.6  |
| Total             | 100.0             | 100.0 | 100.0 | 100.0 | 100.0 | 100.0 |

We felt, therefore, that we could safely take the normal (acid) distributions for age and sex and shift them to the right or left to show the probable distributions of acidity in patients with the three types

Because of the differences between the acidities of men and women, shown by Vanzant and others (7), it seemed necessary to assign different limiting values for these zones in the two sexes. The values chosen were:

|           | Achlor-<br>hydria | Hypochlor-<br>hydria | Euclor-<br>hydria | Hyperchlor-<br>hydria |
|-----------|-------------------|----------------------|-------------------|-----------------------|
| For men   | 0                 | 1-29                 | 30-59             | above 60              |
| For women | 0                 | 1-19                 | 20-44             | above 45              |

The figures represent units of free hydrochloric acid.

Table 5 gives the incidence of achlorhydria found at the end of one hour after our type of test meal in a large number of cases of the three diseases listed. The figures represent percentages of that incidence of achlorhydria which would be expected in a group of apparently normal persons with a similar age distribution. (For technic of obtaining these figures, see Vanzant (4)).

An example of the arithmetic of the final steps of the work is shown in Table 6 where we give the successive calculations by which we derived the first four figures of Table 7. It will be seen that the procedure is the same as already described for step 2. We turned

TABLE IV

*The number of units by which the acidity distribution for normal persons is shifted in the case of the three diseases listed*

| Disease           | Men   | Women |
|-------------------|-------|-------|
| Gastric carcinoma | -14.0 | -8.7  |
| Gastric ulcer     | -5.4  | -6.6  |
| Duodenal ulcer    | +12.3 | +11.1 |

first to our tables showing the distributions of acidities in the two sexes, at the different ages, and with the four types of disease, and found the number of men aged from twenty to twenty-nine years, who would be

expected not to show free acid in the stomach. The four figures there found were multiplied by the corresponding figures in the first column of table 3 showing the incidence of the several diseases in men in this

TABLE V

*Incidence of achlorhydria found at the end of one hour after an Ewald type of meal\**

| Disease           | Percent |       |
|-------------------|---------|-------|
|                   | Men     | Women |
| Gastric carcinoma | 341     | 275   |
| Gastric ulcer     | 78      | 92    |
| Duodenal ulcer    | 10      | 12    |

\*The figures represented percentages of the incidence of achlorhydria to be expected in a group of apparently normal persons with the same age distribution.

age group, and the four results were multiplied by a factor which enabled us to express them as percentages of their sum. This process was repeated many times until Table 7 was completed. Figure 1, A and B, represents graphically the data tabulated in Table 7.

### CAUTIONS

We probably should again emphasize the fact that the probabilities given here apply only to those patients at The Mayo Clinic who, for one reason or another, were sent for gastric analysis. In addition to this, the probabilities are based on age, sex, and the amount of free acid found in the stomach one hour after a certain type of test meal. Naturally, then, the figures in Table 7 are not necessarily applicable to the solving of diagnostic problems in patients seen at another clinic, and they certainly do not apply when the acidity of the stomach is studied after the injection of histamine. It must be obvious, also, that the minute the patient gives a history or submits to roentgenologic examination, other probabilities enter in to modify the diagnostic problem, probabilities which no one has as yet measured accurately or stated numerically.

As we have pointed out elsewhere (4), a single gastric analysis has a large probable error, and hence, when using Table 7, the physician can only hope that the usual variation up or down will still leave a single reading within its usual zone of acidity.

It should be obvious that anyone who wishes to use the figures given in Table 7 must first make sure that the incidence of the several diseases in his clinical material is much the same as it is in patients seen at The Mayo Clinic. He must also be using an Ewald type of meal similar to the one that we use. The incidence of the diseases at different ages and the relation of acidity to age are probably much the same in different clinics, but the number of patients seen with the different diseases may perhaps vary so much in the practices of different gastro-enterologists that each man will have to modify Table 7 to suit his own clinical material.

Anyone who wishes to make his own table should first make a table comparable with our Table 1, based on his own clinical material. If then, for instance, in the case of the "entire group," he should find that the percentage of occurrence of gastric carcinoma in men, instead of being 5.3 per cent, as in our material, is 7.2 per cent, he could multiply each one of the figures for carcinoma with achlorhydria in Table 7 by the fraction  $7.2/5.3$ . If, in his material, the percentage of gastric carcinoma with free acid should be found to be 2.3 in-

stead of 1.2 per cent, he would multiply, one after the other, the figures for carcinoma with hypochlorhydria, euclorhydria, and hyperchlorhydria by the fraction  $2.3/1.2$ .

### COMMENT

One of the most striking features to be noted in Figure 1 is the evidence pointing to the rarity of gastric ulcer. In Table 1, we see that for one man with gastric ulcer, there were five with gastric carcinoma and twenty with duodenal ulcer. Obviously the odds are against the physician who assumes, as so many do, that a gastric lesion seen with the roentgenoscope is probably benign. Table 3 shows the interesting shifts in the odds which come with advancing years. Thus, if a thousand men in their twenties come to The Mayo Clinic and are sent for gastric analysis, these three postulates alone make it probable that eight will be suffering with gastric carcinoma; sixteen with gastric ulcer; 294 with duodenal ulcer, and 682 with some non-gastric or functional trouble. But if one takes a thousand similar male patients, all older than seventy years of age, approximately 129 will have gastric cancer, nine will have gastric ulcer, and 173 will have duodenal ulcer.

Any of these probabilities will, of course, be altered markedly the minute the patient gives his history, and they will be altered again as his physical examination is made and as his laboratory and roentgenologic reports come in. Thus, if a man aged twenty-five years suffering with indigestion is found to lack free acid, his chances of having a gastric carcinoma are quadrupled, while if his stomach is found to be hyperacid, his chances of having cancer are reduced almost to zero, and his chances of having a duodenal ulcer are somewhat increased. If, now, he complains of hunger pain, and the roentgenologist sees a crater-form defect in the duodenum, the chances of his having an ulcer become very high.

TABLE VI

*An example of the calculations by which were derived the first four figures at the top of the first column in table VII*

|                                                                                                                                               | Gastric carcinoma | Gastric ulcer | Duodenal ulcer | Other diseases | Total |
|-----------------------------------------------------------------------------------------------------------------------------------------------|-------------------|---------------|----------------|----------------|-------|
| a. Frequency of occurrence of achlorhydria in men aged from 20 to 29 years and suffering with the diseases listed.                            | 3.4               | 0.8           | 0.1            | 1.0            |       |
| b. Frequency of the occurrence at The Mayo Clinic of the several diseases; male patients aged from 20 to 29 years. See Table 3, first column. | 0.8               | 1.6           | 29.4           | 68.2           |       |
| a x b                                                                                                                                         | 2.72              | 1.28          | 2.94           | 68.2           | 75.14 |
| Percentages representing probable occurrence of the several diseases in men aged from 20 to 29 years with achlorhydria.                       | 3.6               | 1.6           | 3.9            | 90.9           | 100.0 |

One of the many interesting things to be learned from Table 7 and Figure 1 is the high degree of probability that a man aged seventy years or more with hyperchlorhydria is suffering with duodenal ulcer.

Figure 1 shows the increasing diagnostic value of hyperchlorhydria with advancing years. As one would expect from the greater susceptibility of men to ulcer, the significance of hyperacidity is greater in men than in women, but curiously, this sexual difference does not stand out until the fourth decade of life.

The importance of studies such as these can be seen particularly when one examines some of the differences between the probabilities for men and women. For instance, in the fifth decade of life, if a man and his sister are suffering with indigestion and are found to be achlorhydric, he will have a 20 per cent chance of

to about forty-five years, and then falls. Curiously, the difference between the percentages of nongastric disease in men and women is fairly constant until the eighth decade of life when it is almost wiped out.

In Table 7, it should be noted how little diagnostic value achlorhydria has in the first forty years of life, and particularly in women. The difficulty is that an anacid stomach is to be found so commonly in apparently normal persons. Its diagnostic value is greatest, perhaps, in the occasional case of early macrocytic anemia in which the blood picture or the nervous lesions are not quite characteristic.

TABLE VII

*Percentages of men and women referred to the gastric laboratory of The Mayo Clinic in different decades of life and with different grades of gastric acidity who are likely to be suffering with gastric carcinoma, gastric ulcer, duodenal ulcer, or some other disease\**

| Disease           | Men          |                 |               |                  | Women        |                 |               |                  |
|-------------------|--------------|-----------------|---------------|------------------|--------------|-----------------|---------------|------------------|
|                   | Achlorhydria | Hypochlorhydria | Euchlorhydria | Hyperchlorhydria | Achlorhydria | Hypochlorhydria | Euchlorhydria | Hyperchlorhydria |
| Age 20-29         |              |                 |               |                  |              |                 |               |                  |
| Gastric carcinoma | 3.6          | .7              | .2            | .1               | 1.9          | 1.0             | .4            | .1               |
| Gastric ulcer     | 1.6          | 1.8             | 1.1           | .5               | 1.2          | 2.0             | .8            | .3               |
| Duodenal ulcer    | 3.9          | 6.4             | 17.2          | 38.1             | 1.9          | 5.0             | 13.7          | 33.9             |
| Other diseases    | 90.9         | 91.1            | 81.5          | 61.4             | 95.0         | 92.0            | 85.1          | 65.7             |
| Total             | 100.0        | 100.0           | 100.0         | 100.0            | 100.0        | 100.0           | 100.0         | 100.0            |
| Age 30-39         |              |                 |               |                  |              |                 |               |                  |
| Gastric carcinoma | 10.0         | 1.7             | .4            | .1               | 2.6          | 1.2             | .4            | .2               |
| Gastric ulcer     | .7           | 1.7             | 1.0           | .4               | 1.1          | 1.4             | .6            | .3               |
| Duodenal ulcer    | 2.8          | 8.2             | 21.2          | 44.4             | 1.3          | 3.1             | 9.5           | 25.2             |
| Other diseases    | 86.5         | 88.4            | 77.9          | 55.1             | 95.0         | 94.3            | 89.5          | 74.3             |
| Total             | 100.0        | 100.0           | 100.0         | 100.0            | 100.0        | 100.0           | 100.0         | 100.0            |
| Age 40-49         |              |                 |               |                  |              |                 |               |                  |
| Gastric carcinoma | 20.3         | 4.2             | 1.1           | .3               | 3.8          | 1.6             | .6            | .2               |

\*Values: Hypochlorhydria for men, 1-29; for women, 1-19.

Euchlorhydria for men, 30-59; for women, 20-44.

Hyperchlorhydria for men, 60 and above; for women, 45 and above.

suffering with carcinoma of the stomach, while she will have only about a 4 per cent chance. After the age of seventy, their danger will be about equal, and represented by a figure of about 37 per cent.

So far as we know these important probabilities have never been expressed numerically before. The nearest approach to such an analysis known to us was attempted by MacLagan (3) who unfortunately did not have enough data at hand to solve the problems which he had the vision to outline.

Table 1 shows that in approximately three out of four men and five out of six women with indigestion, no disease can be demonstrated in stomach or duodenum. What surprised us was that in men and women the percentage of nongastric disease rises with age up

## NEW LIGHT NOW ON THE PROBLEM OF THE PHYSICIAN WITH A PYLORIC LESION

To return now to the problem of the physician whose case we described at the beginning of this paper: On turning to Table 7, it will be seen that solely on the basis of his sex, his age, and his hyperacidity, there were 561 chances in 1,000 of his having a duodenal ulcer against three chances in a 1,000 of his having a gastric cancer. The unfortunate feature was that we did not have, and for that matter, we still do not have, figures with which to express the probability that the roentgenologist might be mistaken as to his location of the lesion, and we did not have then, and we still do not have, statistics that would enable us to appraise the value of a short history of indigestion at different

## Men

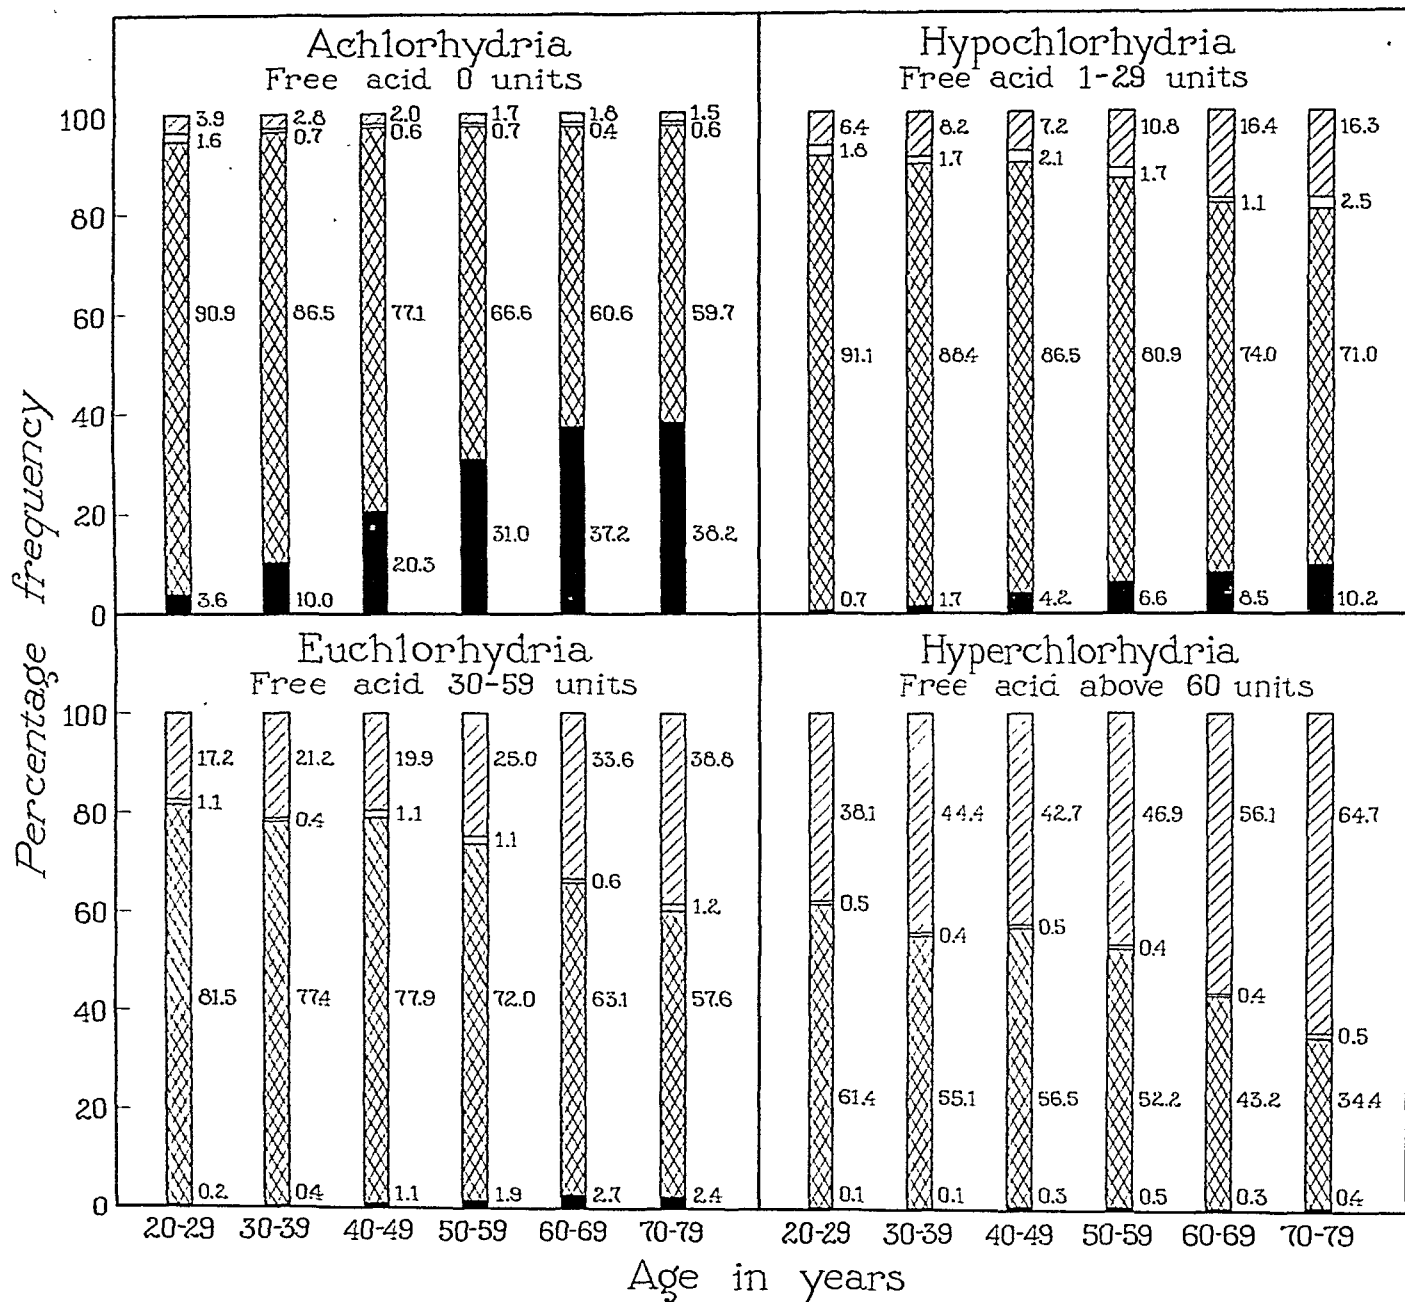

Fig. 1a. Percentage incidence of duodenal ulcer, gastric ulcer, and gastric carcinoma in men of different ages with achlorhydria, hypochlorhydria, euchlorhydria, and hyperchlorhydria. In the residual group, designated "normal," roentgenologic examination of stomach and duodenum was negative.

ages. If we had had such figures we could have corrected the percentages derived from the study of this patient's gastric acidity, and we could then have balanced them against the risk of operation.

Obviously, of course, many a person must refuse to take comfort in the fact that the odds are, let us say, nine to one against his gastric lesion being carcinomatous, because if he should happen to be the one unfortunate man in ten, his life will be forfeit. But, even so, it is a step in advance to secure some figures on which to base what may be, for the patient, the most momentous decision of a lifetime.

## SUMMARY

Using large masses of data collected and analyzed

during the last several years, the writers have attempted to express in figures the probability that a man or woman submitting to gastric analysis at The Mayo Clinic in a given decade of life, with a given gastric acidity, measured one hour after an Ewald type of meal, is suffering with gastric carcinoma, gastric ulcer, duodenal ulcer, or one of a residual group of other diseases or neuroses.

Many interesting and surprising and diagnostically helpful facts have emerged from a study of the material here analyzed.

Obviously the figures published would not be applicable in the case of a patient seen in an office or

## Women

Fig. 1b. Percentage incidence of duodenal ulcer, gastric ulcer, and gastric carcinoma in women of different ages with achlorhydria, hypochlorhydria, eucharhydria, and hyperchlorhydria. In the residual group, designated "normal," roentgenologic examination of stomach and duodenum was negative.

hospital if the composition of the clinical material seen there varied widely from that observed at The Mayo Clinic.

The arithmetic of calculating these probabilities is described for the use of those who may wish to con-

struct their own tables.

It is hoped that a contribution has been made to the methodology of diagnosis; surely the technic here described, or others similar to it, must one day be applied to many other diagnostic problems.

## SECTION III—*Nutrition*

### A Year's Exclusive Meat Diet and Seven Years Later

By

CLARENCE W. LIEB, A.M., M.D.  
NEW YORK CITY, NEW YORK

IN 1926, the writer published the following article: "The Effects of An Exclusive Long-continued Meat Diet," based on the history, experience and clinical survey of Vilhjalmur Stefansson, Arctic Explorer.\*

This paper brought out the following medical facts regarding Stefansson's life in the Arctic.

1. He spent altogether eleven and one-half years within the Arctic Circle.
2. He lived for a number of days, totaling nine years, on an exclusive meat diet.
3. He lived for nine successive months on an exclusive meat diet.
4. He reached his maximum weight while subsisting on meat (fish).
5. His sense of physical and mental well being was at its best during that period of his life.
6. He found that the exclusive meat diet worked as well when he was inactive as when active, and as well in hot weather as in cold.
7. Constipation was never present. One month's entire absence from exercise produced neither constipation nor muscular weakness. (Stefansson avers that not a single case of constipation was observed in 600 exclusively meat-eating Eskimos for a period of three years).
8. His hair thickened, and his scalp became healthier.
9. Tooth decay was apparently much less rapid.

A physical inventory made of Stefansson in 1922 when he was 43 years old, was as follows: Weight—70.8 kg. He was 5 feet 11 inches (180.3 cm.) tall, and well developed and nourished. He looked his years, but no older. The hair was thick and brown with a dry scalp. The face was somewhat asymmetrical. The eyes were normal. The von Graefe, Möbius and Dalrymple signs were not present. The pupils were equal and reacted to light and accommodation. The ears and nose were normal. The tonsils were medium sized and cryptic, with a slight purulent secretion on aspiration. The teeth, objectively, were in good condition, with healthy gums and normal gingival margins. There was no struma. The posterior cervical glands could not be palpated.

The chest measurements were: inhalation, 37 inches (94 cm.); exhalation, 34½ inches (87 cm.): at rest, 35½ inches (90 cm.). A pea-sized cyst was present on the third rib to the right of the sternum. The

lungs were normal throughout to auscultation, palpation and percussion. Fluoroscopy showed peribronchial thickening. The apex beat of the heart was mediad to the left maxillary line; the aortic second beat equaled the pulmonic second; no murmurs were elicited. There was normal response to cardiac functional tests. The pulse was 60, equal, regular, and synchronous. The vessel walls were barely palpable. There was no tremor of the outspread fingers.

The systolic blood pressure was 115 and diastolic, 55, in both arms.

Slight eczema could be seen between the toes, on the right instep and behind the right ear.

The *tache cerebrale* was normal. No dystrophy or cyanosis of the nails was present.

The *crincs* of the abdomen were triangular; the *hirci* were of the female type. No tenderness or masses were felt.

The liver was not felt, nor was the dullness increased. The spleen was not palpable. The gonads were normal.

The knee jerks were active and equal. The Babinski reflex was negative.

Slight external hemorrhoids were present. The prostate was normal. The spine was straight, with free and painless movements.

Men in the various specialties have examined Stefansson, and reports have been entirely negative. Laboratory examinations of the blood (including morphologic, biologic, and chemical) urine, stool, basal metabolism and kidney function tests were normal.

In 1929, the writer published another article with the following title: "The Effects on Human Beings of a Twelve Months' Exclusive Meat Diet,"\* based on intensive clinical and laboratory studies on two Arctic Explorers living under average conditions in a New York climate. This study was made at the Russel Sage Foundation at Bellevue Hospital, under the supervision of the following scientific committee: Dr. Raymond Pearl (Chairman), Dr. E. F. DuBois, Dr. L. J. Henderson, Dr. E. A. Hooton, Dr. Percy Howe, Dr. E. O. Jordan, Dr. C. W. Lieb, Dr. Graham Lusk, Dr. W. C. McCallum, Dr. Walter L. Niles, and Dr. Clark Wissler.

The following is a clinical and laboratory summary of these findings:

**Caloric Intake:** Stefansson averaged about 2,650 calories a day; 2,100 calories consisting of fat and 550

\**Jour. A. M. A.*, July 3, 1926, Vol. 57.  
Submitted July 3, 1935.

\**Jour. A. M. A.*, July 6, 1929, Vol. 93, pp. 20-22.

of protein. Andersen averaged about 2,620 calories a day; 2,110 calories consisting of fat and 510 of protein. Carbohydrate in the meat varied between 20 and 50 calories a day.

**Blood Pressure:** Stefansson maintained a blood pressure of 105 systolic and 70 diastolic during the entire course of his diet. Andersen's blood pressure was 140 systolic and 80 diastolic at the beginning of the diet and 120 systolic and 80 diastolic on the completion of the year's diet.

**Vitality:** In neither subject was there a decrease in physical vigor. Both led sedentary lives throughout the experiment. No subjective nor objective signs or symptoms of a decrease in physical vigor were observed. The same holds true of their mental vigor.

**Heat Tolerance:** Andersen affirms that he endured last summer's heat, if anything, better than during former years.

**Appearance:** Both men appeared ruddier at the end of the experiment than at the beginning.

**Hair:** Andersen noted that his hair stopped falling out shortly after the meat diet was started and that the progressive loss has been checked up to date.

**Teeth:** In neither case has there been any deterioration of the teeth. The dentist who has watched these two subjects throughout the experiment noted a greatly increased deposition of tartar on Stefansson's teeth while on the meat diet than formerly. This is interesting in view of the low calcium content of meat. There was also a notable absence of pyorrhea in both subjects.

**Bowels:** Andersen's bowels have remained normal throughout the diet regimen and required practically no catharsis. Stefansson, who has had a tendency to constipation while living in civilized communities, found no increase in this tendency while on the meat diet. An interesting point in this connection is that in both these men the stools were non-odorous and there was no evidence of gaseous distention or flatus at any time. The stools were somewhat below average size and usually were formed.

**Pulse, Temperature and Sleep:** There was no variation from the normal and usual.

**Metabolism:** The basal metabolism of these subjects showed a uniform variation between minus 10 and minus 20 per cent by the Aub-Du Bois standards. There was a slight rise in metabolic rate of 5 per cent during the first month. It is therefore noted that meat diets do not produce any striking elevation of metabolism.

**Weights:** Andersen weighed 60 Kg. at the start. At the end of one month he weighed 58.5 Kg.; at the end of the second month he weighed 60.5 Kg.; at the end of the year's meat diet, 58 Kg.; after recovery from pneumonia 57 Kg., and at this writing, three weeks after recovery from pneumonia, he has regained his original weight.

Stefansson's original weight was 72.5 Kg. At the end of the first month it was 68 Kg.; at the end of the second month it was 69, and at the end of the year's meat diet 69.4 Kg. From April, 1928, to March, 1929, there was no change in weight. Stefansson's concluding weight after the calorimeter studies had been completed was 69.7 Kg.

**Effects on Kidneys:** 1. No albumin, casts or blood was found at any time during the course of the experiment.

2. A "red test" on Andersen showed 55 per cent excretion at the beginning of the experiment; 62 per cent after recovery from pneumonia after completion of a year's meat diet. (The red test was not carried out on Stefansson).

3. Urea clearance showed 100 per cent plus.

These tests would indicate an ability on the part of the kidneys to hyperfunction while on a meat diet.

4. Roentgen examination of the kidneys before and at the conclusion of the meat diet did not show any change in size.

**Mineral Metabolism:** As Aub's work indicated that an acid diet increases calcium excretion and calcium drainage, one would suspect that subjects on a meat diet, which is an acid diet and is likewise low in calcium, would in a year show a calcium deficiency. The increased amount of tartar on Stefansson's teeth and the lack of evidence of lowered blood calcium offers an interesting field for speculation. There was no decreased density in roentgenograms of the hands at the end of the experiment when compared with the hand of a man on a general diet.

**Chemical Analysis of the Blood:** The chemical composition of the blood was little affected except for a slight increase in uric acid and a temporary lipemia. The latter occurred only after unusual amounts of fat were taken. Non-protein nitrogen, urea, uric acid, creatinine, sodium chloride, sugar, carbon dioxide combining power, serum calcium, plasma protein albumin (plasma), globulins, total protein (plasma) albumin: globulin ratio, and cholesterol were studied before the meat diet and after an exclusive meat diet for twelve months, and no noteworthy changes were discovered. Of interest was the fact that the dextrose tolerance test, consisting of the ingestion of 100 Gm. of dextrose, developed in Andersen a typical diabetic curve resulting in the spilling of sugar for the two following days.

**Observations on Intestinal Flora (by Dr. John C. Torrey):** No blood appeared in the fecal specimens and rarely any mucus, the latter occurring once in the case of Andersen and twice in that of Stefansson. The stool reactions were generally definitely acid—between pH 6.0 and 6.8—with an inoffensive, slightly acid odor.

The whole meat diet in both subjects caused a simplification of the intestinal flora with a marked reduction both in types and in total numbers of bacteria. The acidophilus, enterococcus and streptococcus types were practically eliminated. The *B. coli* group increased greatly numerically at first but later decreased and for a time in one subject (Andersen) were largely replaced by *B. proteus*. Hemolytic *B. coli* increased in both during the first one to three weeks, then disappeared. No increase in virulence of colon strains occurred. *B. welchii* at the start was present in both subjects in higher counts than usual for normals, and during the first period a great increase occurred. Later the count fluctuated but was generally high. There were very few putrefactive spore-bearing anaerobes at any time. The diet did not appear to introduce them or encourage their growth.

This meat diet did not cause the development of a putrefactive flora in Stefansson and in Andersen only so far as the late appearance of *B. proteus* (noted first after about one year on the diet).

#### PRESENT CONDITION

The writer has made yearly examinations on Stefansson from 1922 up to the present. It may not be

without some scientific interest to know the health status of Mr. Stefansson at this time.

**Age:** 55 years old. Looks healthy and has aged very little in the past four years.

**Weight:** 84 Kg. compared with 70.8 in 1922 and 72.5 in 1928.

**Head:** No headaches, occasional colds, though mild; sinuses normal.

**Hair:** Thick as in 1922. Iron gray in color. Rarely wears a hat.

**Thyroid:** Negative.

**Teeth:** Dr. Henry S. Dunning reports as follows: (April 16, 1935). "The soft tissues are spongy and the gingival margin has been greatly impaired by an accumulation of calcareous deposits that have been allowed to collect over a period of months. He had a couple of pulpless teeth that I removed, namely the lower left second molar and the upper right first bicuspid that was badly broken down. I feel that the investing tissues of his teeth are fairly good in that he has no bone abscesses."

**Eyes:** No *arcus senilis*. Eye grounds normal. Wears glasses only for reading.

**Ears:** Hearing unchanged, though never very acute.

**Smell:** No change. Never very sensitive.

**Taste:** Normal. Never a gourmet.

#### Cardio-respiratory:

**Heart:** Normal sounds. Pulse 72, equal, regular, synchronous. Oculo-cardiac reflex normal. Negative Erben sign. Good response to exercise. Takes no exercise and walks only when absolutely necessary.

**Blood Pressure:** 120/80.

**Arteries:** Slight radial thickening. (See eye grounds).

**Lungs:** Normal.

#### Genito-urinary:

**Prostate:** Normal.

**Kidneys:** No nycturia. Urine normal in every way.

**Gastro-intestinal:** No gas, heartburn or other stomach symptoms. His diet is poorly balanced. He eats three meals a day, taking a very light breakfast of one egg, bread and coffee. His lunch and dinner are of about an equal consistency. He takes a moderate amount of meat twice a day; vegetables in moderation, cheese once or twice daily, no bread at these meals, usually no deserts, particularly of the starchy kind. He very rarely takes fruit and his milk intake is negligible. He drinks a glass of water at meals and none between meals; two to four cups of coffee daily with cream and sugar and tea occasionally without milk or sugar. He has no digestive symptoms either chronic

or acute. His bowels move every other day very regularly with the occasional use of mineral oil. He has had two attacks of "food poisoning" during the past two years. Stool examination recently showed normal reaction and food residue, no mucus and practically normal bacteriological findings.

**Liver:** Dullness normal limits. Not palpable. No tenderness over gall bladder. (Typhoid in Arctic).

**Appendix:** No tenderness or spasm in right lower quadrant. No cecal splash.

**Rectum:** Small internal hemorrhoids, sphincter normal.

**Proctoscopic Examination:** Negative.

#### Neuro-muscular:

**General Neurological tests:** Elicit normal results. No insomnia.

**Joints and muscles and feet:** Normal.

#### Blood Chemistry:

#### Stool examination:

Normal color, odor, consistency. No mucus. Slight reaction for occult blood (hemorrhoidal origin), normal microscopic findings. H- ion conc. pH 6.9. Bacteriological studies showed a high count of normal strains of *B. coli*; many *enterococci* (non-toxic organisms) and a high count of *Strep. viridans* (alpha) of moderate toxicity.

#### Basal Metabolism:

Minus 8.

Mr. Stefansson has been in excellent general health since his exclusive meat diet. He has led a very sedentary life and has worked fairly strenuously at writing, lecturing and in a consulting capacity with an aviation company.

## ABSTRACTS

GILDEA, M. C. L.; CASTLE, W. B.;  
GILDEA, E. F., AND COBB, S.

*Neuropathology of Experimental  
Vitamin Deficiency. Amer. Jour.  
Path., XI, 65, p. 669, July, 1935.*

The authors report further studies on the attempt to produce experimental lesions of the spinal cord by means of diets deficient in vitamin B complex in the hope of showing a relationship to those types of combined system disease seen in pernicious anemia, pellagra, and chronic alcoholism.

Four series of dogs were used in these experiments. All were placed upon a basal diet deficient in vitamin B complex. Dogs kept upon this diet, and without treatment with vitamin B concentrates, developed early signs of acute disturbance of the central nervous system and soon died. Only minimal histological changes were found in the central nervous system in these animals. In other dogs repeated treatments with vitamin B concentrates were used to prolong their lives. They developed

gradually a degree of spastic ataxia and eventually motor paralysis. Definite histological lesions of the central nervous system were found in all but one animal of the series. Degenerative changes were noted in the cerebral and Purkinje cells and in the cells of the anterior horns in seven dogs. Myelin degeneration in the spinal cords were also observed and in three animals changes in the peripheral nerves were present.

N. W. Jones, Portland.

## SECTION V—*Therapeutics*

### Gastro-Intestinal Diets \*

#### HYPER-NUTRITION DIET

##### *Breakfast*

Fruit—Orange, grapefruit, baked apple or any stewed fruit, prunes in particular.

Cereal—Any cooked cereal with three ounces of cream (oatmeal at least twice a week).

Eggs—Any form except fried, with bacon. May substitute mutton or lamb chop broiled.

Bread—Two pieces of bread or toast with an abundance of butter.

Beverage—Milk, weak tea, cocoa, coffee.

##### *Mid-Morning*

Six ounces of equal parts of milk and cream.

##### *Noon Meal*

Soup—Puree of pea, bean, potato or celery or oyster stew.

Meat—Choice of chipped beef with cream; baked tomato with cream, chicken, cheese or tongue sandwich.

Vegetables—Choice of one vegetable as desired.

Bread—Abundance of bread and butter, whole wheat preferable.

Dessert—Choice of dessert given below.

##### *Mid-Afternoon*

Same as mid-morning or egg and milk and malted milk.

##### *Evening Meal*

Soup—Puree of pea, bean, potato, celery, bouillon, chicken broth with rice, noodles.

Meat—Roast beef, tenderloin, brains, sweetbreads, boiled; lamb or mutton chop; fowl or fresh fish.

Vegetables—All vegetables are allowed. Choose one green and one starchy vegetable.

Salad—Lettuce and tomato. Olive oil and mayonnaise dressing.

Bread—Two pieces of bread and lots of butter.

Dessert—Apple, lemon, peach custard or cream pie; bread, chocolate, rice, tapioca or cornstarch puddings; custard, blanc mange, egg souffle, floating island, ice cream, spanish cream, plain cake or any stewed fruit.

Almonds, pecan nuts, walnuts, dates, raisins, molasses.

Beverage—Same as Breakfast.

##### *9:30 P. M.*

Same as mid-afternoon with crackers and butter.

Avoid tea and coffee except as above, salads except as directed, raw fruits, coarse vegetables, candy, pork,

thin soup, hash, cabbage, scrapple, veal and fried foods or any food highly seasoned.

#### CAUTIONS

ARISE ONE HOUR BEFORE BREAKFAST AND TAKE A BRISK WALK.

TAKE A COLD SPONGE BATH EACH MORNING.

TAKE MEALS AT THE SAME HOUR EACH DAY.

RETIRE AND ARISE AT THE SAME HOUR.

TAKE A MODERATE AMOUNT OF OUTDOOR EXERCISE.

TAKE AT LEAST ONE QUARTER POUND OF BUTTER DAILY.

#### ACHYLIA—SUBACIDITY

##### *Breakfast*

Fruit—Juice of orange, prunes, or grapefruit.

Cereal—Any cooked cereal with cream and sugar.

Eggs—One soft boiled egg.

Bread—Toast or stale bread with butter.

Beverage—Cup of cocoa or weak tea with milk.

##### *Dinner*

Soup—Bouillon, broth or puree of vegetables.

Vegetables—Select two of the following vegetables: baked, mashed or creamed potatoes, macaroni, or spaghetti, asparagus, or spinach (small quantity) or rice, tapioca, hominy, peas, or beans (mashed and strained).

Meat—Boiled or broiled calves brains or sweetbreads; fresh fish, lamb, or chicken finely divided.

Dessert—Jello or simple desserts.

Bread—Toast and butter.

##### *Supper*

Meat or Substitute—Two eggs, any form except fried, raw or stewed oysters, cream or cottage cheese.

Vegetables—Choice of vegetables as above or cooked cereal.

Bread—Bread (white) with butter.

Dessert—Stewed peaches or apricots, baked apple without skin, fruit juice, plain cake, simple pudding or custard.

Beverage—Cocoa or weak tea.

#### CAUTIONS

AVOID ALL UNCOOKED FOOD, ALL HEAVY FIBROUS FOOD, AS CABBAGE, TOMATO, CORN, CELERY, SALADS, PICKLES, RELISH, ETC.

CHEW FOOD THOROUGHLY.

DINNER MAY BE TAKEN IN THE EVENING IF DESIRED.

## SECTION VI—*Abdominal Surgery*

### Gastro-Intestinal Manifestations Accompanying Diseases in the Upper Urinary Tract\*

By

BENJAMIN S. ABESHOUSE, Ph.B., M.D.†  
BALTIMORE, MARYLAND

#### INTRODUCTION

IN this era of instrumental diagnostic precision and highly specialized roentgenographic technique there is a tendency on the part of clinicians and urologists alike to pay but little attention to a careful analysis of the symptoms of urinary diseases. It is not entirely amiss to point out that, now as in the past, an accurate diagnosis of any urinary disorder must be based on a complete history, careful general examination together with a detailed and thorough urological examination. Unfortunately, in the evaluation of the symptoms of any urinary disease, there is a tendency to minimize or overlook symptoms referable to any other organ or system of organs outside of the urinary tract. To facilitate the establishment of an early and correct diagnosis, it is imperative to study carefully the symptomatology of any urinary disease in the light of the body as a whole.

Gastro-intestinal manifestations are by no means uncommon occurrences in diseases of the upper urinary tract. Practically every case is accompanied by some gastro-intestinal complaint of a transitory or permanent character, *i.e.*, nausea, vomiting, epigastric distress, abdominal discomfort, constipation, diarrhea, etc., which is readily forgotten by the patient and glibly dismissed as of no importance by the physician. In most of the older textbooks of urology, there is scant or no reference to the occurrence of gastro-intestinal symptoms of genito-urinary disease. The more recent textbooks discuss the subject at no great length and lay particular stress on their association with movable kidney.

The gastro-intestinal symptoms may be classified as (a) *toxic*, (b) *mechanical*, or (c) *reflex*. The toxic type may be the manifestations of an uremic or infectious process in the kidney. The frequent occurrence of nausea and vomiting in an acute or chronic infection of the upper urinary tract, *i.e.*, nephritis, pyelitis, pyelonephritis, tuberculosis, may be due to the reaction to bacterial toxins or to excessive nitrogenous compounds in the blood. The latter is associated with a

failing renal function and is indicated by a high non-protein nitrogen in the blood.

Friedenwald and Morrison maintain that in the early stages of the various nephritides the amount of toxic substances accumulating in the blood is slight and, being excreted in small amounts in the gastro-intestinal tract, gives rise to minor digestive disturbances. As the disease process in the kidneys progresses and the amount of toxic products in the blood increases, these toxic substances are excreted into the gastro-intestinal tract in excessive amounts and give rise to grave digestive disturbances as a result of the development of a gastro-enteritis or ulceration.

At other times, the gastro-intestinal symptoms are obstructive in character and are due to the pressure of enlarged kidney or renal tumor or to the irritation produced by an accumulation of blood, pus or urine in the perirenal space upon the peritoneum and intestines overlying the ureter, kidney and perirenal tissues. However, in the majority of cases, the gastro-intestinal symptoms are due to the reflex action of the stomach or intestinal tract to stimuli originating in the upper urinary tract and are unassociated with any disease of intestinal origin. Symptoms pointing to a difficulty in urination may be entirely absent and the urine may be normal. Tixier and Clavel have called this phenomenon of stimulation of the entire gastro-intestinal tract or a specific portion thereof by nerve impulses originating in the retroperitoneal area, *i.e.*, ureter, kidney or perirenal space "the retroperitoneal syndrome."

Every surgeon of wide experience has encountered patients who were suffering from primary disease of the upper urinary tract and presented acute or chronic gastro-intestinal symptoms which have been mistaken for a gastro-duodenal, hepatic, appendiceal or colonic lesion and have been so confusing as to cause unnecessary surgical intervention. To the surgeon's extreme disappointment, operation disclosed a normal appendix, stomach, duodenum, gall bladder and pelvic organs with an absence of fluid or pus, although the bowel may be dilated in some areas and contracted in others. Immediately following the operation, the intestinal spasm or distension disappears and the patient recovers. Some days or weeks later the patient has another similar attack which is quite confusing until an urolo-

†Attending Urologist, Sinai Hospital. Instructor in Genito-urinary Pathology, Univ. of Maryland Medical School.

Read at the meeting of the Baltimore-Washington branch of the American Urological Association in Baltimore, Md., on January 18th, 1935.

Submitted April 26, 1935.

gical investigation is ordered and the true nature of the underlying urinary disease is revealed.

The importance and necessity of a thorough pre-operative, urological examination in cases with obscure abdominal pain or uncertain diagnoses is clearly established by the statistical studies of the condition of patients before and after major abdominal operations. Connor reported that 10 per cent of all the cases admitted to the Mayo Clinic required urological study. Stevens maintained that urological investigation was indicated in at least one-third of all patients entering a hospital with uncertain diagnoses. Reports from other large clinics revealed that 15 to 20 per cent of patients with renal or ureteral lesions had been previously subjected to abdominal operations for the same complaint. Blesh reviewed 5000 surgical cases in many of which the appendix was removed and found that 40 per cent of the patients complained of the same symptoms after as before the operation. Liek analyzed 1000 cases of chronic appendicitis subjected to operation and observed only 100 cases of genuine chronic appendicitis. Lowsley and Twinem studied 84 urological cases and noted that 39 patients had previously undergone some major surgical operation without relief of symptoms. In this latter group, 31 had the appendix removed.

Beck analyzed 284 private patients with urologic disease examined by Goldstein and Abeshouse and found that 151 patients (57 per cent) suffered from gastro-intestinal symptoms and in 85 patients it was the chief complaint. In this series 207 operations had been performed prior to the urological study. In 137 cases, operation was performed on the abdominal organs which included 58 appendectomies with no relief in 31 cases, 48 pelvic operations with no relief in 26 cases, 9 gall bladder operations with no relief in 2 cases, 2 operations for gastric ulcer with no relief in one case, and 6 exploratory laparotomies with no relief in any case. In a review of 300 cases of urinary tract disease, Cecil found that pain was present in 183 cases and was limited to the abdomen in over 22 per cent. There were 67 cases of stone in the kidney or ureter of which 19 cases (28 per cent) presented abdominal pain and in over 20 per cent the pain was so misleading as to lead to abdominal operation.

#### HISTORICAL BACKGROUND

The present conception of the "retroperitoneal syndrome" is based on the correlation of clinical observations and experimental data. In 1897, Tixier observed that irritation of the parietal peritoneum initiated a series of reflexes culminating in a condition which he described as "abdominal shock" or "peritonism." Later it became apparent from numerous clinical observations that similar reflexes might originate in the kidney and perirenal tissues. In 1929, Clavel presented a comprehensive review of the various surgical affection of the kidney, *i.e.*, tuberculosis, neoplasm, polycystic disease, pyonephrosis, etc., which were accompanied by peritoneal or gastro-intestinal syndromes with no urinary symptoms. Sternberg, Stewart, Quenu and others have reported cases of renal lithiasis which produced severe abdominal and peritoneal phenomena suggesting ileus. Marie, Samuels and Kern, McGlannon, Alle-

man and others have described cases of congenital and acquired hydronephrosis in which gastro-intestinal symptoms were the most prominent manifestation of the renal disease. Any ureteral or renal lesion which is accompanied by an accumulation of urine, pus or blood in the periureteral or perirenal space causing an irritation of the posterior parietal peritoneum may simulate an intestinal obstruction or peritonitis. Such phenomena have been observed following perinephritic abscess (Tixier, Higgins, Berkman), spontaneous perirenal hemorrhage (Greco, Grasman), traumatic rupture of the kidney with retroperitoneal effusion of hemorrhage (Tixier, Eisenklam), and extra-peritoneal rupture of a hydronephrosis (Von Saar). Recently the Author reviewed 64 cases of rupture of the renal pelvis and observed that gastro-intestinal manifestations were a constant feature in every case and occasionally were the predominant manifestations.

#### THE NERVOUS MECHANISM INVOLVED IN THE RETROPERITONEAL SYNDROME

A knowledge of the anatomy and physiology of the upper urinary and gastro-intestinal tracts is essential to explain the symptoms of reflex origin which constitute the retroperitoneal syndrome.

The nerve supply of the kidney has been studied by Papin, Petit-Dutailis, Nisio, Labat and others. The twelfth dorsal and first lumbar segments of the spinal cord serve as the source of the renal nerve supply. The visceral nerves of the kidneys are derived from the renal plexus on each side. The latter plexus originates from the inferior portion of the coeliac (solar) plexus especially from the corresponding aortic-renal ganglion which receives (a) the posterior renal nerve or the third splanchnic, derived from the twelfth thoracic ganglion, (b) some fibers from the lesser splanchnic

Fig. 1. The solar plexus and the nerve supply of the kidneys. (After Labat: Regional Anesthesia).

Fig. 1

nerve and (c) a branch from the first lumbar sympathetic ganglion (Fig. 1). The kidney also receives communications from the vagus nerve whose fibers terminate in the coeliac plexus. The renal nerves form a network, which consists of numerous small parallel longitudinal fibers with transverse anastomoses and surrounds the renal artery. These small fibers follow the renal artery and all its branches into the renal parenchyma to reach the Malpighian corpuscles, Bowman's capsule, tubular epithelium and interstitial tissue. Nerve terminations have also been demonstrated in the smooth musculature of the pelvis, in the renal capsule and in middle layer and adventitia of the blood vessels of the kidney.

Wharton has recently made a detailed study of the innervation of the ureter which confirms some of the observations of the early investigators and further enhances our knowledge of this subject. According to Wharton, the ureter receives a nerve supply which is independent of the innervation of the kidney and the bladder. The efferent nerves of the ureter are derived from (1) the lowest renal ganglion at the upper end of the spermatic plexus and (2) the abdominal sympathetics (aortic, hypogastric and pelvic plexuses) which constitute the coeliac plexus. The aortic plexus receives branches from the upper lumbar sympathetic (prevertebral) ganglia and the pelvic plexus receives direct fibers from the sacral cord. The posterior peritoneum in the region of the kidney and ureter is innervated by the same nerves supplying these organs. Anatomical dissections reveal many anastomoses between the renal plexuses and the superior and inferior mesenteric plexuses.

The innervation of the stomach, small intestines, cecum and transverse colon is derived in part from the same source as the kidney and ureter. These alimentary organs receive their nerve supply from (1) the vagus nerve which contains parasympathetic (excitomotor) fibers, and (2) coeliac plexus whose sympathetic (inhibito-motor) nerves come by way of the greater splanchnic nerve from the fifth to the ninth dorsal segments of the cord and through the lesser splanchnic from the tenth to the twelfth dorsal spinal segments (Fig. 1). The remainder of the gastro-intestinal tract (descending colon, sigmoid, rectum and anal sphincter) and the lower genito-urinary tract have a common nerve supply consisting of (a) sympathetic (inhibito-motor) fibers derived from the lumbar segments of the cord and (b) parasympathetic (excitomotor) fibers originating in the second, third and fourth sacral segments. The physiological response to stimulation of these various nerves has been accurately determined. Stimulation of the vagus nerve results in an initial inhibition of the gastric and intestinal movements of very short duration followed by an increase in intestinal motility (hyperperistalsis). Stimulation of the sympathetic nerves is followed by a decrease in the intestinal movements. The effect of stimulation of the sympathetic or parasympathetic fibers upon the vari-

ous sphincters in the gastro-intestinal tract is usually opposite to that effect upon the intestinal walls.

### PHYSIOLOGICAL RESPONSE TO STIMULI ORIGINATING IN UPPER URINARY TRACT

Inasmuch as the upper urinary and gastro-intestinal tracts are innervated by sympathetic and parasympathetic nerves and one of the chief functions of the vegetative nervous system is to insure proper coordination of the various organs of the body, it is reasonable to suppose that any disturbance or dysfunction in one organ may give rise to symptoms in other organs possessing a similar innervation. Such phenomena have been recognized for a long time and have been described as "viscero-visceral reflexes" by Sir James MacKenzie. He explained the production of pain through viscero-motor reflexes which occurs when stimuli from an affected organ, if of adequate strength, stimulate other nerve cells of the spinal cord in the neighborhood of those from the affected viscus. The response to such stimuli varies according to the intra- and inter-segmental connections of the efferent nerves and the particular function of the afferent nerves reflexly stimulated. A familiar example of this mechanism is the spasm of the gastric and intestinal musculature resulting in nausea and vomiting associated with an acutely inflamed appendix.

The same mechanism may suffice to explain the occurrence of referred gastro-intestinal symptoms in diseases of the upper urinary tract. The coeliac plexus appears to be the center of reflex action for stimuli originating in the kidney, ureter or posterior parietal peritoneum. Some of these reflexes may take a short circuit as they pass through the renal ganglia and the inferior mesenteric ganglia and are referred to the visceral branches supplying the various portions of the gastro-intestinal tract (Fig. 2). Other reflexes undoubtedly have a longer circuit as impulses from the kidney and perirenal area reach the spinal cord and

Fig. 2. Diagram showing the afferent and efferent routes of renal stimuli. The centrifugal route of the various renodigestive, viscero-motor and viscero-sensory reflexes can be readily determined. (After Smith: Canadian Med. Ass. J., 1933; 28:281).

pass upward in the tractus solitarius to the nucleus of the vagus. From this point these impulses are further transmitted through parasympathetic fibers which are distributed to the stomach and upper intestines causing a transitory arrest of gastric and intestinal motility followed by an increase in motility. This interference with the musculature of the stomach and duodenum may produce any of the usual symptoms of dyspepsia, *i.e.*, pain, nausea, vomiting, heartburn, belching, epigastric fullness, etc. By similar reflex connections through the intermedio-lateral column cells of the spinal cord, impulses pass through the sympathetic (inhibito-motor) fibers supplying the large bowel resulting in abdominal pain, cramps, constipation, diarrhea or ileus.

Stimuli originating in the upper urinary tract not only cause reno-digestive reflexes but also are projected in the various skin zones producing referred pain. Head has studied the topography and mechanism of pain projection on the wall of the abdomen in renal colic and other diseases of the kidney. The pain usually is associated with localized muscle spasm or rigidity and cutaneous hyperesthesia which may simulate the findings associated with an acute abdominal lesion. It is also well to point out that other general symptoms, *i.e.*, changes in pulse, respiration and blood pressure, vasomotor disturbances, etc., may accompany many of the reno-digestive reflexes as a result of stimulation of the parasympathetic and sympathetic nerves which act as the centrifugal route of the reno-digestive reflexes.

There is much experimental evidence to support the above data and to confirm the clinical observations that stimuli originating in the kidney or perinephritic tissues may produce motor or inhibitory reflexes in the gastro-intestinal tract. Tixier and Clavel studied the influence of renal and perirenal stimuli on gastro-intestinal motility and observed increased contractibility of the stomach and the intestines when the kidney parenchyma, pelvis and parietal peritoneum were stimulated. They also studied the effect of an injection of salt solution in the retroperitoneal area of guinea pigs and found some intestinal segments dilated and congested as though affected by vasodilatation and paralysis while the intermediate segments appeared pale and contracted. Carnot and Thomas and Wheelan showed that spasm of the pylorus could be caused by stimulation of almost any visceral efferent nerve. The same phenomenon could be induced by rubbing, stretching or crushing the urinary bladder, ureter, kidneys, intestines, parietal peritoneum and anal sphincters. The same effects were also obtained by section of the vagi in the neck.

From a physiological viewpoint, the reno-digestive reflexes concerned in the retroperitoneal syndrome may be classified according to their effects upon the various portions of the gastro-intestinal tract. The principal types are the (a) reno-gastric, (b) reno-intestinal, (c) reno-hepatic and (d) reno-peritoneal. The first two types are by far the most important. The reno-gastric reflexes may be motor, secretory or vasomotor in character and their effect is either a stimulation or inhibition of gastric secretion and motility. These stimuli may affect either the stomach or duodenum or both; the pylorus is particularly susceptible to such stimuli. The reno-intestinal reflexes are also motor, secretory or vasomotor and may produce either

spastic contractions or paralysis of the intestinal musculature. The majority of reno-intestinal reflexes of renal or perirenal origin affect the large intestines, particularly the cecum and colon; those of right ureteral origin may produce similar phenomena in the cecum and appendix and those of left ureteral origin appear to affect the descending colon, sigmoid and rectum. The various types of reno-intestinal reflexes may be associated with each other or combined with reno-gastric or cardiac, respiratory or vasomotor reflexes causing a group of symptoms simulating peritonitis or intestinal obstruction.

#### THE ORIGIN OF STIMULI WITHIN THE UPPER URINARY TRACT

The point of origin of the reno-digestive reflexes varies in the different clinical cases. The majority of the lesions in the upper urinary tract which initiate the reflex stimulation of the gastro-intestinal tract can readily be diagnosed by a thorough urological study including a pyelographic study of both ureters and pelves in the horizontal and upright positions. In a few cases the exact nature of the underlying renal lesion can only be determined at operation. The following indicate the more common sites and lesions which serve as the starting point for the various reno-digestive reflexes:

(a) Stimulation of the mucous membrane of the renal pelvis or ureter by a stone, pus or blood clot, *i.e.*, renal or ureteral calculi, pyelitis, pyelonephritis, intrarenal hemorrhage following trauma, tumor, etc.

(b) Stimulation of the nerve endings in the pelvis or ureter as a result of distension (hydronephrosis or hydroureter) secondary to any intrinsic or extrinsic obstruction of the ureter or pelvis, *i.e.*, congenital or acquired stricture of ureter; aberrant vessels or adhesions crossing the ureter or at the ureteropelvic junction; pressure of an extraurinary tumor upon the ureter, etc.

(c) Stimulation of the nerve endings in the renal parenchyma or capsule by an inflammatory or neoplastic disease process, *i.e.*, pyelonephritis, cortical abscess, renal carbuncle, pyonephrosis, tuberculosis, tumors, solitary cyst, polycystic disease, etc. The response to such stimuli is greater when the disease process is located in the cortex or immediately adjacent thereto.

(d) Stimulation of the fibers of the renal plexus and indirectly of the coeliac plexus as the result of the traction exerted on the renal pedicle and fat capsule of the kidney by a congenital or acquired dystopic kidney, *i.e.*, movable kidney, congenital anomalies of the kidney, etc.

(e) Stimulation of the fibers of the renal and coeliac plexuses as a result of distension, irritation or laceration of the nerve fibers in the perirenal tissues and posterior parietal peritoneum produced by any subcapsular or perirenal collection of urine, pus or blood, *i.e.*, perinephritic abscess, perinephritis, rupture of the kidney with intrarenal, subcapsular or perirenal hemorrhage or extravasation of urine, hemorrhage within a tumor or cyst, etc.

(f) Stimulation of the nerve endings in the posterior peritoneum and the adjacent intra-abdominal organs as a result of the pressure or traction exerted upon these structures by any intrarenal or extrarenal swelling of an obstructive, inflammatory, hemorrhagic

or neoplastic character, *i.e.*, renal tumor, cyst, pyonephrosis, perirenal hemorrhage or abscess.

The response to these stimuli may vary in the same or different individuals. In the majority of instances, the centrifugal route of the above stimuli most often results in the projection of pain in the various skin zones. In only a small percentage of the cases, the response to these stimuli is manifested by reno-digestive reflexes. According to Tixier and Clavel there are several factors which exert a considerable influence upon the development of these reno-digestive reflexes, *viz.*, (1) summation of primary irritative stimuli; (2) sensitization of the nerve centers; and (3) individual predisposition.

1. *Summation of primary irritative stimuli:* The mechanism responsible for the production of reno-digestive reflexes is a complex one. Clinical and experimental studies show that a solitary or isolated renal stimulus is not always sufficient to produce a reflex reaction but that the latter readily follows a summation of different stimuli caused by the same or a co-existing lesion. For example, a large calculus, situated in the renal pelvis and unaccompanied by distention or infection may evoke no greater response than localized pain whereas a small stone totally occluding a ureter and accompanied by dilatation of the ureter and pelvis and by irritation of the ureteral mucosa may produce a more complex response. For the same reason cortical lesions, unless accompanied by a slight traction on the pedicle, distention of the pelvis or irritation of the perinephritic tissue or posterior peritoneum, are not likely to cause reno-digestive reflexes.

2. *Sensitization of nerve centers by chemical or bacterial toxins:* Experimental studies have shown that pilocarpine increases the intensity of reno-digestive reflexes and lowers the threshold of stimulation necessary to initiate these reflexes whereas atropine and nicotine have an opposite effect. It is highly probable that a similar sensitization of the nerve centers occurs in some of the clinical cases. Some nitrogenous compound found in the blood of uremic patients or some chemical or bacterial toxin associated with an infectious process in the urinary or gastro-intestinal tract could well serve as sensitizing agents.

3. *Individual predisposition:* It is a well established fact that certain individuals respond differently to similar stimulations. Some investigators attribute this to nervousness, emotional instability, auto-intoxication, lowered resistance, etc., while others have suggested an imbalance in the vegetative nervous system, *i.e.*, vagotonia or sympathicotonia as a predisposing factor. The occurrence of an inherent tendency or predisposition to reno-digestive reflexes is substantiated by various case reports in which the like or different gastro-intestinal syndromes have recurred in the same individual following repeated attacks or episodes of a disease in the kidney or ureter. (Case VIII).

### SYMPTOMATOLOGY

Clinically the gastro-intestinal manifestations of these reno-digestive reflexes may be classified as (1) gastro-duodenal, (2) biliary, (3) appendiceal, (4) colonic, and (5) peritoneal. Urinary symptoms are usually present together with the gastro-intestinal phenomena although occasionally there are no symptoms pointing to a primary disease in the upper urinary tract and the urine is negative.

(1) *Gastro-duodenal (dyspeptic) type:* The predominant symptoms of this group are nausea and vomiting which may be associated with any disease of the upper urinary tract. It is almost constantly associated with ureteral or renal colic. Less frequently, epigastric pain or discomfort, belching or heartburn may be present. Not infrequently these symptoms follow dietary indiscretion and a diagnosis of acute indigestion is made. Although these symptoms are not typical of gastric or duodenal ulcer, such a diagnosis is often made and the usual therapeutic measures are tried with no success (Case I). The urological origin of these symptoms is disclosed when a complete diagnostic study including cystoscopy and pyelography is undertaken. After the correct diagnosis has been established, careful questioning will reveal some urological symptom or complaint that has been overlooked or minimized by the patient or physician or both.

Another gastric reflex manifestation of diseases of the kidney and ureters especially following operations on these organs, is acute dilatation of the stomach. In 1903 Laffer reviewed 217 cases of acute dilatation of the stomach and found that 11 cases occurred after operations on the kidney. Stoccarda recently reported a similar case occurring after nephropexy. This syndrome is usually mild and responds quickly to gastric lavage. Aerophagy may also be associated with acute dilatations of the stomach.

In 1910 Aglave reported the occurrence of symptoms of duodenal compression accompanying diseases of the kidney, particularly nephroptosis, and also following nephrectomy. From anatomical studies he concluded that the kidney in its descent pulled the colonic flexure and its mesentery with it and exerted the same traction on the mesenteric artery causing a compression of the duodenum. He also pointed out that the symptoms of chronic duodenal compression are relieved when the patient is put in the knee chest or Trendelenburg position. Cases of chronic duodenal disease due to a large right hydronephrosis, which were completely relieved by operation, have been reported by Colby, Fagge and Smith. Ozeki recently reported a case of duodenal stenosis due to compression of the mesenteric artery occurring after pyelolithotomy.

Bumpus and Thompson reviewed 1001 cases of ureteral calculi and found the pain to be entirely epigastric in 162 cases. In this latter group a diagnosis of peptic ulcer was made in 17 cases and of cholecystitis in the remainder. Zallocco recently reported a case of renal calculi with gastralgalic syndrome. Swan reported a case with gastro-duodenal symptoms due to a left renal tumor and demonstrated metastases around the sympathetic nerves (coeliac plexus) having renal and gastric associations.

*Case I:* J. H. C., 50 years, male, car repairman was referred by Drs. Friedenwald and Morrison. This patient was first seen on September 1, 1934. He stated that 18 years ago he had a sharp attack of pain in the left lower quadrant which lasted several hours and required morphine for relief. The pain was accompanied by nausea but no vomiting, chills or fever. There were no urinary symptoms. Since then he has had several attacks of similar pain at intervals of one to two months but for the past year the pain has been present continuously. The pain varied from a dull gnawing to a sharp sticking sensation and did not radiate to the groin or kidney. Occasionally, the pain appeared to be referred to the epigastric region. In the past year, he has complained of marked epigastric

Fig. 3

distress, nausea, belching, heartburn, fullness after eating, and, occasionally, pain after eating. He has lost 11 pounds in the past 2 months. At no time has he had any urinary complaint. He had consulted several physicians in his home town (Keyser, W. Va.) who diagnosed the condition as "dyspepsia," and, in one instance, as gastric ulcer. He was given the usual alkaline medications and put on a modified Sippy diet for 3 months with no relief. He came to Baltimore to consult a gastro-enterologist.

On examination, the positive findings were moderate tenderness in the lower left quadrant and just below the level of the umbilicus and a palpable mass in the left upper quadrant which was slightly tender. The urine contained 8 to 10 p.c. and 2 to 3 r.b.c. per h.p.f. He was sent to a roentgenologist for a gastro-intestinal study and in one of the films a shadow was observed in the left renal area. He was then referred for urological study which revealed a large triangular calculus (2 cm. x 1.5 cm.) in the pelvis of the left kidney (Fig. 3). Pyelogram of the left kidney revealed a marked dilatation of the pelvis and calyces (pyonephrosis). Operation was advised but the patient returned to his home. Several months later, we learned that the kidney was removed by a urologist in a nearby city and the symptoms have disappeared entirely.

**Comment:** This case illustrates the association of gastro-duodenal symptoms with a calculus in the kidney. The patient had been subjected to numerous examinations and various types of treatment for so-called "dyspepsia" and gastric ulcer. The value of a plain plate as a routine preliminary measure in every gastro-intestinal study (barium meal) is brought out by this case. Fortunately, the stone was first discovered by the roentgenologist in one of the films taken to show the outline of the stomach. The stone could very easily have been missed if barium was present in the large bowel and intestine overlying the kidney area. The gastro-intestinal symptoms completely disappeared following the removal of the calculus pyonephrotic kidney.

(2) **Biliary Type:** This type of symptom is not commonly observed in diseases of the upper urinary tract and is more likely to result from mechanical and pressure effects than from reno-hepatic reflexes. The diseases of the upper urinary tract most frequently confused with diseases of the biliary tract are movable kidney, congenital or acquired hydronephrosis, tumors or cysts of the kidney and occasionally renal or ureteral calculi. The presence of one or more ob-

Fig. 3. Case 1: The plain roentgenogram (on the right) shows a large triangular calculus in the left renal region just above the tip of the ureteral catheter. The bilateral pyelograms (on the left) show a relatively normal right kidney pelvis with abnormal course of the ureter at the ureteropelvic junction and a large left calculous pyonephrotic kidney. These films were taken about 18 hours following the ingestion of barium for a gastro-intestinal study.

jective signs in the right upper quadrant, i.e., palpable mass, localized muscle spasm or rigidity or tenderness together with digestive symptoms may lead to an erroneous diagnosis of cholecystitis or cholelithiasis and an unnecessary operation in any of the above mentioned conditions. The author has observed 5 such cases, viz., calculous pyonephrosis (Case II), renal calculi with hydronephrosis (Case III), ptosis (Case VII), hypernephroma, and perirenal tumor. Not infrequently patients with renal diseases exhibit an idiosyncrasy or intolerance to certain foods, especially fatty foods, which is incorrectly attributed to a disease of the liver or gall bladder.

Cases of jaundice diagnosed as cholelithiasis and proved to be due to movable kidneys have been reported by MacLagan and Treves, White, Fenwick, Lawrie, Sherren and others. At times it may be extremely difficult to differentiate between these two conditions as the major symptoms, jaundice and biliary colic, occur in both conditions. However, the fact that attacks of pain at night are rare with movable kidney and that the radiation of pain is characteristic in cholelithiasis aid in establishing the correct diagnosis. Rolleston explains the jaundice and biliary colic produced by a movable kidney in the following manner: The peritoneum over the kidney is continuous with that covering the duodenum and common bile duct and any undue motility of the kidney will lead to traction on and narrowing of the duodenum and bile ducts; at the same time there may occur a displacement of the gall bladder, kinking of the cystic duct and even a torsion of the bile ducts. According to Sherren, the association of jaundice with movable kidney appears to be first recorded by Brochin in 1854 and next by Litten in 1880. The same mechanism may be invoked in the production of jaundice and other biliary symptoms in those cases in which a large tumor of the kidney or a collection of blood, pus or urine in the perirenal space exerts pressure on the posterior peritoneum and adjacent structures. Mathe has recently reported a case of spontaneous rupture of the kidney pelvis resulting in perinephritic abscess and producing jaundice.

**Case II:** J. M., 41 years, Greek, male, employed as a tin mill worker in U. S. A. for past 8 years. He was seen in consultation for the first time on November 28, 1930. He complained of sharp pain in the right upper quadrant. Onset of illness dates back 13 years at which time he was living in Greece and he developed an attack of sharp pain in the right upper quadrant which radiated around to the back and up to the right shoulder and also across the abdomen. This attack was accompanied by chills, fever, nausea but no vomiting. The attack lasted about one hour. Following this episode, the patient stated that he was sick off and on for three months during which time he had similar attacks every two to three days. He thought he had jaundice, itchy skin and clay colored stools. He also noticed blood and mucus in his stools. In 1918, he was subjected to an appendectomy in Athens, Greece, with no relief of symptoms. Following this operation, the pain

Fig. 4

Fig. 4. Case 2: The plain roentgenogram (on right) with ureteral catheter in place reveals the shadows of four calculi in the right kidney region. The pyelogram (on left) shows partial filling of a large right pyonephrotic kidney. The pyelographic medium obscures the shadows of the calculi.

recurred at intervals of three to five days with increasing severity and at times required hypodermic injections for relief. The pain was occasionally brought on by eating fatty foods. He complained of marked digestive disturbances, i.e., nausea, epigastric discomfort, belching, eructations, flatuency and constipation. In the past four months, the attacks of pain in the right upper quadrant and the digestive disturbances had become progressively worse and the patient lost about 20 pounds in weight. He consulted a surgeon who made a diagnosis of cholelithiasis and advised hospitalization.

The patient also gave a definite history of urinary disease but apparently little attention was paid to these complaints. He stated that he had frequently passed "gravel," about the size of a pea, and had pus in his urine for the past 13 years. He had hematuria at least once a year which preceded or followed the passing of a stone. He also complained of dysuria, burning and frequency during the day and night. He stated that the attacks of pain described above were relieved by the passing of a stone.

He was admitted to the hospital on November 16, 1930. *Physical examination* was essentially negative except for an ill-defined mass in the right upper quadrant which was accompanied by slight muscle spasm. There was tenderness over the mass but none was elicited in the right lumbar region or right lower quadrant. The leucocyte count was normal. The urine contained 30 to 40 p.c. and 20 to 30 r.b.c. per h.p.f. Roentgenograms of the gastro-intestinal tract following the ingestion of barium sulphate were made but were reported negative. Unfortunately, a plain plate of the genito-urinary tract was not taken and in the other plates barium covered the renal and ureteral regions.

On November 19, 1930, an *exploratory laparotomy* was performed. The gall bladder, stomach and intestines appeared to be normal. In the right renal region was a large mass about the size of a child's head which was an enlarged kidney. Nine days later, a urological consultation was requested. On November 29, 1930, *cystoscopy and pyelography* revealed a non-functioning calculous pyonephrosis on the right side. There were four shadows (cal-

culi) in the right kidney area (Fig. 4). On December 5, 1930, a nephrotomy was done and about one quart of thick green pus was removed. None of the stones were recovered. He was discharged from the hospital on December 24, 1930, to recuperate at home with the intention of returning in several months for a nephrectomy. While at home he developed "la grippe" followed by pneumonia and empyema of the right lower lung. He returned to the hospital and a thoracotomy was done on February 20, 1931. He recovered from this operation and was discharged on March 29, 1931, with a draining sinus leading to his kidney and a sinus leading to the pleural cavity. Both sinus tracts were treated by Dakinization but failed to close. On August 18, 1931, a nephrectomy was done and he made an uneventful recovery. Both sinus tracts persisted and subsequently operations were performed to close these sinuses.

*Comment:* In this case, the biliary symptoms were due to the pressure of a large calculous pyonephrotic kidney on the duodenum and biliary passages. In other words, the symptoms were mechanical in nature. It was unfortunate that insufficient attention was paid to the urinary symptoms and that an accurate past history was not obtained as the patient undoubtedly would have been saved an unnecessary exploratory laparotomy. This case also emphasizes the value of a plain roentgenogram of the intestinal tract as a preliminary routine measure in every gastro-intestinal or gall bladder roentgenographic study. Undoubtedly, if such a plate had been taken without the presence of barium in the bowel, the shadows of the calculi in the region of the right kidney easily would have been detected. It is interesting to note that this patient also showed an idiosyncrasy to fatty foods which was attributed to a biliary disease.

*Case III:* M. G., 65 years, female, widow, housewife. She was seen first in the gastro-enterological department of the Sinai Hospital out-patient clinic on February 8, 1934, complaining of pain in the right upper quadrant. She had been troubled with attacks of severe pain in this region for the past 10 years. At times the pain radiated around to the right lumbar region and up to the right shoulder and occasionally passed down to the right lower quadrant. This pain was not related to eating, exercise or posture. Occasionally the attacks of pain awoke the patient from her sleep. The pain was accompanied by nausea but no vomiting, chills or fever. The patient also complained of epigastric discomfort, eructations and heart burn. There was no history of jaundice or clay colored stools. At the onset the attacks of pain recurred at intervals of 3 to 4 months but in the past 6 months the pain had become more severe and occurred once or twice a week. There were no urinary symptoms other than nocturia. In the out-patient department a diagnosis of "gall bladder disease" was made and hospitalization advised.

The patient was admitted to Sinai Hospital on June 10, 1934. *Physical examination* was negative except for a palpable right kidney, tenderness in the right upper quadrant and a positive right ureteral point (Legge's sign). The urine was negative and the leucocyte count normal. A *plain roentgenogram* of the abdomen revealed an oval shadow about the size of a lima bean in the right upper quadrant. A gall bladder visualization was done and the report was that this shadow was in the gall bladder. In view of the normal findings in the urine and blood, the

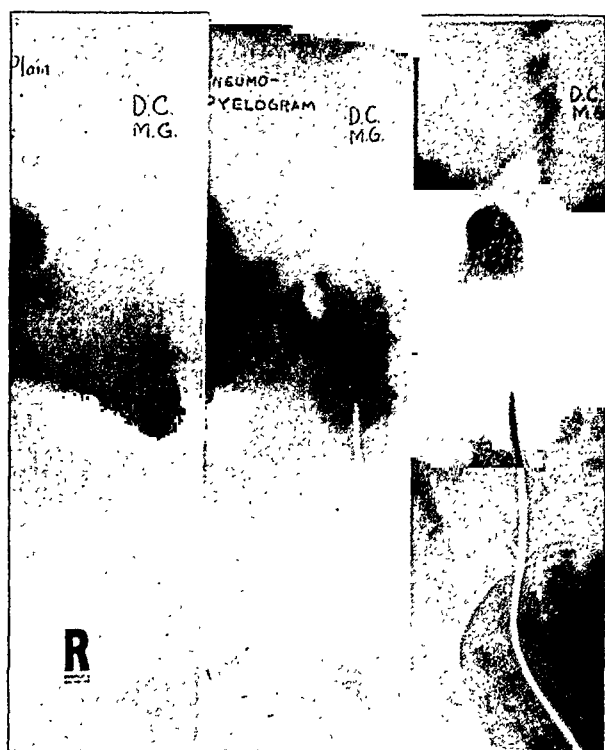

Fig. 5

presence of objective signs of renal pathology and the indefinite type of abdominal pain, cystoscopy and pyelography were performed. The aforementioned shadow was found to be within the right kidney as determined by pneumopyelography and stereoscopic ureteropyelograms (Fig. 5). On June 14, 1934, a pyelolithotomy was performed. Following the removal of the stone, the gastrointestinal symptoms and abdominal pain disappeared and have not returned to date.

*Comment:* This case illustrates the association of gastro-intestinal symptoms simulating cholelithiasis with renal lithiasis. The diagnostic problem presented in this case was solved by pyelographic study.

(3) *Appendiceal type:* It is a significant fact that pain in the right lower quadrant is seldom due to disease of the appendix in the absence of other signs and symptoms of this condition, i.e., fever, leucocytosis, tenderness, nausea and vomiting. Certain diseases of ureter (stone, stricture) and kidney (stone, hydronephrosis, pyelonephritis) may present a symptomatology similar to appendiceal disease which leads to frequent errors in diagnosis. As a rule, the occurrence of gastro-intestinal symptoms is not observed as frequently in diseases of upper urinary tract as in appendicitis. The lesions in the upper urinary tract most commonly confused with acute appendicitis are acute pyelitis or pyelonephritis, renal or ureteral stricture, ureteral calculus and hydronephrosis, respectively.

Hunner reviewed 100 cases of ureteral stricture and found that 30 of these patients had been subjected to an appendectomy. Loring has reported a case of right renal ptosis producing symptoms of an acute appendicitis. The Author has recently observed two cases of perinephritic abscess which were incorrectly diagnosed as acute appendicitis, one of these patients was subjected to an appendectomy. Too often, these patients are subjected to a needless abdominal operation and

Fig. 5. Case 3: On the right side the plain roentgenogram shows a large oval shadow situated between the 11th and 12th ribs which was mistaken for a large gall stone. In the center, the pneumopyelogram shows the shadow to be within the kidney outline. On the left, a stereoscopic pyelogram shows the shadow to be located at the junction of the pelvis and upper major calyx.

shortly there after pass a stone or have a recurrence of symptoms in an exaggerated form a few days or weeks later (Case IV). In view of these diagnostic difficulties and unpleasant postoperative experiences, it would seem advisable to take a plain roentgenogram of genito-urinary tract as a routine examination measure in every case of pain in the right lower quadrant but unfortunately this is not always obtained either because of the patient's poor financial condition or the surgeon's desire to operate. Certainly, this procedure is indicated in every doubtful case as the added expense may be adequately compensated by finding a stone in the ureter or pelvis whereby the cost of an abdominal operation is eliminated.

One cannot emphasize too strongly the importance of a thorough urological examination in those patients presenting indefinite appendiceal syndromes with concomitant renal symptoms to confirm the diagnosis of the former or determine the precise nature of the ureteral or renal lesion (Case V). Occasionally in spite of a urological study, a correct differential diagnosis cannot be made, especially in cases of retrocecal appendicitis with periappendicular changes which may give rise to a ureteritis or peri-ureteritis with interference to the urinary flow and resulting hydronephrosis. The Author is of the opinion that in doubtful cases and in those cases extremely difficult or impossible to diagnose accurately, it is best to err on the safety and subject the patient to an appendectomy rather than run the risk of developing a peritonitis (Case VI).

*Case IV:* F. W., 19 years, male, clerk was referred by Dr. M. Miller. The patient was first seen on July 29, 1930. The patient's history was extremely interesting. On November 15, 1929, patient developed sudden sharp pain in the right lower quadrant accompanied by nausea and vomiting but no chills or fever. Pain lasted 15 minutes and recurred one hour later. No urinary symptoms. Four days later had a similar attack but the pain radiated to the groin, and the following day had another attack. There was no history of hematuria or passing of stone or of urinary symptoms. On November 20, 1930, he was referred to a surgeon who advised taking a roentgenogram of the genito-urinary tract which was negative. The surgeon, who also practiced urology, failed to make a cystoscopic examination but removed the appendix. On the 10th postoperative day, the patient had another attack of right renal colic lasting 4 hours and requiring morphine for relief. He was discharged from the hospital on the 12th postoperative day and was in good health until July 26, 1930, when he developed right renal colic and again two days later. In the latter attacks the pain was accompanied by nausea, vomiting and epigastric distress. There were no urinary symptoms. The urine contained an occasional r.b.c.

*Cystoscopic and pyelographic examination* was performed on August 1, 1930, and revealed a double (fused supernumerary) kidney on the right side with a complete duplication of the ureter. There was a small calculus (2 mm. in diameter) about 3 cm. up in the ureter leading to the lower renal segment. The following day the patient passed this small stone.

Fig. 6 A

Fig. 6 A. Case 5: Plain plate with catheters in both ureters showing a large shadow opposite the junction of the 1st and 2nd lumbar vertebrae. Note the abnormal course of the left ureteral catheter.

*Comment:* Gastro-intestinal symptoms present in this case were of the colonic and appendiceal type. The causative lesion was a stone in the crossed dystopic kidney. This patient was saved from an exploratory laparotomy by the finding of pus cells in his urine by the Internes. This abnormality in the urinary constituents was the first indication of the presence of a urinary disease and led to a cystoscopic examination which disclosed the true nature of the urinary disease causing the gastro-intestinal symptoms.

*Case VI:* S. H., 41 years, male, attorney. He was seen at home on March 25, 1930, complaining of sudden sharp excruciating pain in the right lower quadrant radiating up to the right lumbar region. Pain lasted about three hours and was accompanied by nausea and vomiting but no chills or fever. A history of dietary indiscretion on the previous day was obtained. There were no urinary symptoms present. The urine contained an occasional r.b.c. and p.c. Examination disclosed tenderness with muscle spasm in right lower quadrant and tenderness on deep palpation in the right lumbar region. Leucocyte count was 12,000 with 82 per cent polymorphonuclears. A tentative diagnosis of right ureteral calculus was made and cystoscopy advised. The family physician disagreed with the diagnosis and insisted upon calling a surgeon who made a diagnosis of acute appendicitis and advised operation. The patient was sent into the hospital on March 25, 1930, at 6 A. M. After much persuasion on the part of the urologist, a cystoscopic examination was performed before subjecting the patient to an appendectomy. At 10 A. M. a cystoscopy was performed and a wax tipped catheter was passed up the right ureter encountering an obstruction 14 cm. up which produced a scratch on the wax. Stereoscopic roent-

*Comment:* This case illustrates the occurrence of appendiceal symptoms secondary to an impacted calculus in the lower third of the ureter. It was rather surprising to learn that this patient had been seen by a surgeon who practiced urology and who failed to make a cystoscopic examination. Obviously, the latter was misled by the negative findings of a flat plate of the genito-urinary tract.

*Case V:* I. A., 33 years, male, was referred by Drs. Ullman and Zinberg. He was seen for the first time on July 23, 1934. For the past four to five months he has complained of a dull pain in lower abdomen in the midline which lasted a few minutes and recurred at irregular intervals. For the past month, the pain has shifted to the lower right quadrant and has become cramp-like in character. The pain was not related to meals or exercise and was not accompanied by chills or fever. There was nausea but no vomiting. Marked constipation was present. There were no urinary complaints. Three days prior to admission to the hospital, he had the last attack and consulted a surgeon who made a tentative diagnosis of chronic appendicitis and advised hospitalization.

He was admitted to the hospital on July 22, 1934. *Physical examination* was negative. The leucocyte count was normal. The urine contained several r.b.c. and p.c. which was the first inkling of the presence of a urinary disease. *Cystoscopy and pyelography* were performed on July 23, 1934, and revealed a large calculus in the middle calyx of a congenital crossed dystopic kidney (Fig. 6, A and B). The anomaly was a unilateral elongated kidney of the sigmoid type. Operative removal of the calculus was advised but has been postponed by the patient.

Fig. 6 B

Fig. 6 B. Case 5: Bilateral stereoscopic pyelogram showing a unilateral elongated kidney of the sigmoid type. The shadow was determined to be a calculus in the upper calyx of the lower crossed dystopic kidney.

Fig. 7

genograms with the catheter in the right ureter showed a shadow along side of the catheter at the level of the 4th lumbar vertebra. On withdrawing the catheter a small black calcareous fragment together with some blood was seen to pass through the right ureteral orifice. A diagnosis of right ureteral calculus was made.

The pain in the right lower quadrant and right lumbar region persisted after cystoscopy. The family physician and surgeon failed to agree with the urologist that all the symptoms were due to the ureteral calculus and the associated hydronephrosis. They considered the possibility of an atypical or retrocecal appendicitis. At 10 P. M. of the same day, another surgeon was called in consultation who concurred in the diagnosis of an atypical acute appendicitis and advised appendectomy on the basis that it was best to err on the side of safety. At midnight, an appendectomy was performed under spinal anesthesia and a normal appendix situated anteriorly was removed. Following this operation, the pain in the right lumbar region and right upper quadrant persisted. Cystoscopy and pyelography were repeated on April 11th and a small calculus at the ureteropelvic junction was found. Following subsequent ureteral dilatations a small calculus was passed on June 5th, 1931.

**Comment:** This case illustrates the difficulty that may arise in differentiating between a ureteral calculus and a chronic or subacute appendicitis. Despite the positive findings, *i.e.*, scratch on the ureteral catheter and the presence of a shadow along side of the ureteral catheter on the plain plate, it was difficult to convince the family physician and surgeon that all the appendiceal symptoms were the result of a reflex disturbance. This case also illustrates the advisability of performing an appendectomy in the extremely doubtful or atypical cases or cases in which it is almost impossible to determine the exact causative lesion.

(4) **Colonic Type:** This type of syndrome may be associated with any disease of the upper urinary tract but chiefly with ureteral lesions because of the close proximity of the ureter to the colon on each side. Hunner has repeatedly stressed the association of gastro-intestinal symptoms with ureteral stricture in the female and has pointed out that the failure to recognize the presence of this lesion has been responsible for more needless and fruitless surgery than any other pathological lesion. Recently Morrison emphasized the importance and frequency of ureteral stricture as a cause of abdominal pain and has classified the gastro-intestinal manifestation according to the site of the stricture. He has pointed out that a stricture at the ureteropelvic junction producing a temporary or complete obstruction to the urinary flow usually causes

Fig. 7. Case 7: Pre-operative pyelo-ureterograms taken in the prone (H) and upright (E) positions indicating ptosis of the right kidney (grade II).

lateral epigastric pain with nausea and vomiting and during the quiescent period with good renal drainage is accompanied by an indefinite aching pain just below and lateral to the umbilicus. When the lesion occurs at the point where the ureter crosses the iliac vessels, the pain is referred to the inguinal region or somewhat medial to the usual site of appendiceal pain. The pain is usually insidious in onset, dull in character and lasts from one to three hours with frequent intermissions for days or weeks. If the lesion is present in the intramural portion of the ureter, the pain is referred to the suprapubic area and is accompanied by urinary symptoms. Ptosis of a kidney with kinking may produce essentially the same symptoms as a stricture in the upper third of the ureter (Case VII).

Patients with ureteral disease or movable kidney occasionally complain of tenderness along one side of the abdomen and on examination present areas of cutaneous hyperesthesia at various points about the umbilicus described by Morris, Hunner, Kummell and Legge. Many of these patients complain of abdominal discomfort after assuming an upright position (Case VII) and of irregular post-prandial discomfort which is often relieved by taking bicarbonate of soda, expelling flatus or evacuating the bowels. Constipation is a complaint which persists or is made worse by the use of cathartics or purgatives. In some cases diarrhea is the predominating symptom and may be so severe as to suggest an ulcerative colitis (Case VIII).

Occasionally, the chief complaint is frequent attacks of spasmodic or cramp-like pains which may be confined to one side of the abdomen or radiate downward and across to the opposite side (Case IX). Pyelographic study may reveal a dilated pelvis in a congenital or acquired hydronephrotic kidney (Smith, Author's case IX) or in a ptosed kidney (Case VII and VIII). The usual conservative measures fail to relieve the condition. At operation there are found numerous adhesions between the dilated pelvis and the posterior peritoneum and adjacent large bowel. The dilatation of the renal pelvis may be due to a congenital or acquired stricture in any part of the ureter or to adhesions, bands, aberrant vessels crossing the ureter or at the ureteropelvic junction.

Congenital anomalies of the kidney, *i.e.*, horseshoe kidney, sigmoid kidney, congenital ectopic kidney, frequently are confused with tumors of the intestines, pancreas, omentum, etc. Although these anomalies are often unaccompanied by subjective symptoms, pain or a sensation of pressure in the abdomen is relatively common. When these anomalous kidneys become infected or enlarged, gastro-intestinal symptoms are prominent but cause increased difficulties in diagnosis due to their atypical character and position. Pyelographic studies are essential to establish the correct diagnosis.

**Case VII:** O. E., 25 years, female, single, nurse, referred by Dr. Zinberg. She was admitted to Sinai Hospital on September 18, 1928, complaining of pain in the right upper quadrant. For the past 9 years she has been complaining of a dull pain in the right upper quadrant which occasionally radiated to the lower right quadrant and right inguinal region. At times the pain has been

rather sharp but never colicky. The pain had no relation to eating and appeared to be relieved by lying down and was worse after being up on her feet. The pain was accompanied by frequent spells of nausea and vomiting but no chills or fever. There were no urinary symptoms other than an occasional burning on urination. Her appetite was poor and she had lost 10 pounds in the past 3 months. She had been taking one to three morphine tablets (one-half grain each) daily for the relief of the pain.

The patient had been subjected to four abdominal operations and one minor operation in the search for the cause of her abdominal pain, *viz.* appendectomy (diagnosis: chronic appendicitis) 9 years ago; dilatation and curettage of uterus and suspension of uterus, 8 years ago; cholecystectomy (diagnosis: chronic cholecystitis) 3 years ago; tonsillectomy, 2 years ago; and a hysterectomy 1 year ago. The pain recurred after each operation. About 8 months ago, she was examined by another urologist who diagnosed her condition as bilateral ureteral strictures and gave the patient 8 ureteral dilatations at intervals of two to four weeks. No pyelographic studies were made.

*Physical examination* disclosed tenderness in the right lumbar region and right upper quadrant. There was a positive right ureteral point (Legge's sign). The lower pole of the right kidney was palpable when the patient was in the erect position. The urine was negative.

Cystoscopic and pyelographic study revealed a marked ptosis of the right kidney with a sharp kink in the right ureter about 2 cm. from the ureteropelvic junction (Fig. 7). On September 21, 1928, a nephropexy was performed and the patient made an uneventful recovery. The patient was followed for two years after operation during which time all symptoms disappeared and she gained 20 pounds.

*Comment:* The gastro-intestinal symptoms were due to a ptosis of the right kidney. Unfortunately, the patient had been subjected to four major abdominal operations and one minor operation in a fruitless search for the cause of her abdominal pain before an urological examination was requested. This case also emphasizes the importance and value of pyelography in horizontal and erect positions in the diagnosis of movable kidney. Undoubtedly if this procedure had been employed by the urologist, who saw the patient first, the correct diagnosis would have been made easily and the patient spared the suffering of eight ureteral dilatations.

*Case VIII:* L. G., 38 years, female, married, housewife, referred by Dr. H. Beck. She was admitted to Sinai Hospital on April 17, 1932, complaining of nausea, vomiting and diarrhea. The patient stated that 8 years ago she was confined for 4 weeks at another hospital receiving a modi-

fied Sippy treatment for a gastric ulcer. During her stay in the hospital she had her appendix removed. Her chief symptoms were dull pain in the epigastrium and right lower quadrant, belching, heartburn, alternate constipation and diarrhea. These symptoms recurred about 2 months after operation and she received further treatment for a gastric ulcer with no apparent relief. About 5 years ago the patient developed a marked diarrhea with vague abdominal pain and cramps which persisted for several months; such were attributed to an ulcerative colitis. A roentgenographic study of the gastro-intestinal tract at this time failed to disclose any pathological condition responsible for her symptoms.

Three years ago, she was referred for urological examination and a diagnosis of ptosis of the right kidney was made. Lumbar fixation of the kidney was advised but the patient refused. She was lost sight of until she presented herself for admission to the hospital on the above date. For 6 months prior to admission she had a marked exacerbation of all the gastro-intestinal symptoms. She complained of a persistent nausea and frequent vomiting after meals. She was having 6 to 8 soft watery stools daily. She had lost 35 pounds in the past 3 years.

*Physical examination* was negative except for slight tenderness in the right upper quadrant and in the right lateral epigastrium. Urine examination was negative. *Cystoscopic and pyelographic studies* were repeated and disclosed a marked ptosis of the right kidney with a kinking of the ureter (Fig. 8). A nephropexy and denervation of the right renal artery, vein and pelvis were performed. The patient made an uneventful recovery. She had been followed for the past 2 years during which time the symptoms have disappeared entirely and she has regained 25 pounds.

*Comment:* This case illustrates the various gastro-intestinal manifestations associated with a movable kidney. This case also illustrates the fact that the response to the same stimuli may be different in the same individual. The varied response to the reno-digestive reflexes in this patient resulted in a mistaken diagnosis of gastric ulcer, chronic appendicitis and ulcerative colitis respectively. This patient is an example of an individual predisposition to reno-digestive reflexes. This inherent tendency was also manifested by extreme nervousness, marked emotional instability and vasomotor disturbances.

*Case IX:* J. P., 52 years, male, grocer, was referred by Dr. F. T. Leitz. Patient was referred for urological study on June 1, 1932. Patient had been treated for "stomach trouble" for the past 10 years. He has had cramp-like pains in the lower left quadrant, which lasted 5 to 6 hours and recurred at intervals of 3 to 4 months. Patient described the pain as a constant dull cramp-like pain in the lower left quadrant which radiated across the abdomen and occasionally passed around to the left lumbar region. Pain was accompanied by nausea and vomiting, particularly after eating. There was a moderate amount of epigastric discomfort, belching and eructation and heartburn. Patient also complained of a marked constipation, often passing 2 to 3 days without having a bowel movement. Between the attacks of pain, patient felt perfectly well but after the attack was left with a residual soreness in the left epigastric region which persisted for two days.

Fig. 8. Case 8: Pre-operative pyelograms of the right kidney. The roentgenogram on the extreme left was taken in prone position and the one in the center was taken in the upright position. On the extreme right is an eight minute retention plate showing a moderate amount of the dye retained within the renal pelvis.

Fig. 9

The present attack began on May 25, 1932, and persisted for 4 days. Enemas were effectual but did not give complete relief. Sedatives likewise failed to give relief. Patient gave a history of diurnal frequency, q. 1 hr. and nocturia 2 to 3 times, hesitancy and burning. No hematuria or passing of gravel. Patient had been subjected to repeated gastro-intestinal X-ray studies, stomach analyses, proctoscopic examinations, etc. He was admitted to the hospital on May 29th.

*Physical examination* was essentially negative. Urine was negative except for an occasional pus cell. The leucocyte count was normal. Cystoscopy and pyelography were performed on June 8, 1932, and revealed a large hydronephrosis of the left kidney with an obstruction at the ureteropelvic junction (Fig. 9). On June 14, 1932, the left kidney was exposed under spinal anesthesia. There were marked dilatation of the pelvis which was of the extra-renal type and a constriction of the ureter at the ureteropelvic junction. The posterior peritoneum and descending colon were intimately adherent to the anterior surface of the pelvis for a distance of approximately 8 cm. These structures were dissected off the pelvis and a plastic operation was performed removing an elliptical piece of tissue from the anterior and posterior aspect of the pelvis. The stricture at the ureteropelvic junction was corrected by a Heinicke-Mikulicz repair. Patient made an uneventful recovery and was discharged from the hospital in two weeks.

Three months later he developed a sudden sharp pain in the operative area following the lifting of a heavy object and two days later presented a soft fluctuating mass in the upper end of the wound. Cystoscopic and pyelographic studies at this time revealed a rupture of the pelvis and a perinephritic abscess. Nephrectomy was done and the patient made an uneventful recovery. Following the operation, the patient has been observed for two years and there has been no recurrence of the gastro-intestinal symptoms.

*Comment:* The gastro-intestinal symptoms in this case were due to the adhesions between the descending colon and the pelvis of the kidney. Undoubtedly, the

Fig. 9. Case 9: Pyelogram showing a large left hydronephrosis. The dilation of the pelvis is of the extra-renal type. There is an abnormal obstruction of the ureter at the ureteropelvic junction which was found at operation to be due to a dense stricture at this point.

sequence of events was as follows: The stricture at the ureteropelvic junction produced a large hydronephrosis which became infected and as a result of the peripelvic infection, adhesions were formed between the pelvis and the descending colon and the overlying posterior parietal peritoneum. This lesion produced a mechanical interference with the function of the bowel which was responsible for the patient's intestinal symptoms.

(5) *Peritoneal Type:* This type is characterized by an abdominal syndrome simulating an intestinal obstruction or general peritonitis and is not as frequently observed as the other types. There are numerous references in the urological literature to the development of intestinal obstruction, or rather an apparent ileus, in the various diseases of the upper urinary tract. The earliest report of this phenomenon is by Desnos in 1887 who described two cases of ileus secondary to renal lithiasis. The majority of cases of ileus secondary to disease of the upper urinary tract has been associated with renal lithiasis (Desnos, Sternberg, Stewart, Quenu, Smith, Loeper, Gayet and Ricard, Seze and others) and with ureteral lithiasis (Legueu, Tixier, Gauthier and Clavel, Denechau and Prieur, Frugoni, Jankelson, Rinaldi, Ramon and others). Clavel reviewed the literature and found cases of ileus associated with many diseases of the upper urinary tract other than renal or ureteral calculi, viz. congenital or acquired hydronephrosis, ruptured hydronephrosis, renal tumors, polycystic disease, renal tuberculosis, pyelonephritis, phonephrosis (Case XI), perinephritic abscess, perirenal hematoma, etc., but failed to mention its occurrence in cases of movable kidney. This phenomenon has also been observed in movable kidney by Plenz, DiMaio, Ducuing and Biscard and others. Ileus has also reported following various operations on the kidney, viz. nephrolithotomy (Albarran), pyelotomy (Iselin), nephropexy (Tansini, Chardonnek, Hildalgo and Cano), and nephrectomy (Caravan, Duvergey, Ouard, Ammon). Nogues maintained that development of a paralytic ileus following operations on the upper urinary tract may be due to one or more of the following causes, viz. (1) mechanical obstruction of the intestines produced by placing clamp on intestines; (2) mesenterico-aortic adhesions; (3) obstruction due to torsion or adhesions; (4) toxic manifestations of uremia; (5) traction of pedicle of kidney; and (6) action of anesthetic particularly spinal anesthesia, upon intestines. It is interesting to note that ileus has also been reported following operations on the bladder, prostate and seminal vesicles. The Author has recently observed a case of ileus following a bilateral vasectomy done under novocain infiltration anesthesia as a preliminary measure to prostatectomy.

The ileus associated with diseases of the upper urinary tract is of the adynamic or paralytic type and is accompanied by complete abdominal calm, although peristaltic movements suggesting a true intestinal obstruction are noted occasionally. At times it is extremely difficult to differentiate this apparent ileus from a genuine partial or complete intestinal obstruction.

Fig. 10

tion. One point that greatly aids in differentiating the apparent ileus associated with diseases of the kidney and ureter from true intestinal obstruction is the fact that in the former condition the pain precedes the abdominal distention while in the latter condition it follows the distention. Another useful observation is that the general status of the patient is less affected by a reflex ileus than by a true obstruction. Vomiting, *i.e.*, regurgitation of contents of stomach and small intestines or bile stained fluids, may occur in both conditions but fecal vomiting is rarely observed in ileus secondary to diseases of the upper urinary tract as only three such cases have been reported, *viz.* Desnos' two cases secondary to renal calculi, Ducuing and Giscard's case secondary to ptosis. The diagnosis of reflex ileus secondary to upper urinary pathology is confirmed by the presence of pain, tenderness or a mass in the renal region, the demonstration of renal pathology by ureteral catheterization or pyelo-ureterography and by the failure to discern a true intestinal obstruction roentgenographically (Case X).

Krechi has emphasized the importance of gas retention as a symptom of renal or ureteral disease. The same phenomenon is seen less frequently following ureteral catheterization, pyelography, hydronephrosis, pyonephrosis (Case XI), perinephritic abscess, etc. These patients complain of abdominal discomfort, particularly in the right upper quadrant, which is described as—"gas tries to come up but sticks somewhere." The inability to rid the stomach and colon of gas is due to a reflex disturbance originating in the kidney or ureter. Those cases may be mistaken for ileus or appendicitis and not infrequently are subjected to an exploratory laparotomy by inexperienced surgeons. The same phenomenon is occasionally seen in very nervous and highly emotional people.

Fig. 10. Case 10: Plain plate of the abdomen showing the marked distension of the large intestines by gas. The arrow points to a small calculus in the lower third of the left ureter which was responsible for the reflex ileus.

One cannot stress too strongly the necessity of establishing a correct diagnosis and determining the etiological factor in every unexplained case of intestinal obstruction or peritonitis in order to avoid an unnecessary operation. The following procedures often prove to be invaluable diagnostic aids, *viz.*, urine examination for blood and pus cells; plain roentgenogram to determine the presence of a renal or ureteral calculus and retrograde or intravenous pyelography with the patient in the flat and upright positions to rule out a movable kidney.

*Case X:* L. R., 45 years, white, male, sculptor was referred by Dr. M. Baylin. Patient was seen first on July 3, 1933, at 7 P. M. complaining of sharp pain in the lower left quadrant. The pain radiated up to the left lumbar region and across the abdomen. Pain awoke patient at 4 A. M. and recurred several times during the day. Patient also complained of epigastric discomfort, belching and abdominal distension which he described as "being ballooned up." He was given several enemas without relief. There were no urinary symptoms, chills or fever. The urine contained an occasional pus and blood cell. A tentative diagnosis of left ureteral calculus was made and hospitalization for complete urological study advised but was refused by the patient.

At 11 A. M. on the following day (July 4th), the family of the patient insisted upon calling a general surgeon who thought the patient had an intestinal obstruction and sent the patient to the hospital. At 2 A. M. on July 5th, I was requested to see the patient again in consultation with the surgeon and an internist. The patient still complained of sharp pain in the left lower quadrant. There was marked abdominal distension present with slight tenderness in the left lower quadrant and left lumbar region. Temperature and pulse were normal. The urine showed an occasional red blood cell. My impression was that the patient was still suffering from an impacted calculus in the lower third of the left ureter and that the abdominal distention was due to reflex irritation. The patient was given turpentine stipes for one hour followed by one ampule (1 c.c.) of surgical pituitrin and obtained almost immediate relief after evacuating a large amount of feces and expelling a great deal of flatus.

At 10 A. M. (July 5th) a *cystoscopic examination* was performed. A wax tipped catheter was passed up the left ureter and encountered an obstruction 2 cm. up which produced a scratch on the wax. A roentgenogram of the genito-urinary tract showed a small shadow in the lower left ureter and a marked distention of the bowel with gas (Fig. 10). Stereoscopic roentgenograms were taken with a catheter in the ureter and showed a small stone. There was a moderate hydronephrosis present. A no. 6 F. ureteral catheter was passed beyond the calculus and left in place for 48 hours. It was removed after injecting 8 c.c. of sterile olive oil through the catheter. On July 9th, the patient passed a small stone and was discharged from the hospital the following day.

*Comment:* This case illustrates the diagnostic difficulties occasionally encountered in differentiating between a true intestinal obstruction and an apparent adynamic ileus due to the reflex disturbances from an impacted calculus in the lower third of the ureter. The use of surgical pituitrin and high medicated enemas afforded the patient immediate relief from the abdominal distention. Following ureteral dilatation and the

insertion of a retention catheter in the left ureter, the stone was passed.

*Case XI:* J. F., 35 years, male, clerk was referred by Dr. A. Hornstein. He was seen for the first time on January 24, 1930. The onset of present trouble dates back 12 years when he developed sudden sharp pain in the right lumbar region radiating around to the right upper quadrant but not to the groin. The attacks of pain lasted several hours and recurred at intervals of one to two months up to four months ago. The pain was not accompanied by nausea, vomiting, chills or fever. There were no associated urinary symptoms. About 4 months ago, he developed sharp pain in the right lumbar region which at first radiated to the groin and became localized in the right renal region as a dull dragging pain. This attack lasted about 6 hours and was accompanied by no unusual symptoms other than a moderate diurnal and nocturnal frequency and burning on urination.

On January 14, 1930, patient developed generalized pain over his entire body and called his physician who thought he had "la grippe." Two days later he developed a dull pain in the right lumbar region which did not radiate. The pain was accompanied by nausea, vomiting, chills and fever. The patient was kept in bed for two weeks. The vomiting persisted but on the 21st of January became rather severe. There was marked abdominal distention, high fever and chills. The family physician thought that the patient had an acute intestinal obstruction and advised hospitalization. In view of the history of renal colic in the past and the presence of frequency, burning and pus in the urine during the present illness, a urological consultation was sought.

On abdominal examination, there was marked distention of the right abdomen. There was tenderness on palpation in the right upper quadrant and right lumbar region. There was a moderate amount of spasticity of the muscles of the right upper quadrant. There was a tympanic note over almost the entire abdomen. All ill-defined mass could be palpated in the right upper quadrant. A voided specimen of urine showed a slight trace of albumin and many pus and red blood cells. A white blood count was 18,000 with 82% polymorphonuclears leucocytes.

On January 24, 1930, *cystoscopy* and *pyelography* were performed and a diagnosis of a large pyonephrotic kidney was made. There was a very sharp angulation in the ureteropelvic junction. There were no shadows indicating stones in the kidney region. Patient became progressively weaker and more toxic. There was a sudden rise in the blood urea to 160 mgm. per cent. On February 3, 1930, a nephrectomy was done under gas anesthesia and about 500 c.c. of thick, greenish pus was removed. Patient made an uneventful recovery and on April 4, 1930, a nephrectomy was done. Convalescence was uneventful.

*Comment:* This case illustrates the association of symptoms of an adynamic ileus secondary to a large pyonephrotic kidney. Drainage of the infected kidney resulted in a prompt relief of symptoms. The infected kidney was removed and there has been no further return of symptoms.

### SUMMARY

The purpose of this paper is to point out the various types of gastro-intestinal symptom that may be associated with diseases of the upper urinary tract and to emphasize the diagnostic difficulties encountered in differentiating between the latter conditions and disease of the gastro-intestinal tract. However, the difficulty of making a diagnosis of disease of the upper urinary tract is greatly enhanced by the fact that there are several clinico-pathological entities which singly or in combination, produce corresponding gastro-intes-

tinal and urinary disturbances, the preponderance of the symptoms depending on which pathologic changes dominate the field. Recognition of the following entities is of importance from the standpoint of establishing an accurate diagnosis: (1) the production of real pathological changes in the gastro-intestinal tract by diseases of the upper urinary tract; (2) the development of symptoms suggestive of disease of the upper urinary tract by extra-renal disease, particularly of the intra-abdominal organs; and (3) the concomitant occurrence of lesions of the upper urinary and gastro-intestinal tracts.

1. *Gastro-intestinal lesions caused by disease of the upper urinary tract:* Not infrequently the information gathered by the various diagnostic methods does not enable the urologist or clinician to establish an accurate diagnosis of the underlying renal or ureteral lesion or to determine the extent of pathologic changes produced in the upper urinary and the gastro-intestinal tracts due to the fact that the usual subjective symptoms and objective findings may be negative, absent, misleading or overlooked.

It is not generally recognized that various pathological changes may occur in the mucous membrane of the stomach and intestines in many diseases of the upper urinary tract, particularly in the acute or chronic nephritides. In the acute or subacute forms of nephritis with edema or those of the hemorrhagic type including the acute nephroses, well defined changes are observed in the gastro-intestinal tract, i.e., thick mucus covering the lining of the stomach, swelling, distortion and disintegration of the glands of the stomach and intestines. In the chronic forms of nephritis with edema, the pathological changes in the gastro-intestinal tract are more extensive, especially in the pyloric area. The mucosa appears to be of a grayish color and in some areas is congested and of a reddened color with ecchymotic patches or small hemorrhagic ulcerations. The glands of the stomach and intestines lose their characteristic appearance as a result of enlargement and distortion. The glandular cells show marked degenerative changes, i.e., cloudy, granular, fatty or mucoid degeneration. There are also changes in the submucosa and muscularis varying from round cell infiltration to fibrotic changes. In the chronic forms of nephritis without edema but with hypertension, the inflammatory and degenerative processes are replaced by extensive fibrotic changes in all layers of stomach and intestines resulting in an atrophic gastritis or enteritis. Punctuate hemorrhage with areas are seen in the mucosa of the stomach and small intestines. Superficial ulcers are also observed in the stomach and intestines which gradually increase in size and produce extensive changes in underlying layers. Sloughing ulcers are not infrequently found in the large intestines associated with profuse diarrhea and simulate the clinical picture of an ulcerative colitis. Occasionally these ulcerative lesions cause extensive secondary fibrotic changes in all the layers of intestines which lead to an occlusion of the intestinal lumen with the clinical signs and symptoms of true intestinal obstruction as occurred in the case reported by Reynier and Le Chevallier. Any lesion of the urinary tract wherein an obstruction or chronic infection supervenes resulting in a chronic pyelonephritis, may

produce changes in the gastro-intestinal tract similar to those already described.

Gastro-intestinal disturbances also may develop during the course of certain diseases of the kidney, *i.e.*, chronic diffuse nephritis, arteriosclerotic kidneys, polycystic disease, etc., as result of the cardio-vascular disturbances attending this condition. With the onset of decompensation in the circulatory system, chronic passive congestion of the gastro-intestinal tract ensues. An early enlargement of the liver and congestion of the gastro-intestinal tract develop as a result of portal stasis. Changes in gastric and intestinal secretory and motor functions occur resulting in the production of digestive symptoms of varying intensity.

Another type of gastro-intestinal lesion caused by disease of the upper urinary tract is the development of a peritonitis following the spontaneous or traumatic intraperitoneal rupture of an infected or hydronephrotic kidney as observed by Gottstein, Kappel, Rost and others. A different type is the development of a fistula between the kidney and the gastro-intestinal with subsequent irritation and ulceration of the intestinal walls which occurs as a result of a spontaneous or traumatic rupture of a normal or pathological kidney (Higgins and Hicken, Vermooten and McKeown and others) or following operative injury to the intestines during a renal or ureteral operation (Young, Davis).

2. *Symptoms of renal disease produced by extrarenal conditions:* There is scant reference in the urological literature to extrarenal conditions which may be accompanied by symptoms suggestive of pathology in the upper urinary tract. In this connection, it is important to mention briefly the fact that the lower genito-urinary tract, *i.e.*, pathologic conditions of the prostate, seminal vesicles, and vas in the male (Goldstein, Block) of the pelvic organs in the female (Dannreuther, von Lichtenberg), and the urethra in both sexes (Folsom, Stevens), may produce symptoms suggestive of upper urinary tract pathology or serve as the principal etiologic factor in the development of pathologic conditions of the entire urinary tract.

It is also well to point out that a diagnosis of appendicitis is not infrequently made in patients suffering from an acute infection of seminal vesicles or prostate, especially on the right side. Careful rectal examination will reveal the lesion responsible for the appendiceal symptoms. Chronic infections of these same organs may produce an afebrile right iliac pain which is frequently mistaken for chronic appendicitis but examination of the strippings from the prostate and seminal vesicles reveals an excessive amount of pus. The pain in the inguinal region produced by an acute vasitis has also been mistaken for an acute appendicitis.

Every urologist has undoubtedly had the unfortunate and unpleasant experience of making an incorrect or mistaken diagnosis of disease in the upper urinary tract in the presence of abnormalities or lesions of the gastro-intestinal tract, especially of the appendix, pylorus, intestines, biliary tract, spleen, etc. Stevens has reported two cases which illustrate this point. In his first case, a diagnosis of two ureteral calculi was made by cystoscopy and radiography and at operation a large tortuous appendix containing two fecoliths was found adherent to the ureter. In the second case, the chief symptoms were pain and tenderness in the right upper quadrant which were attributed to a ptosis of

right kidney with kinking of the ureter. Nephropexy was performed with no relief and one month later an exploratory operation revealed a carcinoma in the first portion of the transverse colon. Surgeons and urologists not infrequently encounter cases in which the inflamed appendix is situated retroceally or is intimately adherent to the parietal peritoneum overlying the kidney or ureter and is accompanied by urinary symptoms, pus or blood cells in the urine and pain referred anteriorly to kidney or ureteral regions or posteriorly to the costovertebral angle. These are the cases which are commonly confused with an acute infection of the kidney (pyelonephritis) or perinephritic abscess and are extremely difficult to diagnose even with the assistance of a thorough urological examination. It is in this type of case in which no gross urological lesion can be demonstrated that the author believes it is best to perform an exploratory operation rather than run the risk of the development of a localized abscess or general peritonitis.

It is also well to bear in mind that pathologic conditions in organs other than the above, *i.e.*, lungs, adrenals, heart, lymphatics, spinal cord, etc., occasionally may produce symptoms suggestive of disease in the upper urinary tract.

3. *Concomitant occurrence of lesions in the upper urinary and gastro-intestinal tracts:* Although this phenomenon is relatively uncommon various concomitant lesions or anomalies of the upper urinary and gastro-intestinal tracts have been reported. The combination observed most frequently is a lesion of the kidney or ureter associated with a lesion of the biliary tract (Case XII). Chauffard and Colali have reported cases of renal and biliary lithiasis and the Author has also observed two similar cases. Stevens has reported several interesting cases of co-existing lesions of the upper urinary and gastro-intestinal tracts, *viz.*, (a) hepatitis associated with ureteral strictures, and pyelonephritis, (b) hepatitis associated with pyonephrosis, (c) cirrhosis of liver and diabetes associated with rotation of right kidney and stone in left ureter, (d) large Riedel's lobe of liver associated with tumor of right renal pelvis, and (e) carcinoma of sigmoid associated with left ureteral stricture.

*Case XII:* I. D., 52 years, male, married, hat cleaner. He was first seen in the medical clinic of the out-patient department of the Sinai Hospital on June 9, 1932, complaining of epigastric discomfort and pain in the right upper quadrant. He stated that for the past 25 years he has suffered from epigastric discomfort, belching, heartburn, dull pain in right upper quadrant and nausea which was especially marked after eating fried or fatty foods and was relieved by taking bicarbonate of soda. There was no history of jaundice or clay colored stools. The pain was dull in character and occasionally radiated around to the lumbar region and to the right inguinal region. In February, 1932, he had a bilateral hernioplasty done at another hospital. Following this operation, he complained of dull pain in both groins radiating up to the lumbar regions which was more pronounced on the right side. He had lost 25 pounds in the past 4 months. He also gave a history of frequency. (q. 1 hour, during the day and 4 to 6 times at night), hesitancy, urgency, and incomplete bladder emptying. He had never had renal colic (?) or hematuria. Physical examination essentially was negative. The urine and blood examinations were also negative.

In the medical clinic a diagnosis of "chronic cholecystitis" with cholelithiasis was made but no roentgenographic studies were made. He was referred to the genito-urinary clinic for further study. Cystoscopy and

pyelography were performed on June 10, 1932. The plain roentgenogram of the abdomen revealed a group (10 to 12) of small shadows in the gall bladder region and an oval shadow, about the size of a lima bean, opposite the third lumbar vertebra in the line of the ureter. Pyelographic studies showed that the latter shadow was a calculus in the upper third of the ureter and the right kidney was a large pyonephrotic sac (Fig. 11). The patient was admitted to the Sinai Hospital on August 19, 1932, and 9 days later the pyonephrotic kidney and the upper third of the ureter containing the stone were removed. Recovery was uneventful. The patient has been followed for two years and his general health has been excellent. The majority of his gastro-intestinal symptoms have disappeared, although he still complains of epigastric discomfort occasionally following dietary indiscretion. He has been advised to have his gall bladder removed but refused.

*Comment:* This case is presented to emphasize the occurrence of concomitant lesions of the upper urinary and biliary tracts, viz. right ureteral calculus, right pyonephrosis and cholelithiasis.

It is often difficult to determine whether both lesions have a common etiological factor or are independent of each other. Helwig and Schutz have described a renohepatic syndrome in which certain pathological changes in the kidneys, *i.e.*, parenchymatous degeneration simulating a nephrosis, are caused by certain pathological changes in the liver which are usually secondary to long standing gall bladder diseases. Ferranini has observed similar changes following hepatic cirrhosis. Renal disease is known to occur as a result of pyloric or high intestinal obstruction. In this condition, gastric tetany may appear and signs and symptoms of a severe toxemia may be manifested. Brown, Eusterman, Hartman, and Rowntree reported 11 cases of duodenal toxemia resulting from high intestinal ob-

struction and found changes in the kidneys which they described as either a diffuse nephritis or nephrosis. Zeman, Friedman and Mann described a toxic degenerative nephrosis in four clinical cases of pyloric obstruction and obtained similar findings experimentally following occlusion of the pylorus in cats. Cooke observed calcification and degeneration of the renal tubules in 6 fatal cases of pyloric stenosis with excessive vomiting. The pathological changes in the kidney were attributed to an excessive alkalosis. Occasionally, an acute exacerbation of a pre-existing chronic nephritis, manifested by toxic symptoms of uremia or alkalosis, may occur during the course of treatment of a gastric disease. Hardt and Rivers observed toxic symptoms in two patients receiving alkaline medication for peptic ulcer. Tucker reported the development of fatal uremia following gastro-enterostomy in 8 cases.

### CONCLUSIONS

1. An accurate diagnosis of a lesion in the upper urinary tract must be based on a detailed history, careful physical examination, complete laboratory studies of urine and blood, and a thorough urological study. Every pathological condition in the kidney and ureter should be studied not only from the standpoint of its effect upon the urinary tract but also upon the body as a whole.

2. Pathological conditions in the upper urinary tract usually are accompanied by well recognized symptoms complexes but occasionally are unaccompanied by any urinary symptoms. In many instances they produce symptoms referable to other organs or systems or organs outside of the urinary tract, particularly in the gastro-intestinal tract.

Fig. 11. Case 12: Roentgenograms in a case of concomittant ureteral and biliary lithiasis. On the left, the arrow (A) points to a group of 10 to 12 small round shadows in the gall bladder and the arrow (B) points to a large irregular calculus in right ureter. The pyelogram of the left kidney reveals a normal pelvis. On the right, the roentgenogram was taken following the injection of 40 c.c. of a pyelographic medium and shows a large pyonephrotic kidney. The large right ureteral calculus situated above the tip of ureteral catheter is partly obscured by the opaque medium in upper ureter.

3. The gastro-intestinal manifestations of diseases in the upper urinary tract may be classified as (a) toxic, (b) mechanical or (c) reflex. The toxic type is associated with an acute or chronic inflammatory or obstructive lesions of the kidney and is due to the reaction to bacterial toxins or increased amount of nitrogenous compounds in the blood (uremia). The mechanical symptoms are obstructive in character and are due to pressure upon or irritation of the posterior peritoneum and adjacent intra-abdominal organs by an enlarged kidney, renal tumor or by perirenal accumulation of pus, blood or urine. The reflex type represents the response of the gastro-intestinal tract to reflex stimuli originating in the upper urinary tract and is known as the retroperitoneal syndrome.

4. The reno-digestive reflexes concerned in the retroperitoneal syndrome are classified according to their effects upon the various portions of the gastro-intestinal tract: the principal types are the renogastric and reno-intestinal reflexes. These reflexes may be motor, secretory or vasomotor. They may be associated with each other or combined with cardiac, respiratory or vasomotor reflexes or occur simultaneously with other visceromotor reflexes.

5. The point of origin of the reno-digestive reflexes varies in the different clinical cases. The response to these stimuli varies in the same or different individuals.

6. Factors influencing the response to these reno-digestive reflexes are (a) summation of primary irritative stimuli, (b) sensitization of nerve centers, and (c) individual predisposition.

7. The gastro-intestinal manifestations of these reno-digestive reflexes may be classified as (a) gastroduodenal (dyspepsia, ulcer); (b) biliary (cholelithiasis, cholecystitis, hepatitis); (c) appendiceal (acute or chronic appendicitis); (d) colonic (ulcerative or spastic colitis); and (e) peritoneal (ileus, intestinal obstruction). Cases illustrating each type are presented by the Author.

8. A complete urological examination is indicated in every obscure abdominal condition especially in those patients who have been subjected to an abdominal operation without relief. Every urologist should familiarize himself with the symptomatology of pathological conditions in the gastro-intestinal tract. Every surgeon should recognize the fact that lesions of the upper urinary tract may produce symptoms of a pathologic condition in the gastro-intestinal tract, and *vice versa*.

9. Pyeloureterography, retrograde or intravenous, is of immeasurable value in the differential diagnosis of lesions within the upper urinary tract and in their differentiation from other pathological conditions in the gastro-intestinal tract and in other organs adjacent to the kidneys and ureters. A "flat" roentgenogram of the genito-urinary tract should be adopted as a routine diagnostic measure in every obscure abdominal condition, especially in cases of so-called chronic appendicitis. The roentgenologist should also take a similar plate before administering any of the opaque substances used to delineate the gastro-intestinal or biliary tract in order to avoid overshadowing any radiable shadows in the renal or ureteral regions. A negative roentgenogram of the genito-urinary tract does not exclude a disease of the kidney or ureter. Pyeloureterographic studies should include pictures taken in the horizontal and upright positions in order to rule out a movable kidney. Stereoscopic pyeloureterograms are of great value in determining the exact location and size of any abdominal mass and its relation or effect upon the upper urinary tract.

10. The Author urges the establishment of adequate follow-up system to determine the incidence of cures and failures in the operative treatment of abdominal conditions in view of the high percentage of failures to obtain relief of abdominal pain as reported in statistical studies of large series of abdominal operations.

## SECTION VIII—*Editorial*

NOTE: The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Gastroenterological Association is in no way responsible for editorial expressions.

### President's Address\*

By

B. B. VINCENT LYON, M.D.  
PHILADELPHIA, PENNSYLVANIA

IT is now thirty-eight years since this Association was founded. Under able leadership gradually it has risen to a position of very real influence, nationally and internationally, in the field of gastro-intestinal medicine and surgery.

It has been the custom to have the annual meeting opened by a Presidential Address. This year it becomes my high privilege to serve. I am fully conscious of the honor and of the dignity of the office to which you have elevated me and I desire to express my appreciation of your confidence and my hope that I may achieve a measure of that success accomplished by my predecessors in office.

In reviewing previous presidential addresses, one is struck by the fact that periodically they view with pride our past achievements, view with alarm our evident delinquencies, or, still again, paint the future of gastroenterology in rosy hues, in which, prophetically, our Association will play a leading rôle.

Let me attempt a brief mingling of the three. During the first ten years, our Founders devoted themselves chiefly to the problem of organizing this Association on a sound foundation by the establishment of it as a forum before which our members could annually exchange views which crystallized into new deeds with startling rapidity. Our Founders were, for the most part, original thinkers in advance of their day. They were pioneers and subsequently became stimulating teachers in their field. They were men of indefatigable energy and zealous in their effort that this Association should achieve distinction. Many of this small band of original members are dead; the majority who survive have reached the position of honor that our Senior membership group now enjoys. To these members, our Association—and medicine in the large sense—owes a debt without a moratorium.

During the second and third decades, our Association further was strengthened by certain changes in organization; by the creation of an Associate group of members constantly bringing in new blood, among whom will be found the brains of future leadership, and by the creation of that most necessary adjunct to progress our Research membership group—now small in number but each name of which adds lustre to our Association because of outstanding accomplishments.

Throughout this thirty year period there poured forth from the pens of our members hundreds of articles which helped to fill the pages of American and European medical journals, articles which stimulated and challenged the interest of internists and surgeons throughout the world, and which put gastroenterology on the map of medicine.

The historically inclined Hemmeter, in commemoration of our thirtieth anniversary, carefully reviewed them all and stated that, in his opinion, fifty-three of the contributions could be classed in the A or double A group—that is, publications that were pivotal, of exceptional merit and which sharply modified views previously held; or publications which were epochal, in creating an entirely new view of some aspect of digestive diseases, etiologic, diagnostic or therapeutic.

During this now closing fourth decade, our Association has made further progress. There is not time to go into details, but I will briefly allude to nine items of endeavor which I consider worthy of special mention. *First*, the discovery, by Ivy, of a new hormone which possesses the power to produce a contraction of the gall bladder, assisting its evacuation of bile. We are eagerly awaiting the "purification" of *cholecystokinin* to a degree sufficient for it to be safely used in human beings. It should be a great addition to our gall bladder therapy. *Second*, Alvarez' able discussion of functional gastrointestinal disease and the importance of its recognition and management as set forth in his book, "Nervous Indigestion." In my opinion, it is already a classic. *Third*, the discovery of a new clinical entity by Crohn and his associates, which has been called "Chronic Regional Ileitis" and which appears to be proved and accepted. *Fourth*, the excellent work of William H. Stewart in so greatly improving the technique of oral cholecystography by his "intensified" method. *Fifth*, the very intriguing new conception of Cole regarding the genesis and pathological sequence of gastric ulcer. To conceive of its starting as a mural rather than a mucosal lesion is most novel and revolutionary and is a testimonial to Gregory Cole as an original thinker. But it still remains to be proved, as do the *sixth* and *seventh* meritorious efforts, namely, Lay Martin's announcement of urease as a new component of gastric juice, and the views of our lately lamented Founder member, Willy Meyer, regarding

\*Presented before the 35th Annual Session of The American Gastroenterological Association, Atlantic City, N. J., June 10, 1935.

the etiology of cancer. Time alone will prove them right or wrong.

The *eighth* and *ninth* achievements are to be considered tactical rather than scientific, but are of great potential value to the future of our Association. I refer, first, to our completion last year of an affiliation with the "American Journal of Digestive Diseases and Nutrition" by which that periodical becomes the Official Journal of our Association. This is a great accomplishment, for it now gives us something which we have lacked and wished for these many years. In it will henceforth appear, as long as our agreement mutually is satisfactory, all papers and discussions presented and certified as meritorious by a Council at our Annual Meeting, together with a large number of articles from other authoritative sources. It should be a great help to students of this subject to find such a large percentage of the more important papers on gastroenterology published in one Journal, instead of scattered through several. Besides this, our Transactions will now be published at an annual saving to our Association of approximately five hundred dollars. This can go into our "war chest" to help out with the funding of purposes which may be suggested.

The *ninth* achievement consists of our attempt to set up a Board of Examiners properly to certify the qualifications of a candidate in becoming a Specialist in gastrointestinal medicine. This is of vital importance to our future. Unless we can define and prescribe what a student of gastrointestinal medicine *must do* and *must be* in order to be classed as a Specialist in this subject, then gastrointestinal medicine never will exist as a recognized specialty. However, it is well that we remember that the so-called "Stomach Specialist" who, because of inadequate training in the clinic, in the operating room, in the research, pathological or X-ray laboratories or in the autopsy room, practices his subject within too narrow limits: he himself becomes a menace both to his patients and to gastroenterology. The subject is so immense, so intimately interwoven with clinical medicine, surgery and neurology, that no one can become a really able gastroenterologist until he has first become a good medical clinician. These last two endeavors have required much individual and joint labor and the work is not yet finished.

Let me now allude to two additional thought-provoking objectives of this fourth decade. The first is the constructive criticism of Frank Smithies in his presidential address in 1929 in which he called our attention to the great necessity of establishing standards in gastroenterology, so that when any of us is discussing any special topic he may talk in language which is "standard" and recognized as such by all of us. Particularly important was his criticism of the present lack of any suitable "standard" for the truer understanding of the secretory mechanism of the stomach, and in pointing out that we might properly discard all of the carbohydrate test meals and substitute instead a suitable mixed test meal as a test of gastric function in which the stomach itself is more concerned.

Secondly, let me mention the excellent work begun by Aaron of Buffalo and his co-workers in connection with an attempt to standardize usefully workable tests for enzymes. Last year we heard and approved the preliminary report of this Committee and with an increased personnel this important study is being continued. Perhaps, I should, in this connection, call your

attention to David Riesman's suggestion on our 30th Anniversary, that more work is urgently required in regard to salivary digestion. All such constructive criticism should not be ignored for so many years but should encourage some of us to carry the idea to a conclusion.

Currently, there are some who say that the American Gastro-Enterological Association is nothing but a smug medical club and not representative in its subject. Much of such talk is loose. Our record speaks for itself. If there is a headache in such gossip I shall leave it to my successor to use his own brand of aspirin.

So much in retrospect. Now let me call to your attention the following things which I would like to see accomplished by our 40th Anniversary, two years hence.

First, that our Active and Associate membership quotas of a hundred members and twenty-five members respectively should be *filled*, and a waiting list for each created. Thereafter membership in our Association will be coveted even more than now.

Furthermore, since our present financial security now depends wholly upon our membership dues and since each year a larger number are admitted to Senior membership, exempt from dues, a full list of Active and Associate members would yield a revenue which might permit us to create funds for special purposes. Among such might be a prize or medal for the best paper at each annual meeting—awarded either by membership vote or committee selection; funds to create additional lectureships similar to the Alvarez Lecture so generously founded by Smithies in 1929; or funds that could be devoted partly or wholly to defraying the expenses of guest speakers. The annual saving, now made possible by the publication of our Transactions, might be devoted in part to these purposes. But, in the effort to fill our Active and Associate memberships, our Committee on Admissions and Ethics and our Executive Council should exercise extreme care that only the most meritorious candidates be given consideration: candidates who are gentlemen in medicine, imbued with the highest respect for the ethics, the altruism and the scientific accuracy of our honorable and honored profession.

Secondly, I should like to see a change in our Constitution, which now prescribes the publication of papers sufficient in number and in merit as a condition of membership but which will not automatically debar an otherwise outstanding candidate. I can think of several men who are good clinicians, keenly interested in gastroenterology, who each year attend our meetings as observers. These men are wide awake, often capable teachers and are men who would become valuable and enthusiastic members. But, because they are not gifted in writing, these men, by Article II of our Constitution, are now debarred from membership. In my opinion this is wrong. Too often a native fluidity of pen is accompanied by a paucity or vacuity of ideas. As a result, such a candidate is eligible for election and is not infrequently elected. Such men weaken rather than strengthen the prestige of our Association. Of course, the man who genuinely contributes to the literature of gastroenterology advances the progress of our profession and should always be given the preference, but I feel that the otherwise capable clinician, although not gifted in writing his thoughts, should not thereby be considered non-eligible for membership.

In the third place, I should like to see our Research membership, now nearly wholly limited to physiologists, enlarged and strengthened by the election of carefully selected representatives from surgery, pathology, bacteriology, chemistry, biochemistry and toxicology. These men should be—like our physiologists—of national or international reputation and should preferably be under forty-five years of age. What help such authoritative experts could be to us in clarifying our too often muddled views; in more quickly settling our sometimes discordant squabbles; in keeping our feet on solid ground and out of the quicksands of immature speculation which provokes discussions lasting many years, to no purpose except delaying real progress; and lastly, to help us in the development of the project to which I shall soon refer!

In the fourth place, I should like to see our Annual Meeting extended to a three day session, one of which should be devoted to an open forum or round table discussion. Here, as many members as are interested, can "talk it out," can plumb one another's deepest views and ideas, and can have a real opportunity to sift wheat from chaff. What a help that would be! It could be carried on in large groups or in small; men discussing quite informally topics of diagnosis, treatment or research in which they are mutually interested. I am sure—and I know it has been a pet idea of John Bryant and of Walter Alvarez—that such a day would be the most worthwhile of all and the most productive stimulus to each member's next year's work. With our present two day session, which now must be limited to twenty-four papers and run off with impartial precision within the time limits allotted, I often leave a meeting vainly regretting that I had no time to see "So and So" and learn at first hand more of the things we have corresponded about, or that I think he may have "up his sleeve" and is willing and anxious to discuss. But alas, the official program is finished and men are hurrying to pack up and catch trains and the opportunity is lost. For our mid-western and far-western Fellows, a third day, devoid of tiresome papers, but devoted to informal discussions and establishing of closer personal contacts would make the long trip worthwhile. And in the spirit of mutual fairness, I should like to see our Annual Meeting held every third or fifth year in some southern, midwestern, or Canadian city.

These four wishes of mine already are shared by many of our members and can readily be translated into action if they meet with your approval, although one of them will require an amendment to our Constitution.

And lastly, I come to the fifth wish that might be achieved before our Fortieth Anniversary. It is a much larger project but one of vital importance to our Association as a whole and to each and every member of it. It is not impossible to achieve but it will require a united campaign and much hard work. I am convinced that it is a goal worth striving for, and, if and when created, will greatly accelerate the progress of medicine.

But before I state the project, may I ask you a question? Why is it that despite the individual and collective energy, the soul-absorbing work of so many members; despite their many meritorious contributions to medicine, nevertheless such epoch-making discoveries as insulin in diabetes; such as liver extract, ventriculin and addisin in pernicious anemia, as recent ex-

amples, have been the brain-children of research workers or clinicians outside of our membership. What is wrong with us? Haven't we the brains? Yes, we have the brains but what we lack is organization and often the opportunity to work.

*What we need is a Research Institute!* An institute promoted and controlled by ourselves, and devoted solely to solving problems in gastroenterology and metabolism. What we need is *The American Research Institute of Gastro-Enterology!* Think of it, gentlemen, there is no such institute anywhere in the world today. That has been our trouble; not lack of brains but lack of organization and opportunity.

Our trouble has been that when a member in San Francisco, or in Boston, in New Orleans or in Canada, in Chicago, New York, Baltimore or Philadelphia, gets a bright idea, wants to put it to work, to engage in a research, he is handicapped from the start. It is all right for the little problem but not for the big one. Members of this Association from the Mayo Clinic are the only exception. Review the number and merit of the papers they have contributed and you have the answer. Organization through all departments! Few of the rest of us have sufficient gastrointestinal beds and we are too frequently handicapped by the lack of interest, by the indifference or perhaps by the jealous or personal animosities of the heads of other staffs or departments. And so often we are handicapped for lack of funds.

Unusual as it may sound, I fully believe that a wide-awake clinician, cognizant of the deficiencies of our diagnostic and therapeutic knowledge and possessed of the inquisitive rather than the acquisitive mind, might, with the help of the scientific laboratory research-man, prove to be a reliable, perhaps brilliant research worker. It would be most timely, if we pooled our resources, our brains, our energies, our experimental and practical equipment. *Wherefore* the Research Institute.

*If such an Institute were founded, I would make the following suggestions:* First, that it should be incorporated and placed under the wing of an accredited Class A medical school in a Class A medical center. This should, to some extent, be left to the wishes of the donor of the Institute. Likewise, its name. But the controlling influence in its policy should be under the supervision of the American Gastro-Enterological Association.

Second, that its Foundation should be properly trusted and with a suitable Board of Directors.

Third, *when* such an Institute has been founded, that our Association should be empowered to make selection of its major operating personnel: A Clinical Director of Research and a Laboratory Director of Research, or combine the two offices, and hold him or them responsible for the selection of suitable assistants. Such assistants should consist of Chiefs of seven laboratories, (1) general; (2) physiology; (3) pathology; (4) bacteriology; (5) chemistry and toxicology; (6) X-ray, and (7) animal, utilizable by all laboratories under direction; a Business Manager and a Directress of Nurses. Such Chiefs of Department should be experienced men or women and should be allowed to select their co-workers. Among such should be included suitable Fellows, provided by the Foundation, to work on problems in physiology, pathology, bacteriology and chemistry.

Fourth, that in addition to this active personnel of the Institute itself, there should be created two co-

ordinating committees; a local committee, consisting of the heads or suitable members of the various Professional Departments in the Medical School under the wing of which the Institute itself is housed and a National Advisory Committee consisting of acknowledged experts in clinical or research medicine or surgery and in gastro-enterology who should be selected and requested to serve.

Fifth, such an Institute should have a minimum of forty ward beds and twenty private beds devoted exclusively to gastrointestinal problem cases. This is a bare outline of the major requirements. The details are too many to allow of discussion.

Sixth, when we get such an Institute, how do we put it to work? My suggestion would be that before each annual meeting, our Secretary should send out a questionnaire to members requesting information regarding particular research they have in mind. Our Council shall then tabulate it for a vote at each annual Executive Session for the selection of an annual "key problem" and two or more correlated problems. The matter then should go before the Director of Research and his Chiefs of Departments, assisted by the National Advisory Committee, for thorough study of the best way to approach the research in order to carry it to a successful conclusion. Thus we concentrate all our resources on one selected problem; and we pool our brains, our eyes, our ears, our hands and our imaginations. If the research is brought to a successful conclusion and any new discovery thereby announced, the individual whose idea originated the research should be then given a full share of credit.

We must find some way to solve the liver-spleen group of diseases; the severe bowel diseases whether of the peptic ulcer type or ulcerative colitis. We have none of the final answers now but we will have. And many other pivotal researches await us.

My own opinion is that the liver is the first "key problem" we should attack. I should like to see a con-

centrated effort made to study two greatly neglected functions of the liver, its detoxifying ability and its bactericidal power. What a field that one research would open up for profitable study! What a brilliant light it might throw on many clinical problems which now baffle us, such as the recognition of the cirrhoses before the decompensation stage; the large group of hepatic-intestinal toxemias; the migraines; the arthritides with gastrointestinal symptoms or with allergy; the toxemias of pregnancy; the pseudo-epileptics or epileptoids; the psycho-depressives; certain of the blood dyscrasias—to mention just a few problem groups so frequently seen by all of us. For years I have become convinced that faulty detoxifying or bactericidal power of the liver is intimately related both to the etiology and symptom-complex of these groups. This research, on a broad scale, must be undertaken. But this is not the time or place to give the details as to how it might be approached.

And I should like to see a study designed to explain what there is in the *succus entericus* or *enterokinase* that appears to protect against cancer those intestinal segments lying between the pylorus and the cecum. Within that area of the gastrointestinal tract cancer is relatively rare, whereas elsewhere it is common.

But gentlemen, we haven't yet got our Institute beyond a dream on paper. How shall we get it in fact? We must at once bend all of our energies and our abilities as *salesmen* to find a suitable donor and sell him the idea. There must be someone still possessed of a million or more to start such a Foundation. If any of us know of any candidate whom we might thus honor, as Rockefeller, Carnegie, Phipps and others have been honored, make his name known to us! There should be enough prestige for scientific effort and altruism among our combined membership to make him feel the need of our urgings and create for us a Foundation for such an organized effort in the interests of suffering humanity.

## ABSTRACTS

PAINE, JNO. R.

*The History of the Invention and Development of the Stomach and Duodenal Tubes. Ann. Int. Med., VIII, 752, December, 1934.*

The physician who finds interest in Medical history will read the original paper, though more than a mere historical sketch is found in its subject matter. Some attention is given to the clinical use of both the gastric and duodenal tubes, even to description of technique. The paper does not lend itself to abstracting very satisfactorily, since its chronological references are already compact. The origin of the stomach tube is said to be coeval with the Christian era, though credit is given to John Hunter for first recording its use 1790 years later, but Munro claims it for his father, who is said to have used such a tube as early as 1767. Hunter's description of his tube appeared in the Philosophical Transactions in 1776, just about four months before the Declaration of Independence by the American Colonies. It was made of eelskin, sponges, blad-

der, a wooden pipe, all drawn over a probang. From 1800 to 1822 the tube was variously modified and improved in England, France and the United States. In this country it appears that one, Physick of Philadelphia, used urethral catheters for lavaging the stomachs of infants. Strangely, its use was almost forgotten until made popular by Kussmaul about the close of the Civil War in 1865.

The duodenal tube is not of such ancient lineage and claims America as its birthplace. Crude tubes and unsatisfactory use were reported in 1894 by Turk, but fifteen years elapsed before really satisfactory clinical use of such a tube was obtained by Gross and Einhorn almost simultaneously. In 1912 Hess removed duodenal contents from infants with a Nelaton catheter and in 1921 the most satisfactory tube perfected, even to the present time, was described by Levin. The duodenal tube has been used by surgeons as a therapeutic measure since Westermann's report in 1910 and surgeons now use such a tube more frequently, perhaps, than internists.

Virgil E. Simpson, Louisville.

## SECTION X—After “Hours”

### Members of the Journal's Editorial Council Receive High Honors

**A**T the 1935 Annual Session of The American Medical Association held at Atlantic City, New Jersey, by vote of the House of Delegates two distinguished members of this periodical's Editorial Council were elected to the highest honors within the gift of the Association.

Dr. James Tate Mason, Seattle, Washington, nationally and internationally known surgeon, was chosen President-elect and Dr. Kenneth Merrill Lynch, Professor of Pathology and Vice Dean of the Medical College of the State of South Carolina, recognized throughout the world for his researches in Pathology, particularly human parasitology, was made Vice-President-elect.

Seldom has such outstanding recognition simultaneously come to the members of an editorial staff of the same publication. That the honor is well-deserved, amply is demonstrated by the biographical sketches of our co-workers as set forth below.

The Editors, their fellow-members of the Editorial Council and the Publishers of the Journal extend most cordial congratulations to Drs. Mason and Lynch. The American Medical Association, indeed is fortunate in being able to look forward to having at its head men of such outstanding scientific and personal merit.

#### JAMES TATE MASON, M.D.

Dr. James Tate Mason was born at Lahore, Orange County, Virginia, on May 20, 1882. His grandfather, Capt. Claiborne Rice Mason, was one of “Stonewall” Jackson's engineers during the Civil War. He was instrumental in building the old Virginia Midland Railroad and was the contractor who constructed the greater part of the Chesapeake and Ohio. Dr. Mason's father, Dr. Claiborne Rice Mason, also served under “Stonewall” Jackson until wounded and taken to Elmira, where he was kept as a war prisoner until the surrender at Appomattox in 1865. He became a student at the University of Virginia, and later graduated in medicine at Jefferson College Medical School at Philadelphia. Dr. Mason's mother was Mary Moore Woolfalk, born, reared, and lived all her life in Orange County, Virginia, and member of a family prominent from colonial times.

Dr. Mason went to the Locustdale Military Academy when he was 14 years of age, remaining there until 1901, when he entered the University of Virginia Medical Department, graduating in 1905.

Between 1898 and 1904 he served during the summer months as assistant to Col. James A. Frasier, who was owner and manager of the Rockbridge Alum Springs. He entertained his mother and father here for a few weeks every summer. There were no vacations between school attendance and the hotel management.

In the spring of 1905 Dr. Mason graduated in medicine at the University of Virginia. Immediately taking the Virginia State Medical Board in Richmond, he began his two year internship in the Philadelphia Polyclinic Hospital at 18th and Lombard Streets, which is now known as the post-graduate school of the University of Pennsylvania. Following this internship, he

James Tate Mason, M.D., Member of the Journal's Council, Chief Surgeon and President of the Virginia Mason Hospital and Clinic, Seattle, Washington. President-Elect of The American Medical Association.

had a residency at the Municipal Hospital of Philadelphia for the Treatment of Contagious Diseases.

In the spring of 1907 the Pacific Coast Steamship Company built two ships at the New York Shipbuilding Yards in Camden, N. J. To the first of these ships, the “President,” Dr. Mason became ship's surgeon. The ship went through the Straits of Magellan and finally arrived in Seattle in the summer of the same year. Two weeks after his arrival in Seattle, he accepted a position as local surgeon of the Pacific

Coast Coal Company, whose mines were at Franklin and Black Diamond. There he spent two years actively engaged in the practice of medicine and surgery, looking after the miners of the two camps, returning to Seattle in 1909.

In 1909 the late Robert T. Hodge, sheriff of King County, and the county commissioners of the time had a terrific political battle as to who would be responsible for the health of the prisoners. Following a court decision in his favor, the sheriff immediately placed his family and personal physician, Dr. Mason, in charge of the health of the prisoners, both those of the United States government, and those of the local government. In 1911 Dr. Mason was made coroner of King County and performed medical investigations for the county for four years. In 1914 he was appointed Superintendent and Chief Surgeon of the King County Hospital, a position which, with his private practice, he held until 1920.

In 1918 Dr. Mason and his associates organized the Mason Clinic, and in 1919 built the Virginia Mason Hospital, in which he has been Chief Surgeon and President of the Hospital Association for the past fifteen years.

He married Laura DeWolfe Whittlesey of Seattle, on January 3, 1912. His children are James Tate Mason, Mary Virginia Mason, and Frederick DeWolfe Mason.

Dr. Mason is at the present time Consulting Surgeon to the U. S. Marine Hospital; Consulting Surgeon to the American Mail Line, the Alaska Steamship Line, and the Northern Pacific Railway Company; Fellow of the American College of Surgeons; member of the American Surgical Association, the Western Surgical Association, North Pacific Surgical Association, Washington State Medical Association, and the King County Medical Society; he was President, in 1931, of the Pacific Coast Surgical Association; President in 1930 of the American Association for the Study of Goiter. He is a past President of the Seattle Chapter of the Sons of the American Revolution, a member of Nu Sigma Nu, and Phi Gamma Delta. He is also a member of the Rainier Club, the University Club, and the Seattle Golf Club. His home is at 1220 Federal Avenue; his offices in the Virginia Mason Hospital.

#### KENNETH MERRILL LYNCH, M.D., LL.D.

Biographical notes based upon record in  
"Who's Who" in America

Kenneth Merrill Lynch, M.D., LL.D. Born Nov. 27, 1887, Hamilton, Texas. Married 1914. Two children. Member of the Episcopal Church. Educated in the public schools and the University of Texas, M.D., 1910. LL.D. (Hon.) University of S. C., 1930.

Resident Pathologist, Philadelphia General Hospital, 1911. Instructor in Pathology, University of Pennsylvania, and Assistant Pathologist to the Philadelphia General Hospital and the Hospital of the University of Pennsylvania, 1911-'13.

Professor of Pathology and Vice-Dean, Medical College of the State of South Carolina, Pathologist to the Roper Hospital, Charleston, and Consulting Pathologist to various hospitals in South Carolina, 1913-'21 and 1926 to the present. In private practice 1921-'26. Captain, M.C. U.S. Army, 1918. Member (or Fellow) of American College of Physicians, American Assoc. of Pathologists and Bacteriologists, American Society

for Cancer Research. American Society of Tropical Medicine, American Society of Clinical Pathologists, American Assoc. for the Advancement of Science, American Medical Assoc., American Society of Parasitologists, Alpha Omega Alpha, and other scientific and medical societies, having served in official capacity as follows:

Secretary, Medical Section, Pan-American Medical Congress, 1915; Secretary (1920 and 1928-'31) and Chairman (1932) Southern Conference on Medical Education; Secretary (1923) Vice-Chairman (1924) and Chairman (1925) Section on Pathology, Southern

Kenneth Merrill Lynch, M.D., L.L.D. (Hon.) Member of the Journal's council. Professor of Pathology and Vice Dean Medical College of the State of South Carolina. Vice-President-Elect of The American Medical Association.

Medical Association; Vice-Chairman (1923) and Chairman (1924) Section on Pathology, American Medical Association; Board of Governors, American College of Physicians (1925-'27); Councillor (1922-'27) Vice-President (1928-'29) and President (1929-'30) American Society of Tropical Medicine; President (1930-'31) and Member of Executive Board (1931-) American Society of Clinical Pathologists; President (1930-'31) South Carolina Medical Association; Vice-President elect American Medical Association (1935-'36).

Research Medal, Southern Medical Association, 1921. Gold Medal Scientific Exhibit, American Medical Association, 1921; Honorable Mention, 1922. First Award, Scientific Exhibit, Southern Medical Association, 1920.

Member of National Board of Medical Examiners. Member S. C. State Board of Health, Member of the

Editorial Boards of the American Journal of Tropical Medicine, the American Journal of Clinical Pathology and the American Journal of Digestive Diseases and Nutrition.

Professor Lynch has made many notable contributions to the literature of his specialty. In addition to the authorship of two well-known text books ("Protozoan Parasitism of the Alimentary Tract," The Macmillan Co., N. Y., 1930, and—with H. W. C. Vines—the revision and editing of "Green's Manual of Pathology," Balliere, Tindall & Cox, London, and Wm. Wood & Co., Baltimore, 1934). Professor Lynch is a collaborator in "Approved Laboratory Technic" (Kolmer & Boerner), D. Appleton & Co., Philadelphia, and the author of more than 75 scientific monographs, the

major portion of which are concerned with original investigations in the field of human protozoiasis. Prof. Lynch was honored by being selected as one of six recognized authorities who brought practically before our profession the significance of intestinal amebiasis at the important Symposium arranged by the Council on Scientific Assembly of The American Medical Association at its 1934, Cleveland, Ohio, annual convention. Prof. Lynch's contribution to that Symposium was widely and most favorably commented upon.

Since assuming his duties at the University of South Carolina, Prof. Lynch already has published several investigations of outstanding value. He gives promise of steadily advancing the unusually solid and progressive standing of that well-known Institution.

## ABSTRACTS

DR. CHARLES H. FRAZIER AND DR. WILLIAM H. ERE.

*The Superior Laryngeal Nerve and the Superior Pole In Thyroidectomies. Annals of Surgery, Vol. 101, No. 6, June, 1935.*

The authors point out the fact that the treatment of thyrotoxicosis has shown great improvement in the past few years by the accepted agencies; medicinal, the Roentgen Ray, and surgery of which the latter gives eminent satisfaction at present. The authors prophecy, however, that, "In the course of time a new remedy be forthcoming, a specific, an organic compound which will provide the economy with what it needs and arrest this hyperplastic process."

Having reduced the operative hazards to a minimum, the mortality rate for toxic goitre in a well organized clinic, now being from 1 to 3 per cent, we should turn our attention to the elimination of post-operative discomforts such as accumulations of mucus in the trachea, frequent short coughs, efforts at expectoration which are painful, pain on swallowing, and various reflex pains.

Many of the postoperative discomforts, the authors state, are due to injury to the superior laryngeal nerves causing anesthesia of the larynx and the region of the epiglottis. Loss of sensation here abolishes the cough reflex, hence mucus accumulations. The troublesome little abortive cough or "hacking" was an ineffective attempt on the part of the patients to rid themselves of this accumulated mucus. The discomfort and pain on swallowing is due to injury to the constrictor muscles of the pharynx during operation—the inferior constrictor muscle being the one exposed during thyroidectomy.

In their experience, ligation of the vessels of the superior pole without injury to the external or internal branch of the superior laryngeal nerve is possible by avoiding traction or rough manipulation of the pole itself or the structures to the inner side of it. Then with adequate exposure dissecting the superficial flap of skin and platysma at least to the upper level of the thyroid cartilage, and then bisecting the ribbon muscles on one side or the other, with wide retraction of the wound edges, when the pole is clearly in view, Doctor Frazier divides this reflection of the pre-tracheal fascia either by blunt or sharp dissection. In the trough between these two walls of fascia lie the superior thyroid artery and vein and these may be tied either together or separately, thus both branches of the superior laryngeal nerve escape injury.

Charles T. Sturgeon, Los Angeles.

HUNT, VERNE C.

*Operability of Carcinoma of the Stomach. Annals of Surgery, Vol. 101, No. 5, May, 1935.*

The author gives a brief review of the operability and mortality rates of carcinoma of the stomach as found in the literature and in his series of 149 cases. He states that the relatively high inoperability should not obscure the benefits of resection in the truly operable tumors.

He attributes the low operability rate partially to the fact that early carcinoma rarely produces signs and symptoms or produces signs and symptoms of so mild a nature as to pass unnoticed until the tumor has metastasized and become inoperable. Inoperability may often be determined by clinical manifestations at the time of the initial examination; as the firm, fixed, sentinel gland in the left supra-clavicular space, infiltration of the umbilicus, the irregular, firm, nodular rectal shelf, an enlarged hard nodular liver, associated jaundice or ascites. By the foregoing determinations clinical inoperability has been in excess of 50% of all cases of carcinoma of the stomach. In the author's series of 149 cases the operability in terms of resection was 36.1% previous to 1930 and 36.8% during the past four years.

The author attributes the lowering of the mortality rate for gastric resection in the past few years to a great extent to the employment of methods during recent years for the rehabilitation of patients with carcinoma of the stomach previous to surgical exploration such as repeated gastric lavage for gastric retention, intensive administration of physiological solution of sodium chloride and glucose and the preoperative treatment of secondary anemia by blood transfusions.

In speaking of prognosis following gastric resection the author gives Grays statistics on a series of 373 cases. In 100 cases the patients did not survive longer than 12 months after operation; in 145 cases 12 patients had lived more than 5 years; and in 128 cases the patient had lived longer than 10 years. Gatewood, in 1932, stated that 46.1 per cent of patients who survived the operation lived more than 3 years, and 39.5 per cent survived more than 5 years.

In conclusion the author states that, "One opportunity exists to increase the curability of this disease and it is probable that this will come about through its earlier recognition and not through extension of operability, through higher gastric resection or total gastroectomy."

Charles T. Sturgeon, Los Angeles.

## SECTION XI—*Societies, Programs and Proceedings*

### IN MEMORIAM

#### Albert Bernheim

By

DAVID RIESMAN  
PHILADELPHIA, PENNSYLVANIA

**I**N 1896, Albert Bernheim emigrated to this country from the beautiful Black Forest region of Germany and settled in Paducah, Kentucky.

Although Dr. Bernheim had a degree in medicine from the University of Freiburg, he took a course in the Medical School of the University of Louisville and was graduated from that institution in 1897. After practicing for a brief period in Paducah, Bernheim came to Philadelphia. He soon acquired a good clientele and rapidly achieved a high degree of popularity in the profession, being elected, in 1905, President of the Northern Medical Association, the second oldest medical society in Philadelphia. He was keenly interested in gastro-enterology and was one of the first to practice that specialty in Philadelphia, being preceded only, I believe, by the late Dr. D. D. Stewart.

Although Dr. Bernheim was a faithful attendant at the meetings of the American Gastro-Enterological Association, to which he had been elected in 1909, he rarely took an active part in the proceedings, but his kindly and pleasant personality made for him many friends among his contemporaries in the Association.

In 1907 he published an English translation of Boas' book, "Diseases of the Stomach."

Fate dealt Bernheim a cruel blow. Just when the success to which his talents and industry entitled him was within his grasp, he began to show symptoms of paralysis agitans. After a brief but brave fight against that most terrible of maladies, he was forced to the wall and had to give up all medical work. Being a bachelor the doctor sought seclusion and sympathy in the home of a sister. After the death of this devoted relative and the dissipation of his small capital, he entered an institution for chronic invalids where he died on February 15, 1935. Death came in an access of hyperpyrexia, the temperature rising to 108° F. Among Dr. Bernheim's surviving relatives is a nephew, Julius Bloch, a contemporary American painter of note.

Albert Bernheim never spoke ill of anyone and those who knew him never spoke ill of him.

\*Presented at the 38th Annual Session of The American Gastro-Enterological Association, Atlantic City, N. J., June 10, 1935.

DELEGATES ON THE PART OF THE UNITED  
STATES TO THE FIRST INTERNATIONAL  
CONGRESS OF GASTRO-ENTEROLOGY  
APPOINTED BY THE DEPARTMENT OF STATE,  
UNITED STATES GOVERNMENT  
Brussels, Belgium, August 8 to 10th, 1935

Lieutenant Colonel John H. Trinder, Chairman,  
Medical Corps, Retired, United States Army.

Dr. Henry L. Bockus, 250 South 18th Street, Philadelphia, Pennsylvania.

Dr. Russell S. Boles, Rittenhouse-Plaza, Philadelphia, Pennsylvania.

Dr. Max Einhorn, 20 East Sixty-third Street, New York, New York.

## UNDER PAR?

**S**ICKLY, undernourished and therefore frequently subnormal children usually present a difficult nutritional problem. Appetite is often poor or precarious, digestion often impaired, their tastes finicky.

Ovaltine has frequently been found of great assistance in this type of case, in helping to safeguard against child malnutrition by supplementing valuable proteins, carbohydrates, fats, minerals and vitamins in a palatable, easily digested form.

Ovaltine is a good source of the growth-promoting vitamins A, B and C, and an excellent source of the antirachitic vitamin D.

Ovaltine greatly increases the nutritive value of milk and makes it much more easily digested by its softening action on the milk curd.

During convalescence following debilitating diseases or operation, Ovaltine adds food quality to the diet. When given as a warm drink before retiring, it often induces sound, refreshing sleep without the aid of hypnotic drugs.

**This offer is limited only to practicing physicians, dentists, nurses and dietitians**

## SECTION XII—"The Clinic"

### Bilateral Massive Suprarenal Hemorrhage in an Instance of Hyperfunction of the Suprarenal Cortex\*

By

FRANK R. FINNEGAN, M.D.  
ST. LOUIS, MISSOURI

**S**UPRARENAL hemorrhage has been reported numbers of times in medical literature (1). The largest number of cases reported was in infants from two to twenty-four months, a few cases in children up to eight years; in adults, the majority of cases was between twenty and thirty-five years—several above fifty years—divided about equally between the sexes.

A certain symptomatology, physical findings and clinical course was more or less common to all cases reported.

The onset was very acute in the majority of patients. A few cases were preceded by a general three to four day malaise. Then appeared severe pain either in the abdomen or lumbar regions, skin purpurae, nausea and vomiting, fever, signs of circulatory collapse, rapid fall in blood pressure, rapid pulse, frequent respiration, hypothermia, cold sweats, coma and death. According to Rabinowitz (2), an acute illness in a previously healthy child, which is rapidly followed by purpura and collapse, should, in the absence of a meningococcic infection, be sufficient for a diagnosis of suprarenal hemorrhage.

The *etiological factor or factors* of suprarenal hemorrhage have not been definitely proven. Some investigators believe it is due to a single organism, perhaps a streptococcus, but in the cases reported several different organisms have been found. Other investigators favor some form of in-

toxication, either toxins or endotoxins of bacterial origin or autogenous poisons, for example: those that might be produced in the gastro-intestinal tract. Infarction, from any of many causes, may be a common mechanism leading to the bleeding.

#### CASE REPORT

The patient, a married woman, aged 35. Mother of two children (normal

## Announcement Available for Treatment in PEPTIC ULCER

A recent paper in the American Journal of Digestive Diseases and Nutrition\* referred to a specially prepared colloidal Cream of Aluminum Hydroxide. These investigators reported that out of 110 cases with positive findings of peptic ulcer, excellent results were attained in 101, or 92%. We are pleased to announce that this preparation is now available to the medical profession under the convenient name of

*Creamalin*

In collaboration with the laboratory workers associated with its original development, we are now manufacturing this product in quantities sufficient to meet all demands. It is issued in 7 oz. and 16 oz. bottles.

Cream of Colloidal Aluminum Hydroxide (Creamalin) has now been used in several thousand cases of Peptic Ulcer with results justifying a place in its particular therapeutic field.

Creamalin apparently represents a definite advance in ulcer therapy. From clinical reports the advantages may be summarized as follows:

- More prompt alleviation of pain.
- Unusual neutralizing properties—one volume neutralizing as much as twenty-five times its volume of tenth normal HCl by physical fixation (adsorption) as demonstrated by electro-chemical tests.
- Avoids possible danger of alkalosis.
- Tendency to depress HCl output.
- Reduces emptying time of stomach by allaying pylorospasm.
- Ideal demulcent and protective to ulcerated area.
- No toxic effects or contra-indications.
- Economy and simplicity of administration.

#### Clinical Material Available

Gastro-enterologists and clinicians interested in investigating the especial merits of this product can obtain material in any amount they feel necessary to an adequate trial upon application.

Address all communications to Cleveland Chemical Associates, Cleveland, Ohio, stating the number of cases and whether you wish it sent to a clinic or hospital. If convenient, kindly let us know the name of your prescription druggist.

\*Einsel, Adams, and Myers: "Aluminum Hydroxide in the Treatment of Peptic Ulcer." American Journal of Digestive Diseases and Nutrition (September, 1934).

\*From the Soper-Mills Clinic.  
Submitted August 5, 1935.

births). Had usual childhood diseases, appendectomy in 1929 and during the past eight years attacks of severe pain in the kidney regions associated with occipital headaches and nausea. Attacks were always relieved within one hour after considerable vomiting. No apparent distress remained after even a severe attack was over.

The family history was negative except that on her paternal side her father and grandfather had suffered similar attacks of lumbar pain, headaches, nausea and vomiting. None was ever for any length of time, incapacitated from the attacks.

The patient, among her acquaintances, was noted for her Madonna-like beauty. However, since 1931, her friends noticed that her beauty was disappearing and that her features were changing markedly. The face was becoming very full and rounded, appeared swollen, features becoming coarse, the skin looked thick and heavy, comedones appearing over the face, and fine and coarse hair appeared on upper lip and chin. This hirsutism was also present on the legs. The weight gradually increased and her blood pressure, according to members of her family, constantly was mounting, a few months prior to her death the systolic was 162.

The patient was seen by me on November 19, 1934, at two P. M. She was conscious and stated that at three A. M. she had an attack of severe pain in both kidney regions. The pain did not radiate but remained constant; has intense desire for urination but passes only a small amount of urine; severe "thumping" at the base of the skull, nausea, vomiting and high fever. Because of the knowledge of the time element in previous attacks, she had delayed seeking medical attention.

The patient appeared to be rapidly approaching complete circulatory collapse. Her entire body was covered with various sized, purplish blotches on a background of bluish cyanosis. The pupils were dilated, temperature 103; respiration 42; pulse 140-soft, regular, thready; heart sounds faint but distinct; lungs negative; blood pressure 120/70; abdomen negative; palpation in both costochondral angles caused an increase in her already agonizing lumbar pain; reflexes normal. One-third grain morphine intravenously was given and it was advised that she be removed to a hospital immediately.

She arrived at the hospital at four-twenty P. M. and was seen in consultation with Dr. Rogers Deakin, urologist. Catheterized urine specimen showed 3+ albumin, specific gravity 1016, many hyaline and a few granular casts, few red blood cells and a few white cells. Urinary findings indicated an acute nephritis. Because of the circulatory collapse further cystoscopy was thought to be contraindicated. External heat was applied, intravenous glucose and

emergency heart stimulants were given. Patient seemed to improve temporarily after repeated injections of 3 c.c. adrenalin chloride given intravenously. The pain was not controlled by large doses of morphine and pantopon. Patient complained bitterly of pain but remained conscious up until a few minutes before her death, which occurred at five-fifteen P. M.

The diagnosis was made at autopsy by Dr. Ralph W. Thompson of St. Louis. The important findings were as follows: The entire body has a peculiar

bluish-red, livid, splotchy appearance. The lower extremities are abnormally hairy. The facial features are somewhat thickened and coarse in appearance. The pancreas is normal in consistency, size and shape, and exhibits no evidence of recent acute inflammation or hemorrhage. The spleen is distinctly abnormal, measuring only approximately 5 cm. by 3 cm. by 2 cm. in dimension. Its external appearance is a dull-slate color, with whitish granulation resembling a coat of "frosting." The pelvic organs are normal. On ex-

## CAROTENE (PRO-VITAMIN A) IS THE ALL YEAR VITAMIN for ADULTS and CHILDREN

Q Many regard Carotene [Pro-Vitamin A] as a valuable aid in maintaining a healthy condition of the mucous membranes and therefore, believe that it helps to protect against the invasion of pathogenic bacteria. Q Smaco Carotene-in-oil is made from plant sources exclusively. Consequently it has no fishy taste. Small, easy, drop or capsule doses. Q Also offered combined with Vitamin D concentrate. S.M.A. Corporation ©1935 Cleveland, Ohio

GLIMPSES OF SOME OF OUR EQUIPMENT FOR PRODUCING CAROTENE IN QUANTITIES SUFFICIENT TO MEET THE DEMAND.

amination, the kidneys are found to be somewhat edematous, with congestion of the pyramidal tissue and the renal cortex. There are massive hemorrhages in both right and left suprarenal glands which are approximately two and one-half to four times their normal size. The hemorrhages have distorted the suprarenal cortex so that they have the appearance of hemorrhagic cysts.

*Microscopic examination:* Kidney; glomerular nephritis (moderate degree); pancreas negative; spleen, chronic splenitis with increase of trabeculae and hemorrhage (much pigment from old bleeding); adrenals: marked congestion and massive hemorrhage both old and recent. The recent hemorrhage appeared to be into the medulla, but the cortical cells were extensively loaded with pigment thus indicating an old hemorrhage.

#### TREATMENT

Emergency treatment in cases of massive hemorrhage into the suprarenals, producing practically a complete absence of function of these

glands, if diagnosed, resolves itself into the use of enormous doses (as much as 3 c.c.) of adrenelin chloride and cortical hormone exhibited intravenously, in addition to the usual method of combating circulatory collapse and hemorrhage. The large doses of suprarenal extracts are given in the hope of tiding over the patient during an acute severe hypoadrenal period.

#### COMMENT

This case presents several interesting features; *i.e.*, fatal, massive suprarenal hemorrhage, many minute, former suprarenal hemorrhages (infarcts?), splenic hemorrhages (infarction?), and hyperfunction of the suprarenal cortex.

I feel that we can safely hazard the opinion that the pre-terminal attacks of lumbar pain, occipital headaches, nausea and vomiting were due to the small suprarenal hemorrhages. Nature, in attempting to repair the damage done, overcompensated, and the more or less chronic resulting hyperfunction of the suprarenal cortex occurred as evidenced metabolically by the physical changes in the appearance of the patient such as today we recognize as a part of the suprarenals' cortical syndrome (hirsutism, changes in nutrition and physical appearance; progressive arterial hypertension).

The macroscopic and microscopic findings in the spleen add another interesting angle to the picture. The part played by that organ is not understood at the present time.

In considering the differential diagnosis, one must consider with any confused picture of lumbar pain which is associated with headaches, nausea and vomiting, always the possibility of minute suprarenal hemorrhages.

## IN LINE WITH

# Preventive Practice

CONSTIPATION due to insufficient "bulk" is often a result of the average American meal. Unless checked, it may well lead to serious trouble.

However, the continued use of cathartics is often harmful, because of the tendency of these drugs to form dangerous habits. It's much better if people can obtain the needed "bulk" in the foods they eat.

Kellogg's ALL-BRAN is a convenient source of "bulk" to aid regular habits. This "bulk" does not lose its effectiveness when used regularly. ALL-BRAN also supplies vitamin B and iron, an important element of the blood.

The "bulk" in this natural, laxative food is mild in action. It does not break down in the body as much as the "bulk" found in fruits and vegetables. So it is often more effective.

ALL-BRAN may be used with perfect safety by most people. A few individuals have highly sensitive intestines. In these special cases, any form of "bulk" is, of course, inadvisable.

This delicious cereal may be served with milk or cream or used in cooked dishes. Sold by all grocers in the red-and-green package. Made by Kellogg in Battle Creek.

*Abdominal Pain as a Symptom of Disease of the Brain. J. A. M. A., 105:9, August 31, 1935.*

Abstracts of 14 cases are reported by this observer of brain lesions in which abdominal pain was a prominent symptom. He states that it probably occurs more often than appears from a casual observation and that special attention will bring to light a greater number of cases. His paper deals with expanding lesions which are of such great importance to the neurologist and neurosurgeon. Most of the evidence presented points to the cortex and possibly to the frontal, more particularly the premotor area as the source of neurogenic abdominal pains and indicates that the cortex contains visceral autonomic representation. But there is also evidence to show that the hypothalamus and possibly the vagus region may be responsible for the abdominal pains, and that if the cortex is the source of the pain it is mediated by way of the lower levels or centers. The symptom, therefore, cannot be said to have localizing value, though it may point to the frontal part of the brain.

*"Jejunal Diverticulosis." S., G., and O., 60:223-228, August, 1935.*

Autopsy findings are presented in three cases of jejunal diverticulosis—in one, there was an associated multiple diverticulosis of the colon and in another, an associated parasitic infestation of the jejunum. While gastro-intestinal symptoms are usually absent in patients with jejunal diverticulosis when present they resemble in general those of chronic duodenal stasis. Various reports have described pain 1 to 3 hours after eating, nausea, vomiting, distension, barbarygmus relieved by change in position, melena, constipation, a fecal taste associated with vomiting, and a syndrome suggestive of low grade intestinal obstruction.

Two very excellent photographs of contrast X-ray study are included in the article.

*Congenital Megacolon. Am. Jour. Path., Vol. XI, No. 2, p. 365, March, 1935.*

The report of a case of megacolon congenitum (Hirschsprung's disease) is given which presents two points of interest; first, the nature of the death of the patient, which was due to com-

pression of the heart and lungs by the distension of the colon; and second, both the absence of any mechanical obstruction about the rectum which might have been considered etiological in relation to the disease and the absence of any apparent change in the cells of

Auerbach's plexus within the wall. In this case the bladder did not take part in the dilating process, as has been described in some instances.

The author reviews very briefly the theories of causation. It is evident that his case fits into a neurogenic etiology

better than into other groups. The mechanism of death was apparently unusual, for the cause of death in Hirschsprung's disease as recorded in the literature is usually that of cachexia or perforation of the intestine in relation to an ulcerated colon and the related colitis. The patient died suddenly of acute heart failure at a time when he had been in comparatively good health.

"Fundusectomy in the Treatment of Peptic Ulcer—An Experimental Study." *S., G., and O.*, 61:155-161, August, 1935.

The surgical treatment of peptic ulcers has been rather satisfactory in the management of perforation, hemorrhage, and obstruction but much less so in permanently lowering gastric acidity. This latter is true even when an attempt is made to permit easy regurgitation of the alkaline duodenal secretion

and at the same time to eliminate the ulcer bearing area. An ingenious study of the gastric mucosa of a dog showed that while acid secreting cells were present in practically all locations, they were much more numerous in the fundus as has been demonstrated before. These cells were also found more abundant in the greater curvature because of the great reduplication of the mucous membrane by the rugae. In a series of four dogs, the acidity was determined by various analyses and fundusectomy was done, leaving only a tubular passage along the lesser curvature. The immediate post-operative drop in free and total acidity began to ascend after 3 months and at 8 months had reached the preoperative levels. The dogs were then sacrificed and grossly the stomachs showed an approximate return to normal size and shape. Microscopic examination showed a general distribution of acid reacting cells thruout. The conclusion offered is that since the gastric acidity cannot be permanently lowered by excision of the acid bearing portion of the stomach fundusectomy has little to offer as a therapeutic measure in the control of peptic ulcer.

PASS, I. J.

*Infarction of the Liver. Am. Jour. Path.* XI, 64, p. 503, May, 1935.

The rarity of infarction of the liver prompts the author to discuss the literature on the subject and report 2 additional cases with autopsy and histological finding. 3500 autopsies were held at Johns Hopkins Hospital without encountering a single case. There were 2 cases noted in 23,000 autopsies at the University of Minnesota. Chiari saw but 2 cases in 21 years experience. It has been assumed that the simultaneous occlusion of both the hepatic artery and the portal vein was necessary to produce true infarction of the liver.

The author's first case was a white male, aged 27 years, who complained of pain in the abdomen following a trauma suffered a month previously. He lived 48 days after onset. The liver weighed 2000 grams. The surface was bluish red and showed numerous irregularly shaped depressed areas. Cut section showed infarcts of different sizes and shapes. The vessel supplying one large red infarct was closed by a small red plug. Most of the infarcts were white; some contained a brownish fluid. Microscopic examination of the kidneys, liver, heart, and spleen revealed a marked involvement of the small arteries. Thrombi were present in many of the larger arteries of the kidneys, spleen and liver. There was complete necrosis of all the tissue elements in the infarcted areas of the liver. The anatomical diagnosis was periarteritis nodosa; multiple infarcts of kidney, spleen, liver and stomach wall; hemor-

rhage from left kidney; hemorrhage from ulcer of stomach.

The second case was a white male, 24 years of age, who had not recovered from an "influenzal attack" four months previous. He suffered abdominal pains and died of inanition. The liver weighed 1500 grams; was olive green in color and the surface was nodular. These areas on cut section were yellowish, and proved to be infarcts. The hepatic artery was closed by the tumor mass originating in the stomach. The anatomical diagnosis was carcinoma of the pyloric end of the stomach with metastases to the pancreas, periaortic lymph nodes and lesser omentum; obstruction of the common bile duct and hepatic artery; ascites; multiple infarcts of the liver and spleen.

CANTAROW, A., AND STEWART, H. L.

*Alteration in Serum Bilirubin and Bromsulphalein Retention in Relation to Morphological Changes in the Liver and Bile Passages in Cats with Total Biliary Stasis. Amer. Jour. Path., XI, 64, p. 561, May, 1935.*

An attempt is reported to correlate changes in hepatic function with the morphological changes in the liver at

varying intervals during the bile stasis in experimental animals.

Determinations of the serum bilirubin concentration and degree of bromsulphalein retention were made almost every 24 hours in 29 cats with complete ligation of the common bile ducts over periods of time as long as 16 days. Sections of the livers were made simultaneously. The sections showed early dilatation of the bile ducts, proliferation of the smaller ducts, and, particularly after the 10th day, a marked proliferation of the mucosa of the larger ducts. Regressive changes were noted in the inner portion of the nodule, immediately beneath the capsule, sporadically throughout the parenchyma and about the larger bile ducts. Necrotic cells were constantly being replaced by regenerated hepatic cells until a terminal stage of stasis was reached. Local areas of necrosis began by the end of 5 hours, were most marked between 24 and 48 hours, and were absent after the 13th day. Hyaline necrosis of the hepatic cells within the lobules began within 24 hours and they were constantly replaced by newly regenerated cells. After the 5th day a concentric avascular fibrosis began. The branches of the hepatic and portal veins were often occluded by hyaline or fibrinous thrombi. Evidences of regeneration characterized by bud-

ding and fission of the nuclei were formed within 8 hours and this gave way to mitotic division of the hepatic cells by the end of 48 hours.

From the chemical studies conducted daily on the animals the authors found that a marked degree of individual variation in serum bilirubin concentration existed. The highest incidence of concentration occurred early in the second week of stasis, and declined thereafter. The time of the initial fall seemed to coincide with the disappearance of mitotic figures in the hepatic cells. There was no demonstrable correlation between the morphological changes and the concentration of serum bilirubin at any given time during the period of total bile stasis. The degree of bromsulphalein retention varied greatly and was not consistently related to the duration of stasis or to the concentration of serum bilirubin. There was no apparent correlation between the degree of dye retention and the morphological changes present in the liver or bile ducts. And, finally, the variation in dye retention might be dependent upon several variable factors, namely, destruction, storage, or extra-hepatic elimination of the dye.

*Primary Perforated Jejunal Ulcer.*  
*Annals of Surgery, Vol. 101, No. 5,*  
*May, 1935.*

The author gives a detailed case history of a patient under his observation with a primary perforated jejunal ulcer—this being the 26th case of this kind reported in the literature.

This condition is a very rare clinical entity having been found in only 17 instances among 17,518 autopsies at Bellevue Hospital, New York City. Dr. McCarty, Department of Pathology at the Mayo Clinic, does not know of a case of primary jejunal ulcer with perforation during the 25 years he has been at the Mayo Clinic.

The etiology remains unknown and the author has no adequate explanation to add.

From a review of the 25 cases reported in the literature and from the history of the case he reports, which was operated upon with suture of the ulcer and recovery, the author states that the most frequent symptoms noted are pain, localized above and to the left of the umbilicus; usually made worse by eating; non radiating; appearing at no appointed time as regards meals and of a dull boring character. Some

patients would be free of pain for intervals of 2 or 3 months at a time. Nausea occurred occasionally but there were few cases with vomiting. The stools in all suspected cases should be searched for occult blood.

Pathologically the ulcers have shown no exact pathological picture except of inflammation and ulceration. The size varied from 2 mm. as in the authors case, to 2 cm. These ulcers in the majority of cases were found on the antimesenteric border of the jejunum—the chronic ones having the tendency to cicatrize and occlude the gut.

The author includes in his article brief case reports of each of the other 25 cases of primary perforated jejunal ulcer found in the literature.

The author suggests the term, "Primary Jejunal Ulcer" to mean an ulceration of the jejunum where there had not been a preceding operative procedure on either the stomach, duodenum or jejunum, and the term "Secondary Jejunal Ulcer" to denote an ulcer in the jejunum following some operative procedure on the stomach, duodenum, or jejunum.

Charles T. Sturgeon, Los Angeles.

## RECORD FORMS FOR THE ASKING

It has been our privilege and pleasure to work with the medical profession in compiling clinical record forms that have furnished the basis of findings in the successful treatment of diseases of the GASTRO-INTESTINAL TRACT.

To assist you in keeping the proper clinical records we have created a clinical record form, double letterhead size, folding to 8½ x 11. The first page is a case history, the second page physical examination, the third page laboratory report and the fourth page is progress records. These forms are furnished to the medical profession WITHOUT CHARGE . . . they are yours for the asking.

## TAUROCOL

(TOROCOL)

### Bile Salts Tablets

Recent clinical tests show that Taurocol "stepped up" the flow of bile as much as 150%.

TAUROCOL is a combination of bile salts, extracts of cascara sagrada, phenolphthalein and aromatics and is an agent recognized by the medical profession and widely prescribed for about a quarter of a century.

## GALL STONES

By

A. J. DELARIO, M.D.\*  
PATERSON, NEW JERSEY

IN a study of 14,000 gall bladders, Mentzer (21) found 57% of the surgical specimens, and 20% of the autopsy specimens to contain stones. If cholesterosis were to be included, then gall bladder precipitation was found in 69.87% of the surgical specimens, and in 37% of the necropsies. This study shows that precipitation of bile constituents is very frequent, and it seems therefore that a discussion of this subject would be of value.

### CHEMICAL COMPOSITION OF GALL STONES

Gall stones may consist chemically of pure cholesterol, or of 20 to 90% of cholesterol, in conjunction with calcium carbonate, calcium phosphate, and especially calcium bilirubinate. Cholesterol stones are found mainly in humans; they may be round or faceted.

Some stones are made up only of bilirubin, or its calcium salt. These are small, black or greenish. This is the most common type of stone in oxen and pigs, where they may reach the size of a walnut.

Occasionally biliverdin and bilifuchsin will form a stone which likewise will be small and green.

In about 3% of cases calcium carbonate or phosphate may be the sole constituent of a stone. These stones are hard, and show very well by X-ray. About as often as it forms stones, calcium carbonate precipitates in the form of a mud or milk. Calcium stones are very frequent in cattle and pigs.

Iron and copper are found in minute quantities in stones. Manganese and zinc have been found occasionally, and in some stones have been found cell debris, bacteria, mucin, etc. (15).

Depending upon the amount of cholesterol present, stones are either heavier or lighter than water. Pure or nearly pure cholesterol stones float, those with a great deal of calcium will sink.

Cholesterol is the main constituent of human gall stones. Most investigators have failed to find it in the stones of other animals. Mentzer, however, found it in the gall stones of swill-fed hogs. Those fed on grain did not have it. He found three cholesterol gall stones in 252 swill-fed hogs, and he found four bili-

rubin calcium stones in 712 grain-fed hogs. Only 0.72% of 964 pigs' gall bladders had stones. In 400 sheep, 1.75% of which had stones, one cholesterol stone was found. In the other six, bilirubin-calcium stones were found (22).

Gauss and Davis found cholesterol-rich stones in 1% of cattle (13). Whales have large biliary concretions known as ambergris, sometimes weighing as much as 100 pounds, which are claimed to be cholesterol stones (10).

Cholesterol is a monatomic alcohol ( $C_{27}H_{45}OH$ , or  $C_{27}H_{43}OH$ ) (19), and is a solid at temperatures as high as 148.4 degrees C (body temperature is 37 degrees). It is insoluble in water. It is soluble in bile salt solutions. When cholesterol is precipitated slowly, beautiful compact crystals are formed, usually flat, with a corner broken off one end; the angles of the sides are 76° 30' and 87° 31'. A solution of these crystals in chloroform or ether is levorotatory. A 2% solution turns the plane of polarized light 31° 12'.

When cholesterol is allowed to precipitate rapidly it forms a feathery network of almost amorphous material, with fine perfect crystals at the end of each network.

It is interesting, especially in the study of the etiology of cholesterosis to note that cholesterol is excreted by the whole gastro-intestinal tract, mainly by the large bowel. It is present in biliary and pancreatic excretions, and the cholesterol found in the mucous membrane of the gall bladder in cholesterosis is probably an expression, therefore, of excretion rather than absorption.

Bilirubin ( $C_{33}H_{36}N_4O_6$ ) (31) and its salts can be of reddish yellow or brown crystals, or amorphous material. The crystals are relatively insoluble in water. Bilirubin crystallizes in long needles from chloroform solution. Solutions of bilirubinate easily precipitate with lime salts, especially in dilute alkalies.

Salts of biliverdin ( $C_{33}H_{38}N_4O_8$ ) (18) are usually amorphous and also insoluble in water.

Salts of calcium, such as carbonates and phosphates, are insoluble in water.

As one can see, the biliary constituents that form stones are insoluble in water. Cholesterol is held in solution when the bile salts are present to the extent of 13 times the amount of cholesterol present. This is the critical level of cholesterol precipitation (1).

\*Assistant in Gastroenterology and Associate in X-ray, St. Joseph's Hospital, Paterson, N. J.  
Submitted July 22, 1935.

Thanks are due to Dr. Harry Golding, Head of the Roentgen Ray Department, St. Joseph's Hospital, for his kindness in permitting the use of many of the X-rays presented in this paper, and to Dr. Kim, Pathologist, of St. Joseph's Hospital, for his aid in obtaining certain gall bladders and stones illustrated here.

Fig. 1. Group of pectolite crystals showing one method of crystallization in nature, with crystals radiating from a given point or center.

Bilirubin stays in solution up to a certain point, and according to Elton (9) precipitation occurs when its concentration by the gall bladder is 50.9 in dogs, 40.4 in cats, and in humans even much higher.

Calcium carbonate and phosphates are extremely insoluble, and have a great tendency to be present wherever cholesterol is found, as is evident in atheromas of the blood vessels and calcification in the lung, etc.

Calcium is probably normally excreted by the gall bladder, and its excretion is increased in the presence of infection and stasis (23). One gathers from Phemister's article (23) on calcium carbonate stones, that calcium carbonate may be excreted as such by the gall bladder in some cases or that calcium exists in a soluble ionic form and is rendered insoluble by its union with carbon dioxide ions when pH or the number of carbon dioxide ions reach a high level in the gall bladder under pathological conditions. And this may occur even though the amount of soluble calcium ions found in the gall bladder is higher or lower than normal (24).

The precipitation of biliary elements, like crystallization in nature, takes place in the main by two methods:

1. Crystallization may occur about a given point or center, just as is shown in the crystallization of pectolite (Fig. 1). Additional layers may be added on to it later.

2. Crystallization may take place from the outside first, crystals being deposited on the inner shell from the salts present in the liquid captured at the center, as is shown in the geode of quartz (Fig. 2). The crystals at the outside being very small, and those toward the center being large, due to the slower rate of crystallization.

The stones that form from a given center are round when they are formed in the fundus of the gall bladder, and if they occupy the entire fundus they become oval, just as the gall bladder fundus is oval.

If two such stones are formed in the fundus of the gall bladder, then, where the two stones meet, crystallization continues in a fashion that makes the stone flat at this point. Crystallization at the flat surfaces is crammed. The crystals are smaller. Peculiar de-

formed, crowded or flattened "liesegang," ring phenomena, are seen at this area of contact, that show the cramming of crystallization.

As the various centers of crystallization in the gall bladder fundus increase, then of course the number of flat or irregular surfaces increase to a point at which the stones are called "facetted."

In this type of stone, in which crystallization proceeds from the center, crystallization is usually very slow. The crystals can be seen, large and shiny, radiating from a given center (Figs. 3 and 4); as crystallization occurs the calcium bilirubinate is pushed outward, and but very little of it is caught between the plates of cholesterol. If crystallization is a little faster, then the plates are smaller, and more pigment is caught between them (Fig. 5). As the rate of crystallization increases in this type of stone, the centers of crystallization usually increase. The cholesterol crystals are very fine, needle-like, and more pigment is found between crystals, and in fact, quite a clump of it may be found at the very center of the stone (Fig. 6).

When the rate of crystallization is very rapid in a large stone, the stone will have a moth-eaten appearance. The crystals will be small and needle-like, and radiate not from a given point, but from a large mass of pigment which may even contain a cavity (Fig. 7).

We have round, or nearly round, stones and facetted stones in which crystallization started from the outside first, and proceeded inward (Fig. 8). In these stones there is usually a hollow center, as one examines them some time after they have been removed from the body. This is due to evaporation of water which normally exists at the center. If one cracks one of these stones immediately after removal he will find the shell thin, and the center moist, or filled with fluid. In this type of stone the crystallization has been much more rapid, as one can tell by the size of the crystals as seen under the microscope when compared with the size of the crystals removed from the stone in which crystallization took place from the inside first (Fig. 9). The size of the crystals from the facetted stones is similar to the size of the crystals when cholesterol

Fig. 2. A geode of quartz showing another method of crystallization in nature in which crystallization occurred in the periphery first and proceeded inward, crystals on the outside being small and those toward the center being large, due to the slower rate of crystallization.

Fig. 3. Large cholesterol stone in which crystallization proceeded from a given center. Crystals are large, flat, and shiny, with very little pigment caught between crystals. These facts point to a slow rate of crystallization.

is allowed to precipitate rapidly from a solution of acetone (Fig. 10).

The cholesterol stone has no crystalline form at all when seen grossly, but is fatty and compact in nature, and at the center bile pigment is found in large amounts. The cholesterol seems to be in compact or flat layers.

In this type of faceted stone in which crystallization occurred from the outside first and proceeded inwardly, it seems that it is the cholesterol which precipitates first in definite zones throughout the gall bladder, the facets being determined by these different zones which cause stress upon one another. The crystallization is very rapid, all the zones crystallize at the same time, and due to the nature and composition of the bile at that time, each stone would be more or less of the same form, size, shape, color, and each stone would have the same identical internal pattern. The size of the stone, the amount of fluid caught at the center, the "liesegang" or ring phenomenon, all depend upon the speed of crystallization.

Figure 11 shows a stone which has the characteristics found when crystallization radiates from the

Fig. 4. A photomicrograph of crystals removed from the center of the stone in Fig. 3. Shows large crystals of cholesterol.

Fig. 5. Cholesterol stone in which crystallization proceeded from a given center at a slightly faster rate than in the stone seen in Fig. 3. The cholesterol crystals are smaller; more pigment is caught between crystals.

center, and also a flat band typical of the rapid crystallization found in a faceted stone in which crystallization started from the periphery first. This stone therefore signifies a rate of precipitation midway between that found when crystallization starts from the center and that found when crystallization starts from the outside.

I have mentioned the speed of crystallization many times, and in this connection the chart (Chart I) taken from the book "The Natural History of Crystals" by A. E. Tutton (29) is interesting. Here one can see

Fig. 6. Cholesterol stone in which crystallization proceeded at a still faster rate than in the stone in Fig. 5. The cholesterol crystals are smaller, more needle-like, and more pigment is found between crystals.

Fig. 7. Cholesterol stone in which the crystals radiate from a cavity containing pigment or fluid. Here crystallization has been faster than in any of the previous stones.

Fig. 8. Facetted type of stone; shows crystallization starting from the outside and proceeding inward. They have a hollow center, grossly appear fatty and compact in nature, and in flat layers. The cholesterol crystals are very small, indicating very rapid crystallization.

Fig. 9. Photomicrograph of scrapings of stone seen in Fig. 8, showing the small crystals of cholesterol at "A", crystals similar to those found in Fig. 10.

that there is a definite relationship between concentration and temperature and the rate of precipitation and that when the concentration is very large, precipitation will take place very rapidly. This must occur in faceted stones, especially those with a hollow center, because here the size of the crystals is very small and indefinite.

How long it takes the faceted stone to precipitate in the body has yet to be proved clinically. Can it take place overnight? I believe it can.

Harries (16) found that gall stones probably can occur within three months. A patient, from whom he removed two stones, one-half inch in diameter, had one year later, over a dozen stones, one-eighth to one-fourth inch in diameter. However, the patient gave symptoms of stones three months after the first operation.

I know of a case which, after cholecystectomy, continued to pass stones through a drainage wound for weeks, although at the time of operation no stone was

Fig. 10. Small crystals of cholesterol formed when cholesterol is allowed to precipitate rapidly from an acetone solution. Note close similarity to crystals in Fig. 9.

Fig. 11. Facetted stone in which the rate of precipitation is nearly midway between that found in a cholesterol stone in which crystallization proceeded from a given center and one in which crystallization proceeded from the outside first. Notice the flat band at the top of the stone characteristic of facetted stones.

left in the biliary tree, as could be seen by exploration of the common duct.

One can also see from Chart 1 that temperature plays an important part in crystallization. Not only does temperature allow more cholesterol to go into solution when patients are afflicted with temperatures of long duration, but whatever causes a rise in temperature usually causes more cholesterol, bilirubin, etc., to be destroyed. When the patient's temperature is restored to normal, the cholesterol which was held in solution due to higher temperature, tends to precipitate.

If one examines these facetted stones closely by cutting into them, no matter how many stones are present in a single case, the internal form is always the same.

Fig. 12. Cholesterol precipitation upon a previously formed stone. The outer layer of crystals can be completely removed. Air spaces and potential spaces exist between the two areas of crystallization.

In order for so many stones of this identical internal structure to have been formed, they would all have had to be formed at one time, because the chemical composition of bile is constantly changing and the chances are that the same chemical composition and the same factors which have existed at one time in the bile may never occur again, except in a probable ratio of one to millions. If this is so, it would mean that all of the stones would have to be formed at one time.

Occasionally two different types of facetted stone may exist in the same patient, which means that gall stone formation took place probably at two different times, and often facetted stones may exist in which a second precipitation occurred upon a previous stone (Fig. 12). Occasionally round stones signifying a slow rate of crystallization, and facetted stones signifying a rapid rate of crystallization, may be found in the same patient, but both types were probably not formed at the same time. Facetted stones are characteristic of the patient from whom they come. The outside form of gall stones from ten different patients

Chart 1. Diagram illustrating the conditions for crystallization from solution or liquid states. Taken from: *Natural History of Crystals*. (Kegan Paul, Trench Bruben & Co., Ltd., London, 1924). A. E. Tutton, page 44.

may be the same; however, the internal form of the stones of these different patients is different. In fact one can pick all of the stones that come from each different patient merely by opening the stone and examining it.

#### "LIESEGGANG" RINGS

"Liesegang" phenomena can occur in stones of both types of crystallization, internal, and external, in round or facetted stones. Most people believe that the rings signify additional layers deposited on previously formed stones, but Sweet (25) believes otherwise. He believes that the preliminary step must be a colloidal formation, partly a jelly, as often cholesterol can be, and that the black rings are due to rhythmic precipitation of calcium bilirubinate throughout a colloidal cholesterol mass. That this is probably true is clearly shown in the facetted stones, where the precipitation at the corners has been duplicated by him artificially by

Fig. 13. Showing in a faceted stone the "liesegang" rings formed by the rhythmic precipitation of calcium bilirubinate, the source of which was the bile entrapped at the center of the stone.

means of silver nitrate and potassium bichromate jelly. Usually the source of the calcium bilirubinate is in the bile around the cholesterol mass. Occasionally it is the entrapped bile at the center of the faceted stone (Fig. 13).

Up to this point cholesterol stones only have been discussed. Now calcium and pigmented stones will be briefly dealt with. Calcium salts may exist in great amounts in cholesterol stones either in the "liesegang" rings, or when caught between cholesterol crystals, or when caught along with biliary pigments at the center of the hollow stones.

Sometimes calcium bilirubinate is laid in layers around a previously formed cholesterol stone. How-

Fig. 14. Calcium carbonate stones found in the cystic duct, and calcium mud found in the fundus of the gall bladder at "A".

ever, calcium may form pure calcium carbonate stones or those in which calcium carbonate is associated with calcium phosphate in smaller amounts. These stones are hard, irregular, and spikey, although the general form tends to be round (Fig. 14). Calcium carbonate may be present as a milky mud just as often as it is present as stone (Fig 15). In fact the bile in the whole gall bladder may have this milky-mud appearance. The X-rays show this mud as a dense shadow. The gall bladder does not visualize with dye, although the cystic duct is not actually blocked, for bile, or this mud, can be squeezed from it.

Biliary pigment may be associated with cholesterol stones in about the same fashion as are calcium salts. In fact they may both appear together as calcium bilirubinate.

Bilirubin, or calcium bilirubinate, may form round or irregular stones which are black, or silvery black, soft, or hard, depending upon the amount of calcium

Fig. 15. Test tube with calcium carbonate mud taken from gall bladder.

present (Fig. 16). In some cases it appears that these pigmented stones are merely concentrated masses of pigment due to ante—or even—post-mortem precipitation.

Up to this point it has been shown that the rate of crystallization determines the shape and size of the stone, whether it will be round or faceted, whether crystallization will proceed from the center, or the periphery of the stone and whether or not there will be entrapped bile at the center. It has also been seen that the rate of crystallization depends upon the temperature and concentration of biliary constituents. The factors which cause abnormal concentration of these constituents of bile are given in Table 1.

If these factors are kept in mind in treating patients the conditions essential for gall stone precipitation may be avoided. For instance, if a patient is being treated for a condition in which temperature is of long duration, and the patient is refusing food, he should probably be given bile salts three times a day. Bile salts keep the upper biliary tree free from stasis. They

Fig. 16. Two types of pigmented stone.

Working on lower animals, especially the dog, in 1930, in a paper on the paths of absorption and excretion of sodium tetraiodophenolphthalein (6), I showed, that as far as this dye was concerned, it could be absorbed from the gall bladder wall. In 1931 in a paper on the interpretation of gall bladder roentgenograms (7), I again was of the opinion that all experimental work and data up to that time pointed to the fact that the gall bladder could absorb its dye.

But the Roentgenograms in Figs. 17, 18, 19, present to my mind conclusive evidence that the gall bladder may also empty its contents by contraction. One can see in these roentgenograms that as the gall bladder

Fig. 18. Fifteen minutes after a fat meal the gall bladder shadow is getting smaller, and the dye in the duodenum is increasing in amount, having the density of bone at "A".

shadow diminishes after a fat meal, the shadow in the duodenum gets larger, and also in this case much denser. This can be explained by the fact that when the bile-containing dye comes into contact with pancreatic juice and alkali juice of the intestines, together with fat present there, the dye is precipitated by the fat, and this precipitate is soluble in neither strong alkalies or strong acids, and casts a stronger shadow than if the dye were in solution. However, not all cases present roentgenograms with this finding after a fat meal, not even if they are taken at short intervals after the administration of fat. Is this an

Fig. 17. Five minutes after a fat meal, the dye shadow appears in the cystic duct, common duct, and duodenum.

stimulate the liver cells to form more bile salts and other secretions, and these of course will keep the cholesterol which is formed in more abundance during periods of temperature and in starvation more in solution. During chronic disease, the patient should be forced to eat, especially of fatty food, because fat not only stimulates the liver to form more bile salts, but also keeps the gall bladder free from stasis.

Fig. 19. Twenty-six minutes after a fat meal. There is still more dye in the duodenum, and even greater contraction of the gall bladder.

      - (b) Duodenitis.
      - (c) Appendicitis, etc.
  7. Starvation (20).

B. FACTORS CAUSING AN INCREASE IN TEMPERATURE ALLOW MORE BILIARY CONSTITUENTS TO BREAK DOWN, AND MORE BILIARY CONSTITUENTS TO GO INTO SOLUTION. AS THE TEMPERATURE FALLS THERE IS A TENDENCY FOR BILIARY CONSTITUENTS TO PRECIPITATE.

Fig. 21. Roentgenogram of the stones in Fig. 20 taken with moderate quantity of X-ray.

indication that in some gall bladders absorption of dye may occur as it does in a dog?

According to the figures of Ferguson and Palmer (11) in a grand total of 552 patients in which stones would probably be found, 15% would have stones which would cast a positive shadow, that is, stones in which calcium would form part, or all, of the shadow; 20% would have stones casting a negative shadow, that is, stones in which cholesterol was the major ingredient. These negative stones cast a negative shadow on the film, not only because of the dye around them, but also because they are usually faceted stones which have a hollow center, or a center containing fluid from which all crystallizable material has been precipitated.

In the remaining 65% in which stones would be presumably present, no shadow could be seen, and the gall bladder either did not fill with dye, or filled poorly, and the stones in these cases also, are cholesterol stones, or occasionally, pigmented stones. In this latter group the gall bladder did not fill with dye because it could not empty, for if the gall bladder cannot empty its old contents it also cannot be filled with new bile containing dye. It is also interesting to note in another series of cases that of the gall bladders which gave a faint shadow or no dye shadow at all, three-fourths contained stones.

By giving these patients a fatty meal and bile salts for several days before their gall bladder X-ray examination, a great many more of these stones can be brought out, because the majority of them are faceted. As a matter of fact even if no dye entered the gall bladder the very nature of these stones makes it

possible to visualize them, though I admit a great many more roentgenograms have to be taken, and technique must be greatly varied.

It has happened repeatedly in our roentgen-ray department that where gall stones were missed at the first visualization, they were found at the second. Figures 20, 21, and 22 show a series of different types of gall stones, and illustrate how it is possible, by giving too much X-ray, to go right through the stones without seeing them.

Now again, of what value is the information as to the type of stone present in a case as determined by the roentgenograms, or even as determined by the structure after removal?

First of all, one can focus his attention, if the stone is a cholesterol stone, upon the factors which are apt to produce cholesterol stones, even after removal of the gall bladder. If the stone is a calcium or a pigmented stone, the attention can be focussed upon the factors which produce these types of stone. After cholecystectomy all the biliary elements secreted by the liver are greater in amount than those coming down when a gall bladder is present. Bile coming from animals in which there is no gall bladder is also richer in all the elements than that in one in which there is a gall bladder. The reason that stones are not formed after cholecystectomy oftener because of this greater concentration of elements is, first, there is a dilatation of the ducts, a greater secretion, a quicker emptying time. The Papilla of Vater is dilated, and thus no

Fig. 22. The same stones as shown in Figs. 20 and 21. When the amount of X-ray is increased it actually goes through all the stones except those which contain a great deal of calcium.

stasis is allowed. Nevertheless, gall stones may form after cholecystectomy, either in what is left of the gall bladder, or in the rest of the biliary passage.

Cholecystectomy is not a 100% sure proof therefore,

that no more stones will form, and treatment should be started after operation which has a tendency to prevent precipitation of cholesterol or formation of the type of stone found at operation.

## Abdominal Pain as a Misleading Symptom of Spinal Cord Lesions\*

By

EVERETT D. KIEFER, A.B., M.D.

BOSTON, MASSACHUSETTS

IN many cases of tumor of the spinal cord the earliest and most outstanding symptom is pain caused by irritation of the posterior nerve roots. When pain is present for considerable time before the onset of sensory and motor disturbances (which result from cord compression), its cause may be thought to lie in the region supplied by the affected nerve, thus leading to gross errors in diagnosis. When the cord lesion is situated at some level between the 7th and the 12th thoracic segments, abdominal pain may occur and frequently results in fruitless abdominal surgery.

Spinal tumor is not a common disease. Tumors involving the cord are considerably less frequent than intracranial tumors. Nevertheless, the condition is not rare, and it has been said (1) that in about ten per cent of cases serious diagnostic errors are made before the true nature of the complaint is suspected. In almost every reported series of cord tumor cases there is listed one or more patients who has undergone abdominal operations for pain which was finally found to be produced by irritation of spinal

nerves. It is evident, therefore, that this condition is worth consideration in abdominal diagnosis.

The condition known as "cord bladder" is well recognized as a complication of spinal cord disease. Similarly, constipation is almost universal in cases of cord tumor because of disturbances of the rectal reflexes. For example, a patient with a cord lesion presented herself to the gastro-intestinal department of this Clinic with the chief complaint of obstinate constipation. This patient would go for several days with the rectum distended with soft feces but experiencing no inclination to go to stool. Usually the bowel disorder is troublesome and difficult to overcome. As cord compression increases, incontinence of feces develops, but by this time there may be other definite neurological disturbances which indicate the nature of the trouble.

A complete survey of the literature has not been attempted, but one of the most striking cases of abdominal pain arising from a cord lesion is found in Elsberg's book (2) on spinal cord tumors. This patient was a woman, aged 36, who for two years had had attacks of pain in the right hypochondrium and back. The gall bladder containing stones was removed without relief. The pain spread to the right lower quad-

\*From the Department of Gastro-enterology, Lahey Clinic. Read before the 35th Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., June 10-11, 1935. Approved by the Publications' Committee of the Association.

rant and an appendectomy was performed without relief. Later she was operated upon for right inguinal hernia, again without relief. Definite motor and reflex disturbances developed and a subsequent laminectomy disclosed a tumor compressing the right 5th, 7th and 8th thoracic posterior roots.

Frazier and Spiller (3) have reported the case of a woman aged 52, who 5½ years before examination had complained of burning pain in the epigastrium and vomiting without relation to meals. Although the vomiting subsided the pain persisted with some radiation to the left and was usually worse at night. Her bowels were extremely constipated. Neurologic examination, however, indicated a spinal lesion, and at operation there was disclosed a tumor at the level of the 7th thoracic vertebra.

Beckman (4) has reported the case of a patient with intermittent attacks of pain in the gall bladder region and vomiting. A cholecystectomy had been performed without relief before it was finally determined that the pain was caused by a tumor pressing upon the right 7th dorsal root.

A representative case which has come under our observation is that of a girl, aged 21, who came to this Clinic complaining of intermittent attacks of pain in the right upper quadrant of the abdomen over a period of two years. The pain was aggravated by sudden twisting of the neck, also by coughing but was not associated with nausea or vomiting. There was marked constipation but no bladder symptoms. There had been a slight sensation of stiffness in the right leg for two weeks.

There was tenderness in the right lower quadrant. The deep reflexes of the lower extremities were hyperactive particularly on the right. A bilateral Babinski reflex was present. Very slight hyperesthesia was present in the right first and second lumbar skin areas. Vibratory sense was slightly diminished on the right. The spinal fluid was slightly xanthochromic. A laminectomy by Dr. Horrax revealed a neurofibroma at the level of the seventh thoracic vertebra.

Rectal pain simulating that caused by rectal disease may be produced by tumors of the cauda equina. An instance of this is reported in Elsberg's book (2) in the case of a woman, aged 43, who had complained of rectal pain over a period of 12 years. Operations including hemorrhoidectomy, removal of the coccyx, division of the sphincter ani, sigmoidopexy and suspension of the uterus had been performed without relief. At the time of the neurologic examination there was also pain in the lower extremities, bladder control was lost at times and the rectal pain was accentuated by lying down. There was only slight weakening of the reflexes and slight diminution of sensation in the lower limbs, but a laminectomy revealed a tumor at the level of the first sacral vertebra.

A similar case from our series was a man, aged 41, who came to this Clinic complaining of pain in the region of the sacrum and severe constipation of three and a half years' duration. The pain was aggravated by lying down. For about four months he had had some difficulty in emptying his bladder.

There was tenderness over the lumbosacral spine. The knee jerks and ankle jerks were absent. The abdominal reflexes were absent on the right side. There was some loss of sensation around the rectum and along the left thigh.

A laminectomy by Dr. Horrax disclosed a tumor extending from the level of the 10th dorsal vertebra to the 3rd lumbar vertebra which proved to be an ependymoma of the cauda equina.

Spinal lesions other than tumor may be productive of abdominal pain through pressure on appropriate nerve roots. These include compression fractures of vertebra, tuberculosis of the spine, hypertrophic arthritis and herniation of the nucleus pulposus, and chronic spinal arachnoiditis.

Chronic arachnoiditis is another condition which if present in the spinal canal may act as a tumor equivalent, giving rise to almost identical clinical pictures with the same difficulties in differential diagnosis. This condition has been recognized for many years as a definite pathological entity characterized by thickening of the arachnoid membrane, engorgement of the pial blood vessels and the formation of dense adhesions in the subdural space. Little is known of its etiology. Because of the tendency to recurrence the surgical treatment of chronic arachnoiditis is less satisfactory than that of cord tumors, but the relief derived from the division of subdural adhesions or of the sensory nerve roots may persist a long time making operative interference well justified.

#### ARACHNOIDITIS CASE REPORTS

In this Clinic three patients have been examined for abdominal pain arising from chronic spinal arachnoiditis verified by laminectomy.

*The first case* was that of a man, aged 43, who, two years previously had begun to have pain in his upper right back. The gall bladder which contained gall stones had been removed without relief. Later, because of continued attacks of upper abdominal pain resembling biliary colic, the common duct had been explored. No stones were found and no relief followed the operation. A third operation had been performed at which time periduodenal adhesions were found and separated but the pain remained unrelieved. At no time were there definite motor, reflex or sensory disturbances but because of increased protein content of the spinal fluid, he was referred to this Clinic for laminectomy by Dr. Horrax. Freeing of arachnoid adhesions and division of the seventh pair of sensory roots gave relief.

*The second case* was that of a girl, aged 15, who came to this Clinic complaining of pain in the epigastrium and right abdomen with constipation of two months' duration. There was extreme tenderness of the epigastrium and of the right lower quadrant. An appendectomy did not relieve the pain or tenderness and urinary retention developed after the operation. Neurologic examination showed hyperesthesia on the right side up to the 12th thoracic vertebra, atrophy and slight loss of power of the right leg, hyperactive reflexes with a questionable Babinski of the left lower extremity and slight loss of vibratory sense on the right side. Abnormalities in the spinal fluid dynamics and in the lipiodol studies indicated disease in the subdural space. At laminectomy freeing of arachnoid adhesions between the levels of the 8th and 12th thoracic vertebrae gave relief of symptoms.

*The third case* was a girl, aged 17, who came to this Clinic complaining of intractable constipation and pain in her right side of six weeks' duration. For a year she had had pain in the lower back. Her appendix had been removed without relief of pain or of constipation. Physical examination showed exaggerated tenderness in the right lower quadrant. The rectum was dilated and filled with soft feces. The temperature and white blood count were slightly elevated. While she was under observation it was noted that she was incontinent of urine at night and

occasionally there was urinary retention requiring catheterization. The knee jerks were absent. There were some vasomotor disturbances in both lower extremities, some loss of sensation to pain, touch, temperature and vibration over the left lower extremity. The extensor muscles of the left foot and left thigh were weak.

The spinal fluid was slightly xanthochromic and lipiodol studies appeared to localize a lesion at the level of the 7th thoracic vertebra.

At laminectomy performed by Dr. Horrax, the arachnoid was found to be gray, thickened and adherent.

Following the operation the pains were relieved and the bowel function became normal. Two months later she again had to resort to small enemas to initiate the act of defecation but her course was satisfactory until a year after the operation when she developed mild fever, pain in the right arm and right back and increasing constipation. When conservative measures did not relieve her, a second laminectomy was performed with the separation of additional arachnoid adhesions resulting in relief of pain and return to normal bowel function.

The fact that abdominal pain resulting from dorsal root irritation may be unilateral, that it may occur in sharp intermittent attacks and that it may be associated with vomiting, constipation or urinary tract symptoms, makes the similarity to visceral disease striking and misleading. However, there are certain differential characteristics of this symptom which when properly elicited and recognized should serve adequately to arouse suspicion as to its true nature. If the pain has definite localization and persists for several months or longer without variations except in degree, spinal tumor should be thought of as a possible diagnosis. Pain which is induced or aggravated by sneezing, coughing, grunting or lying down and which is relieved by the sitting position, is particularly suggestive. Although root pain may appear first, pain in the lower back and in the lower extremities usually develops when the tumor increases sufficiently in size to cause pressure upon the spinal cord (5). Girdle sensation, a third type of pain associated with cord tumors is described as a sensation of a tight cord about the trunk. Therefore, when abdominal pain is accompanied by pain in the lower back and lower extremities or by girdle sensations, its diagnostic significance becomes more apparent.

Pain with the above characteristics indicates that a search should be made for motor, reflex and sensory disturbances. Although it is true that in a large proportion of the reported cases such changes were present when the laminectomy was performed, it is impossible to determine just when, in the usually long history of pain, objective neurologic signs appeared. Nevertheless it seems probable that if attention could be focused upon the central nervous system and appropriate examinations carried out, earlier diagnoses would be possible.

On examination of the patient there may be hyperesthesia or hypesthesia in the region of the pain but it is not a constant finding. As cord compression develops lively tendon reflexes, ankle clonus or plantar extension may be elicited. If there is found diminution in the pain and temperature sensations over the lower extremity on the opposite side from the pain, the diagnosis is fairly definite. However, it is more common to find slightly diminished sensation on both sides below the suspected level.

Sphincter disturbances, although not usually the earliest manifestations, may complete the clinical

picture in such a way as to lead to the correct diagnosis. The usual sequence of bladder disturbances is frequency, hesitancy, retention and incontinence.

## CASE REPORTS

*Case No. 1.—Neurofibroma at the level of the seventh thoracic vertebra (6).*

M. S., a girl, aged 21, unmarried, came to this Clinic complaining of pains on the right side of the abdomen, which had been present intermittently for two years with no associated nausea or vomiting. At first the pains were located mainly in the right upper quadrant. A gall bladder visualization showed normal function. The pains were aggravated by sudden twisting or bending of the neck and also by coughing. There was marked constipation but there were no bladder disturbances. There was a slight feeling of stiffness in the right leg for about two weeks previous to her entrance to the hospital. The rest of the history was irrelevant.

*Physical examination* showed moderate superficial and deep tenderness in the right lower quadrant. The abdominal reflexes were brisk and equal. The patellar and Achilles reflexes on the right were markedly hyperactive (///) and slightly less active on the left (/). A bilateral Babinski reflex was present. A very slight relative hypesthesia could be detected over the first and second lumbar skin areas on the right. Vibratory sense over the right internal and external malleoli was slightly diminished. The lumbar puncture showed an initial pressure of 120 mm. of water. Prolonged jugular compression brought an immediate rapid response, the fluid rising rapidly to 260 mm. and descending with the same speed on the release of the jugulars, the patient breathing normally throughout the procedure. The fluid, when compared with water, was slightly tinged with yellow. The total protein of the spinal fluid was 60 mm. per hundred cubic centimeters. Iodized poppy-seed oil injected into the cisterna twenty-four hours later stopped at the seventh thoracic vertebra; a few drops of the oil passed the obstruction after several hours. A laminectomy revealed a firm neurofibroma which was large enough to cause a pressure furrow in the spinal cord. There were no adhesions.

*Case No. 2.—Ependymoma of the Cauda Equina.*

Mr. E. P. Clinic number 34157, male, age 41, came to this Clinic June 22, 1933, complaining of "arthritis" and constipation. For three and a half years he had had pain in the region of the sacrum and the sacro-iliac joints, for which he had worn a belt and had had most of his teeth removed without any relief. For five or six years he had increasingly severe constipation which seemed to aggravate the pain in the lower back. He was unable to sleep in bed and most of the time slept in a chair. The constipation had become so severe that it required a laxative after every meal. The stools were normal except for some mucus. There was some bloating but no marked abdominal distention. For about four months he had noticed increased difficulty in micturition. There was no complete stoppage at any time but the stream had become smaller and at intervals there was some difficulty in voiding.

The general *physical examination* was negative except for tenderness to palpation over the lumbo-sacral spine, with considerable limitation of motion of the lumbar spine. The knee jerks and ankle jerks were not obtained. There was no Babinski reaction or ankle clonus.

X-rays of the lower spine and sacro-iliac region showed asymmetry of the lumbo-sacral articulations. The posterior portion of the first sacral vertebra was not closed in. An X-ray examination of the colon by means of a barium enema was not remarkable except for some spasm of the left side of the colon and some dilatation of the right side. There was complete evacuation of the enema. Other laboratory work, including urine, blood counts, blood Wassermann, blood sugar, blood non-protein nitrogen, comple-

ment fixation test for gonorrheal infection, was normal. Gastric analysis showed free hydrochloric acid of 45.

On admission to the hospital the patient developed urinary retention with distention of the urinary bladder and it was found to be very difficult to get his bowels to move. On cystoscopic examination a diagnosis of a cord bladder was made. A neurological examination showed absent knee jerks and ankle jerks, no Babinski or ankle clonus, absent cremasteric reflexes, abdominal reflexes present on the left side but absent on the right. There was some loss of sensation around the rectum and along the left thigh.

Lumbar puncture was performed but no fluid was obtained in the 3rd, 4th and 5th lumbar spaces or the first sacral. Intrathecal injection of lipiodol showed a definite block at the level of the 10th dorsal vertebra.

A laminectomy by Dr. Horrax and Dr. Poppen disclosed a tumor extending from the level of the 10th dorsal vertebra to the 3rd lumbar vertebra which proved to be an ependymoma of the cauda equina. The large tumor was completely removed.

The patient's convalescence was not remarkable. Seventeen months after the operation the patient's condition was improved but he still had some difficulty in walking and had some pains in his legs.

#### *Case No. 3.—Localized spinal arachnoiditis.*

Miss D. S., case number 37597, female, aged 15, came to this Clinic on January 9, 1934, complaining of pain in the epigastrium and in the right side of the abdomen of two months' duration. There was no vomiting but considerable nausea. Food taken aggravated the pain and caused considerable gaseous eructation. The pain was sharp in character, was more severe in the upper abdomen and did not radiate down the back or into the extremities. About one year previously she had had severe back pain for a few weeks thought to be due to wrenching of her back while doing exercises in a gymnasium. She complained of constipation but had noted no bladder difficulty and complained of no sensory or motor disturbances.

Physical examination was not remarkable except for extreme tenderness and hyperesthesia of the epigastrium and the right lower quadrant of the abdomen. The slightest touch caused wincing.

Gastro-intestinal X-rays by means of a barium meal and a barium enema showed no organic disease. The colon was dilated and redundant throughout and the barium enema was not well evacuated. It was noted in the X-ray films that the urinary bladder was apparently dilated. Because of the short history and the localized tenderness in the right lower quadrant an appendectomy was advised and carried out. The appendix showed no signs of acute inflammation and the exploration of the abdomen at the time of the operation was negative except that the urinary bladder was distended. Spinal anesthesia, metycaïne, was used.

Because of persistent abdominal pain and tenderness after the operation and persisting urinary retention to the extent that on the ninth postoperative day there were forty-eight ounces of urine in the urinary bladder, a neurological examination was carried out. The positive findings were regions of hypesthesia on the right side up to the 12th thoracic vertebra; definite atrophy and loss of power of the right leg; hyperactive reflexes of the left lower extremity but no clonus; questionable Babinski on the left side; vibratory sensation diminished over the right external and internal malleoli; slight change in position sense.

A combined cisternal and lumbar puncture showed markedly differing pressures in the lumbar and the cisternal regions, indicating a complete block of the subarachnoid space. Lipiodol injected into the cisterna passed down into the sacral canal in two hours with the exception of two or three drops which stayed at the level of the 12th thoracic vertebra. When the patient was placed in a marked Trendelenburg position the lipiodol moved rapidly until it

reached the level of the 12th vertebra, then stopped for a few seconds and then kept going upward in a small, thin stream and again stopped completely at the 9th thoracic vertebra.

On February 1, 1934, a laminectomy was performed by Dr. Gilbert Horrax and Dr. James Poppen, which showed localized arachnoiditis involving the cord from approximately the 8th thoracic vertebra to the 12th. The arachnoid adhesions were freed.

The postoperative course was uneventful. The abdominal pain and tenderness cleared up. The function of the bowel and the bladder became normal and up to the present time she has had no recurrence of her symptoms. Diagnosis: Localized subarachnoiditis at the level of the 8th to the 12th thoracic vertebra.

#### *Case No. 4.—Localized spinal arachnoiditis.*

Mr. H. C. T., Clinic No. 44555, male, age 43, registered at this Clinic December 4, 1934. The patient had been in excellent health until four and one-half years ago, when after stooping over he was seized with a sudden severe pain in the middle of the back. He practically collapsed but was able to be up and about with difficulty after several days. He was quite well except for some low back pain until 1932, when he complained of abdominal discomfort and pain in the upper right back occurring in attacks. A cholecystogram showed gall stones and in December, 1932, a cholecystectomy was performed.

However, the pain was not relieved after the operation and in June, 1933, an examination of the spinal fluid by means of a combined cisterna and lumbar puncture showed increased protein; 78 mgs. in the lumbar region and 34 mgs. in the cistern fluid, indicating some disturbance in the flow of cerebrospinal fluid, although no definite dynamic block was demonstrated. Lipiodol injected into the cisterna flowed downward normally except for deviation of the stream to the left at the level of the 3rd and 4th dorsal vertebrae.

Because of continued attacks of upper abdominal pain resembling biliary colic and because the abdomen was more suspicious as cause of the pain, a second operation was performed in July, 1933, for possible common duct stone. There was no jaundice.

At the operation many periduodenal adhesions were encountered but no stones were palpated in the common duct.

The pain was still unrelieved and in October, 1933, X-ray examinations showed partial obstruction of the jejunum.

He was again operated upon, the obstructing adhesions were broken up and the common duct was opened and explored. No stones were found.

The pain was still unrelieved and the patient had become to depend more and more upon opiates. In April, 1934, orthopedic treatment was instituted although the only finding was a rather sharp lateral curvature in the upper dorsal region.

Since there was no satisfactory relief from this he was referred to Dr. Gilbert Horrax for exploration for a probable intraspinal lesion. There were no bladder or rectal symptoms. The blood and spinal fluid Wassermanns were negative. Neurologic examination showed no sensory or motor disturbances except increased deep reflexes throughout.

At operation by Dr. Horrax and Dr. Poppen, the dorsal laminae from the 5th to the 9th were removed. The arachnoid was distinctly thickened and opaque and when this membrane was opened there was seen to be a meshwork of adhesions from it to the underlying cord throughout the whole extent of the area exposed, but was particularly dense in the region of both of the 7th sensory roots and the 8th on the right side. The adhesions were freed as much as possible and the 7th pair of sensory roots were divided.

The postoperative course was uneventful and the symptoms have been entirely relieved.

*Case No. 5.—Diffuse generalized chronic arachnoiditis.*

Miss M. G., Clinic No. 36193, female, age 17, was registered in the gastro-intestinal department at this Clinic October 13, 1933, complaining chiefly of severe constipation and pain in the right side.

The patient had been totally deaf since birth but appeared to be of average intelligence and could read lips fairly well and speak a few words. She was a full term baby and delivery was without instruments. Since birth she had been troubled with constipation and moderate abdominal distention. Enemas and laxatives had been used throughout her life.

For about one year she had complained of low back pain. About six weeks before admission she began to have pain in her right side of the abdomen associated with frequent vomiting. After about ten days her appendix was removed without relief of pain. Because of the severe constipation she was kept in the hospital for four weeks, during which time she lost weight and showed no improvement in bowel function. Even with enemas she would go as long as 11 days without having a stool. For about a week before coming to this Clinic, she had been urinating in bed while asleep.

Physical examination showed her to be rather poorly developed and poorly nourished. There was tenderness in both lower quadrants particularly in the region of the appendectomy scar. However, the tenderness appeared to be superficial in the nature of marked skin hyperesthesia. There was slight scoliosis of the lower dorsal spine. The rectal examination showed a large rectum distended with soft feces. The knee jerks were present and equal. Blood pressure 115/70. Weight 91 lbs.

The laboratory tests showed the urine to be normal. The red count was 5,170,000, the white count 8,200 and the hemoglobin 87%. The gastric analysis showed a free acidity of 15 after an Ewald meal. The blood Wassermann was negative.

A barium enema filled the colon slowly with some distress to the patient. The colon was moderately redundant and only slightly dilated. The rectum was filled with a large amount of fecal material.

She was treated in the hospital from October 28, 1933, until November 17, 1933. During this time she had a slightly elevated temperature scarcely ever over 100° F. The white count was 13,000. She complained considerably of pain in her back and of headache. The bowel function remained sluggish and it was noted that bowel action appeared to be normal but the feces accumulated in the rectum without producing a desire to defecate. However, very slight stimulation of the rectum produced a normal movement. There was some bed wetting in the hospital but this stopped before discharge.

A neurological examination by Dr. Gilbert Horrax showed both elbow reflexes present. The knee jerks could not be obtained. Achilles jerks active on both sides. Abdominals present and active on both sides. The planter responses were normal, no ankle clonus. There was slightly less strength in the left leg than the right. The optic fundi were normal. There was some hyperesthesia of the left leg but it did not coincide well with the anatomical nerve distribution and was more characteristic of a "stocking" type of anesthesia. A spinal puncture was advised but was not done until her second admission December 16, 1933, when she was readmitted with acute urinary retention. A cystocopy with a right pyelogram was negative.

A neurologic examination showed absent knee jerks, some vasomotor disturbances in both lower extremities, some loss of sensation to pain, touch, temperature and vibration of the left lower extremity, and definite weakness of the extensor muscles of the left foot and left thigh. She still complained of pain in the right back and down the left leg.

A lumbar puncture showed slightly xanthochromic spinal fluid with no change in pressure with jugular com-

pression, coughing or straining. The spinal fluid Wassermann and gold sol reactions were negative. The total protein of the fluid was 60 mgs. per 100 c.c.

Following the lumbar puncture the pain was accentuated. There was a definite level of hyperesthesia corresponding to the 9th rib on the left and a region of hyperesthesia on the right involving the 11th and 12th thoracic segments.

Lipiodol injected into the lumbar subarachnoid space rose to the level of the 7th thoracic vertebra where it appeared to be definitely obstructed. There were scattered drops of iodized oil scattered along the spinal canal below this suggesting chronic arachnoiditis.

On December 20, 1933, Dr. Horrax and Dr. Poppen performed a *laminectomy*, removing the laminae from the 4th to the 8th thoracic vertebrae. The arachnoid was found to be pale gray and thickened. It was adherent to the pia by means of a diffuse mesh of adhesions. These adhesions were broken up and a small, soft rubber catheter was passed both upward and downward in the spinal canal showing no additional obstruction.

The postoperative convalescence was uneventful. Her bowel function and bladder function became entirely normal and remained so for about two months, when she again found it necessary to stimulate the rectum with a small enema in order to have a movement. Repeated examinations of the rectum showed the rectum filled with soft feces. There were no hemorrhoids, fissures or other disease of the anal canal. For several months she showed a slight elevation in temperature but was comfortable except for occasional pain in the back and right leg. In September, 1934, her weight was 99 lbs.

In December, 1934, she was readmitted to the hospital with an indefinite acute infection which apparently aggravated the arachnoiditis causing pain in the right arm and back, with vomiting. There was some hyperesthesia of the entire right side below the neck with the exception of the leg and forearm. Conservative measures failed to relieve the root pain and a second laminectomy was performed at the level of the 9th to the 12th thoracic vertebrae. The posterior roots were markedly involved in adhesions which were separated and the right 10th posterior root was divided because it was so extensively involved. A small mass of fibrous tissue measuring 3 cm. by 2 cm. and 4 millimeters in thickness was removed from the left side of the subdural space at the level of the 10th thoracic vertebra.

She was discharged from the hospital having no pain and with the bowel function returned to normal. About two months later there was some recurrence of pain in the right side accompanied by epistaxis, vomiting and constipation.

## SUMMARY

Clinical reports of several cases of spinal cord lesions have been presented in order to point out that such lesions, through irritation of posterior nerve roots, may produce abdominal pain which is easily confused with that caused by visceral disease. Particular attention is called to the condition known as chronic spinal arachnoiditis as a causative factor and to the fact that its presence may and frequently does lead to fruitless abdominal surgery.

Certain features of abdominal pain caused by spinal lesions should serve to arouse suspicion as to its true nature. These features are persistence in a definite location over a long period of time, aggravation by changes in body position, increase in pain by sneezing or coughing and association with pain in the lower back or lower extremities or with girdle sensation about the trunk.

Mistakes in diagnosis can be avoided by proper appreciation of these characteristics and by examining

the patient for motor, reflex and sensory disturbances which, although usually not marked, are frequently present.

### DISCUSSION:

DR. HOWARD F. SHATTUCK (New York City): We are certainly all indebted to Dr. Kiefer for his interesting and important paper. The conditions he described are not common, but he has made it clear that they may become pitfalls to any of us at any time. For a number of years we have been taught to look carefully to the heart, for example, in patients with acute symptoms in the abdomen.

Dr. Kiefer has forcibly reminded us not to forget the spinal cord. In short, as our President reminded us this morning, we must be competent internists, not to say neurologists perhaps, if we would attain competency in the medical specialty of gastro-enterology.

I was impressed with the length of time it takes to make a diagnosis in some of these patients. It is true some of them could be spared unnecessary abdominal operations if neurological signs and symptoms were looked for and recognized, but some of the patients apparently have their abdominal pain for a long time before the neurological symptoms appear, so I suppose that an occasional unnecessary abdominal operation seems inevitable. The important thing is to think of spinal cord involvement and to look for it.

I was also interested in the cases of chronic arachnoiditis that Dr. Kiefer described. The first of his series did not show the presence of any motor sensory or reflex disturbances, merely an increase in the protein content of the spinal fluid.

I should like to ask what the minimal findings that should lead to an exploratory spinal operation in these cases.

DR. TEMPLE FAY (Philadelphia): Dr. Kiefer's paper emphasizes an experience common to most neurosurgeons. The time required to administer the anesthetic for these fruitless operations would be all that is necessary to establish the error in diagnosis, were the appropriate neurological tests carried out. In suggesting a greater familiarity with early neurological manifestations, it seems reasonable to expect that certain tests for neurological continuity should be routinely employed by the internist, in conjunction with the elaborate gastro-intestinal studies usually carried out:

(1). *Deviation and eversion* of the foot occurs as an important early motor sign of cord compression. With the patient placed flat upon the back, the position of the foot should be almost vertical in the normal, eversion of the foot occurs long before Babinski, clonus or weakness appear.

(2). *Babinski reflex* should be tested by carefully scratching over the outer border of the sole of the foot, using minimal stimuli, so as not to disturb the patient, thus frequently eliciting an early manifestation which otherwise might be concealed in a larger response when this reflex is carelessly or too energetically tested.

(3). *Gnostic sense* or the patient's ability to translate skin writing clearly, should be employed over the lower extremities, and numbers from one to ten quickly written on the skin surface by means of the finger or pencil, test not only serial tactile impressions to the skin, but include

two-point discrimination as well as visual projection of sensation into numerical concepts. This is not only a delicate test for all of the posterior column function of the cord, but determines whether or not the parietal lobe of the brain and visual-speech and motor-speech centers are intact and unimpaired.

(4). *The testing of pain and temperature responses* in the region of the buttocks and about the rectal area, is most important in that early sensory disturbances are elicited at this point, long before they appear on the body surfaces, from lesions producing a cord compression. This is due to the fact that the pain and temperature fibers for the gluteal area lie close to the surface of the cord, on its anterolateral borders. Compression of the cord produces disturbances of these superficial fibers before the deep tracts become involved.

(5). *The level of pain reference* should be carefully traced on the body by the patient and indicated with a skin pencil. The patient should be placed between the examiner and the daylight from a window so that the exposed skin surfaces may be observed from a distance. The light reflex given off from the portions of the skin where the nerve root involvement is present will appear slightly blushed and velvety, whereas, the skin above and below the level of root involvement will show a high glossy sheen. If this zone is carefully marked by a skin pencil and subsequently tested with pin point, heat and cold, hyperalgesic or disturbed sensory phenomena in this area will frequently indicate direct nerve involvement.

(6). *Scratching the skin* from below upward and crossing the zone of vasomotor disturbance noted above will frequently bring forth responses of hyperalgesia and definitely indicate the transition from a zone of hyperesthesia to the normal. Observing the red line produced by the scratch a few minutes later may indicate a wheel-like formation in the band of vasomotor instability. The vasomotor sign is a distinct root irritative phenomenon.

(7). *The sweating reflex* may be elicited by giving one-sixth of a grain of pilocarpin after surrounding the patient with warm blankets and noting the areas of sweating. Sweating occurs freely above the level of the lesion of the cord, disappearing below this point, or is inadequate. If a cord lesion is present, sufficient to give rise to the symptoms which Dr. Kiefer has described, there should be no question about delaying any thought of intra-abdominal surgery until the neurological examination has been carried to a complete interpretation of the findings noted above.

I could relate eight instances in my own experience where abdominal operations have been fruitlessly performed for spinal cord tumors. I believe, however, that the following instance proves not only an exception to this rule, but represents a triumph for the internist. Last Monday I operated a female patient, age fifty-one, who had complained of epigastric pains and weakness for the past three months. The patient sought medical advice, and a large firm abdominal mass, situated in the upper midabdomen, slightly to the left of the umbilicus was discovered upon examination. It was well-defined, movable, and suggested a pedunculated fibroid sarcoma or mesentery tumor. There was no bleeding and no rectal symptoms were complained of by the patient. Constipation was not a factor. The patient had developed a limp in the right leg during the past 6 months. A progressive paralysis of the right leg developed with Babinski, clonus and bilateral exaggeration of the knee jerks; sensory impairment for pain and temperature over the body was discovered as high as the nipple line. The patient was not aware of this change until disclosed at examination. The roentgen ray studies of the chest and spine were negative for metastasis.

The internist made a diagnosis of spinal cord tumor in the upper thoracic region and felt the spinal region should

be operated on before the abdominal tumor. I removed a flattened endothelioma, non-malignant, 4 cm. in length, situated extra-durally on the right side of the cord, extending from the third to the seventh dorsal vertebrae. The abdominal tumor still awaits exposure and identification next week.

Here is a situation where abdominal surgery might easily have been justified, but the fine clinical judgment of the internist demanded that the signs of cord pressure be removed, first, as the abdominal mass could await its appropriate term.

It seems to me that we may all feel proud of such diagnostic acumen based upon an understanding of certain fundamental neurological manifestations. I concur with Dr.

Kiefer in his timely admonitions and appreciate the privilege of discussing this paper.

DR. EVERETT D. KIEFER (Closing the discussion): I have little more to add.

Dr. Fay should be the one to answer Dr. Shattuck's question, but to me laminectomy is a fairly serious operation and one would not explore for arachnoiditis without having some fairly definite neurological signs, or fairly definite evidence of changes in the spinal fluid, or in the case I just mentioned, where one had exhausted every other means of giving relief to the patient. This patient was rapidly becoming a morphine addict and he was explored perhaps on a little less evidence than one would usually want.

## ABSTRACTS

BLOOMFIELD, ARTHUR L.

*Early Cancerous Changes in Peptic Ulcer. J. A. M. A., 104:1197, April 6, 1935.*

The author considers the subject to benign ulcer and its relationship of malignancy of the stomach.

He reviews the criteria for the early diagnosis of carcinomatous gastric ulcer. The roentgen examination is not always conclusive. The assumption that benign ulcer has a long history and cancer a short history cannot always be relied upon. Consideration of age and sex are of little help. The size of the gastric ulcer is generally helpful in the differentiation, but there are many exceptions to this rule. The presence of gastric secretion or absence of it when carefully analyzed is not of much help since cancer may arise in a stomach with an acidity and a chronic gastritis on the one hand and on the other arising from a previous benign ulcer with little change in gastric secretion. Response to a medical regime of the ulcer cannot be used as conclusive evidence either for or against malignancy, because a malignant ulcer may respond to medical treatment and benign ulcers may not.

Prophylactic surgery carries with it definite risk.

The author therefore concludes that patients with benign ulcers should be treated as such until weighty evidence

accumulates to change that impression, realizing that a number of malignancies will be thus overlooked in their incipency.

*The Effect of Oil of Peppermint on the Emptying Time of the Stomach. J. A. M. A., 104:1792, May 18, 1935.*

The Authors have previously reported that oil of peppermint diminished gastric acidity. In this study they report the effect of oil of peppermint on the emptying time of the stomach. In the empty stomach small doses of oil of peppermint had no effect on the hunger contractions of dog or man. Large quantities of oil of peppermint decreased the motility in six tests and produced no change in two.

In experiments with a meat meal and oil of peppermint, shortening of the emptying time was observed.

In six normal young females the addition of two c.c. of oil of peppermint to a barium-milk shortened the emptying time of the stomach as observed fluoroscopically.

These studies seem to explain the popular use of oil of peppermint in many stomach remedies. The use of peppermint candy and peppermint alcohol after a heavy meal appears useful because by increasing motility distension and fullness are relieved more promptly.

Francis D. Murphy, Milwaukee.

## SECTION II—*Experimental Physiology*

### The Autoregulation of the Gastric Secretion\*

By

J. J. DAY, M.D.

and

D. R. WEBSTER, M.D., Ph.D.

MONTREAL, CANADA

THE problem of the autoregulation of the gastric secretion may be considered under two headings. It may be discussed from the point of view of (1) the influence which the gastric juice accumulating in the stomach or the duodenum may have on the secretory activity of the gastric glands, or (2) the changes in the composition of the gastric juice which may occur in the same circumstances, or in other words the quantitative or qualitative changes in the gastric juice due to its own presence in the stomach or duodenum. These two aspects should be carefully differentiated, as in this field recently some of the workers have been considering the quantitative aspect and others the qualitative, and this has led to some confusion.

More than thirty years ago, Sokolov (1904), working in Pavlov's Laboratory on dogs with a gastric and a duodenal fistula, Pavlov pouch and the stomach disconnected from the duodenum, established that the introduction of 0.5 per cent hydrochloric acid into the stomach caused a marked inhibition of the secretion from the pouch; on the other hand, lactic and butyric acid stimulated the secretion. It was also noted that the introduction of meat and water into the main stomach caused the pouch to secrete, but the secretion was small and in four to five hours had practically ceased. Analysis of this phenomenon showed that the inhibition of the pouch secretion was due neither to the increased pressure on the walls of the main stomach resulting from increase of the gastric contents, nor to stimulation caused by absorption of the products of meat digestion, but to the rising concentration of hydrochloric acid in the stomach. Inhibition of the secretory activity of the pouch was also noted when gastric juice was introduced into the duodenum. Unfortunately very few experiments of this kind were performed. A few years before in the same laboratory Shemiakin (1901) found that, when hydrochloric acid in physiological concentrations was introduced into the duodenum, it inhibited the secretion of the pyloric glands, but that when applied locally it stimulated the secretion of these glands. Pavlov and his pupils, in discussing the autoregulation of the gastric secretion, were considering not one particular constituent of the gastric juice, namely acid, but the gastric juice *in toto* (cf. Babkin, 1928).\*

The idea that the secretion of hydrochloric acid varies under certain circumstances was originated by Rosemann (1907, 1920). His theory created a great controversy, and a voluminous literature arose on the question of the mechanism of the secretion of hydrochloric acid by the gastric glands. It was opposed to Pavlov's theory of the constancy of the acidity of the secretion produced by the gastric glands.

We have no intention of discussing the corresponding literature but shall merely mention a few papers which have direct relation to our problem. The most ardent supporters of Rosemann are MacLean and his co-workers (1928), who developed his theory to the extreme. Whereas Rosemann speaks only of slight variation in the distribution of the chloride between the hydrochloric acid and the chlorides of the gastric juice, MacLean, Griffiths and Williams (1928) believe that at the end of the secretory period the secretion of acid in the stomach of the dog is replaced by a secretion of neutral fluid containing chloride, which reduces the acidity to the fasting level. As was demonstrated by one of us (Webster, 1929), under normal conditions the gastric glands of the dog never secrete sufficient neutral fluid to dilute the gastric contents and reduce their acidity. One of the factors which play an important part in the neutralization of gastric acidity at the end of the secretory period, when the volume of the secretion is greatly diminished, is the alkaline gastric mucus. Bolton and Goodhart (1931 and 1933) came to analogous conclusions.

Further, MacLean and Griffiths (1928 b) came to the conclusion that the concentration of hydrochloric acid in the normal human stomach is regulated automatically by the hydrogen ion concentration of the gastric juice. According to them, a certain concentration of acid in the stomach inhibits the secretion of acid. The secretion of the latter is replaced by the secretion of a fluid containing neutral chlorides, which reduces the acidity of the gastric contents by diluting them.

\*The cause of the confusion of these two different concepts (secretion of gastric juice and secretion of acid) probably originated in an unfortunate English rendering of the corresponding text in I. P. Pavlov's book on "The Work of the Digestive Glands," translated by W. H. Thompson (2nd ed., London, 1910, p. 115). The part where Pavlov refers to the gastric juice reads as follows: "With the same dogs we also discovered a new form of autoregulation on the part of the stomach, which concerns the secretion of hydrochloric acid. It appears that the acid prevents the further secretion of gastric juice when it has accumulated in any considerable quantity within the cavity of the organ."

\*From the Department of Physiology, McGill University, Montreal. Submitted July 2, 1935.

In a series of recent publications Wilhelmj *et al.* (1933, 1934 a and b) arrived at a diametrically opposite conclusion to that of MacLean and his co-workers. They found that solutions of hydrochloric acid of 0.024 to 0.173 N, introduced into a Heidenhain pouch or into the whole intact stomach of a dog, did not inhibit the secretion of acid. The secretion of the gastric juice was activated by means of histamine. This conclusion was reached indirectly by estimating the different inorganic compounds of the mixed fluid aspirated from the stomach cavity or pouch. Neither from MacLean's nor from Wilhelmj's experiments can any conclusions be drawn concerning the volume of the gastric secretion.

The importance of the problem of the autoregulation of the gastric secretion led us to reinvestigate this question. We were in an especially favorable position to study the effect produced on the gastric secretion by the introduction of acid solutions into the duodenum, since we had at our disposal several dogs with oesophagotomy, gastric and duodenal metal fistulae, and the stomach completely disconnected from the duodenum at the pyloro-duodenal junction. This was the more important since Sokolov only performed a very limited number of experiments of this kind. The problem of the autoregulation of the flow of gastric juice was investigated experimentally in the present study, without regard to the changes in its acidity.

#### METHODS

Two dogs ("F" and "L") with oesophagotomy, gastric and duodenal fistulae, and the stomach disconnected from the duodenum, were employed in this investigation. Some experiments were also done on a dog ("T") with a Heidenhain pouch and gastric fistula. The obstructed animals were fed in the usual manner with the food-mixture described by Scott and Ivy (1931), which was introduced into the duodenum through the duodenal fistula (see Webster and Armour, 1932 a). According to the plan of each separate experiment the food-mixture was or was not introduced. In certain experiments solutions of gastric juice of known acidity were introduced into the duodenum through the duodenal fistula. The free acidity of the gastric juice collected during the experiments was determined by titration with 1.50 N sodium hydroxide, with Töpfer's reagent as indicator; the total acidity was estimated in the same way with phenolphthalein as indicator.

#### EXPERIMENTAL RESULTS

In animals such as Dogs "F" and "L", prepared in the manner described above, there is always a long latent period between the time of the introduction of food into the intestine and the resulting gastric secretion. Once the secretion starts, it becomes gradually more and more copious until it reaches a certain point, after which it gradually declines. The whole period of gastric secretion lasts about 12 to 15 hours. If the food-mixture is not introduced into the duodenum, there is hardly any secretion of gastric juice (Webster and Armour, 1932 a). This is a convincing demonstration of the stimulating effect exerted by food substances and the products of their digestion on the gastric glands from the intestine, a phenomenon known as the "intestinal phase of gastric secretion" (see Babkin, 1928, p. 272).

In view of these facts the question naturally arose as to why, in unobstructed dogs with a stomach pouch or with a simple gastric fistula, the influence of the "intestinal phase" of gastric secretion was not more obvious instead of being practically absent. It is a

well recognized fact that in these animals, shortly after the food has left the stomach, the secretion ceases. If the latent period of action of the secretory substances in the intestine lasts several hours, and the secretagogue effect on the gastric glands is manifested for a greater number of hours after that, as observed in our obstructed animals, one would expect the secretion resulting from the chyme leaving the stomach and entering the intestine to continue for a noticeable period. The daily observations in our laboratory show that this is not the case.

Table I shows the results of an experiment on a dog with a Heidenhain pouch and gastric fistula, in which there is little evidence of any intestinal stimulation

| 11:00 a. m. | Dog fed usual daily meal of meat and porridge.                                                                                                                         |
| 4:00 p. m.  | Total secretion from pouch, 70 c.c. Gastric fistula opened; some food remains washed out.                                                                              |
| 5:00 p. m.  | Secretion from pouch during one hour, 1.5 c.c. of acid gastric juice.                                                                                                  |
| 6:00 p. m.  | Secretion from pouch, 0.1 c.c.                                                                                                                                         |
| 7:00 p. m.  | No secretion from pouch; reaction in pouch alkaline to litmus.                                                                                                         |
| 8:00 p. m.  | No secretion from pouch; reaction alkaline. Gastric fistula opened; slight food residue. Mucous membrane of stomach acid. Fistula left open.                           |
| 9:00 p. m.  | No secretion from pouch; reaction of its mucous membrane alkaline. Stomach secreted during one hour 2.1 c.c. of acid gastric juice containing mucus. Experiment ended. |

after the stomach has been emptied. The very slight acid secretion of the stomach might easily be due either to food particles clinging to the fold of the mucous membrane or to some conditioned gastric reflexes. The pouch, however, where any true hormonal effect would be obtained, remained alkaline.

It was apparent that the main difference in obstructed as compared with non-obstructed animals is the prevention of the passage of the gastric secretion from the stomach to the duodenum and the absence of peptic digestion. Several types of experiment were performed to verify the suggestion that the acid of the gastric juice might act as an inhibitory agent on the gastric secretion.

Table II shows the results of sham-feeding in two experiments carried out on a dog with oesophagotomy, gastric and duodenal fistulae, and the stomach obstructed at the pylorus. The Experiment of May 1 is a control sham-feeding experiment. In the Experiment of May 17, 50 c.c. of gastric juice diluted with an equal quantity of water (approximate acidity, 0.25 per cent hydrochloric acid) were introduced into the duodenum before the sham-feeding was commenced. The introduction of gastric juice into the duodenum, as a preliminary to sham-feeding, depressed the secretory effect of the sham-feeding (in the first two ten-minute periods 9.0 c.c. and 13.5 c.c. were obtained, as against 16.5 c.c. and 19.0 c.c. in the control experiment). But the inhibition of the gastric secretion was especially striking when the gastric juice was introduced into the duodenum while the gastric glands were actually secreting. The total volume of the secretion during one hour fell from 47.7 c.c. to 27.3 c.c. The preliminary introduction of twice as large an amount of water into

the duodenum of the same dog did not produce any inhibition, as may be seen from the following figures:

*Dog "F".—Exp. May 11*

Total for one hour: 55.3

Between 10 and 10:30, 100 c.c. of water introduced into duodenum.

Between 10:30 and 10:40 dog sham-fed.

fell, but the absolute figures for the combined acidity did not deviate very much from those of the other samples (except Sample 4). This shows that the neutralizing factors (mucus, pyloric juice, etc.) remained constant during almost the whole of the experiment.

Another proof that acid, when introduced into the duodenum, is the chief factor in inhibiting the gastric secretion is seen in an experiment in which neutralized gastric juice was introduced into the intestine. Table IV shows the results of two experiments on Dog "L", which was prepared in the same way as Dog "F". During the period in which these experiments were performed, the gastric glands of Dog "L" were in a state of hypersecretion. As described by Webster and Armour (1932 b), this state of hypersecretion depends chiefly on the disturbance of the balance between the substances lost with the gastric juice and those introduced into the body. Therefore this type of secretion

That the acid is the chief agent in the gastric juice which produces the inhibition is shown in the following experiments. Table III represents an experiment during which the secretion produced by sham-feeding with meat in an obstructed dog was definitely inhibited by the introduction into the duodenum of a 0.25 per

differs greatly from that activated by sham-feeding. Nevertheless the introduction of 100 c.c. of pure gastric juice into the duodenum almost completely inhibited the spontaneous secretion for one hour (see Experiment March 11). When neutralized gastric juice was introduced into the duodenum, only a weak

cent solution of hydrochloric acid. On the day of this experiment, the dog had a greater fasting secretion than usual, which again appeared when the effect of the acid had passed off. As usual with diminution of the secretion the total and free acidities of the juice

temporary inhibition could be observed (Experiment Feb. 6).

In the next set of experiments on Dog "F", of which two are represented in Table V, the gastric secretion was stimulated by the procedure of feeding. Scott and

Ivy's diet was introduced through the duodenal fistula in amounts of 80 c.c. every 15 minutes. As usual the secretion did not commence till after a long latent period. In the experiment of July 27, the feeding of the food-mixture was replaced at 3 p. m. by feeding 40 c.c. of the food-mixture combined with 40 c.c. of pure gastric juice (free acidity, 0.347 per cent hydrochloric acid; total acidity, 0.474 per cent hydrochloric

mately 0.12 per cent hydrochloric acid. 60 c.c. of food mixture and 20 c.c. of gastric juice (free acidity of undiluted juice, 0.31 per cent hydrochloric acid; total acidity, 0.49 per cent hydrochloric acid) were introduced, as in the previous experiment, at 15-minute intervals in four feedings. As may be seen from the figures of this experiment, the gastric secretion was again greatly inhibited, only 0.95 c.c. of juice being

TABLE IV

*Dog "L".—Oesophagotomy, gastric and duodenal metal fistulae, and obstruction at the pylorus. The gastric glands were in a state of hypersecretion. Both experiments begun at 9 a. m.*

acid). The total volume of fluid introduced into the intestine remained the same, i.e. 80 c.c. This combination of the mixture and gastric juice was again given at 3:15, 3:30 and 3:45 p. m. At 4 p. m. the regular feeding was resumed. In this experiment therefore hydrochloric acid in a solution of approximately 0.25 per cent (probably less owing to the neutralizing effect of the food mixture) was introduced into the duo-

secreted in the last hour. The results of this experiment are the more striking inasmuch as the concentration of acid in the mixture introduced into the intestine was very low and certainly did not exceed that of the duodenal chyme under normal conditions.

### CONCLUSIONS

The experiments here reported demonstrate that the gastric secretion, stimulated through the parasympa-

TABLE V

denum. As a result the gastric secretion was almost completely stopped for two hours.

In order to approach still nearer to the normal conditions of digestion, in which chyme of an approximate acidity of 0.15 per cent hydrochloric acid passes from the stomach into the duodenum, in the Experiment of August 3 the concentration of the gastric juice added to the food mixture was lowered to approxi-

thetic nervous system or by the presence in the intestine of food substances and the products of their disintegration, is inhibited by the introduction of hydrochloric acid into the duodenum. The same phenomenon was noted when the gastric glands of one of the animals was in a state of hypersecretion. Therefore it may be safely concluded from this investigation that, in all cases where the gastric glands are stimulated to

secrete gastric juice by natural means, the presence of acid in the duodenum and upper small intestine markedly restricts their secretory activity. This fact alone is sufficient to explain why in normal animals, in which the passage of the acid chyme from the stomach to the intestine is not restricted, the "intestinal phase" of the gastric secretion is practically absent. The effect which the introduction of hydrochloric acid into the duodenum might have on the gastric secretion provoked by drugs, *e.g.* histamine and pilocarpine, was not investigated by us, but this is now being studied in our laboratory.

The mechanism of the inhibitory action of hydrochloric acid on the gastric secretion is not quite clear. Facts are accumulating which show that a substance inhibiting both the gastric secretion and motility may be extracted from the intestinal mucosa (the "Entero-gastrone" of Kosaka, Lim, Ling and Liu (1932), Lim (1933), Lim, Ling and Liu (1934), Ivy (1935); the "Biodialysate" of Walawski (1930)). Therefore it is very probable that a *chalone* inhibiting the gastric secretion may be formed in the intestinal mucosa when such substances as fat or hydrochloric acid come in contact with the intestinal mucosa. However, the possibility cannot be excluded that the inhibition may be due in part to nervous impulses arising in the intestine, *e.g.* from distension with fluid, and by reflex action arresting the activity of the gastric glands. The relations in respect of gastric secretion may be analogous to those which Quigley, Zettelman and Ivy (1934) found for the motility of the stomach, namely, that the inhibitory process evoked by fat involves both nervous and humoral mechanisms. Undoubtedly the effect of the acid, as such, is the chief factor de-

termining the inhibition of the gastric secretion. However, in some of our experiments (*cf.* Table IV) the introduction of neutral fluid into the duodenum in considerable amounts somewhat inhibited the flow of gastric juice. In such cases we are probably dealing with a reflex inhibition of the gastric secretion provoked by distension of the intestine, but in the majority of the experiments the factor of distension was carefully avoided by giving only amounts which we knew from experience in feeding the dogs would not cause the slightest distension. Further experiments are now being done with the object of clearing up this point and also of determining whether this inhibitory effect is peculiar to the acids of the gastric juice or whether it may be provoked by other acids or chemicals.

### SUMMARY

Introduction into the duodenum of 0.25 per cent hydrochloric acid or of gastric juice, diluted two to four times, inhibits the gastric secretion stimulated (a) through the parasympathetic nervous system or (b) by the presence in the intestine of food substances or the products of their digestion. The same effect was produced by the acid in some cases of hypersecretory activity of the gastric glands. The theory is advanced that the passage of the acid chyme from the stomach into the duodenum causes the gastric secretion to diminish, this being an important factor in regulating the activity of the gastric glands.

### ACKNOWLEDGEMENT

This work was carried out under the direction of Dr. B. P. Babkin, to whom we are indebted for much helpful advice and criticism.

## ABSTRACTS

HILL, F. C.; HENRICH, L. C., AND WILHELMJ, C. M.

*The Mechanism by Which the Acidity of an Acid Meal is Reduced in the Stomach.* S., G. and O., Vol. 60, No. 5, May, 1935, pp. 966-968.

The authors performed experiments to determine the exact mechanism of neutralization of an acid meal in the stomach. That dilution by regurgitation of duodenal contents, and by the secretion of mucus, occurs, is an accepted fact. To what extent the reduction of acidity in the stomach is due to the alkalinity of duodenal contents, and to what extent it is due to dilution, has not been determined.

The authors using a stock solution of approximately

tenth normal hydrochloric acid containing a small quantity of phenolsulphonphthalein experimented on healthy dogs. The test meal consisted of 300 cc. of the stock solution. Samples of this meal were withdrawn every fifteen minutes for an hour, or as long as any fluid could be obtained. By colorimetric tests the amount of dilution of the meal was determined. Chemical analyses of the samples for neutral chlorides, and total chlorides, showed the extent of neutralization.

By that method the authors found that an average of 65 per cent of the reduction was due to dilution, and 35 per cent to neutralization.

and

B. E. BLOMQUIST, M.A.

with technical assistance of

E. F. WHEDON, M.S.

SAN FRANCISCO, CALIFORNIA

NUMEROUS investigators have established the fact that the reticulo-endothelial system plays a part in the metabolism of fats and proteins. Comparatively little work has been done regarding the participation of this system in the metabolism of carbohydrates in spite of the fact that our knowledge regarding the fate of carbohydrates in the body is more advanced than that of other food elements.

Several workers have studied the effect of reticulo-endothelial block on the blood-sugar level, but their results have been conflicting (1). Klein and Levinson (2), during continuous intravenous injections of India ink, observed an initial rise in blood-sugar, followed by a prolonged fall which they ascribed to exhaustion of available glycogen. Nakaya (3), from a study of hepatic glycogen after carbohydrate feedings before and after intravenous injection of India ink, concluded that the formation of glycogen is due largely to activity of the reticulo-endothelial system. Messina (4) performed extensive experiments showing reduced dextrose tolerance and decreased hyperglycemia after epinephrine in blocked rabbits. Unfortunately, the use of toxic blocking substances which caused marked loss of weight and eventually death in all animals rendered the significance of his data uncertain, especially since these findings are similar to those obtained by one of us (T.L.A.) after poisoning of the liver with phosphorus and with chloroform (5, 6).

Our investigation consisted of first depressing the function of the intravascular components of the reticulo-endothelial system by partial block, and then studying the blood-sugar level, the responses of the organism to "loads" imposed on the mechanisms deal-

ing with assimilation and with mobilization of sugar, and the glycogen content of the liver and muscles.

#### METHODS

In blocking experiments, probably more than in any other biological research, the evaluation of the obtained data depends upon the readers' exact knowledge of the experimental conditions.

*Animals.* Jaffé (7) recommends rabbits as being among the animals most suited to blocking experiments. Accordingly healthy, growing rabbits weighing about 2 kg. were used in this work. They were kept on a diet consisting of rolled oats and alfalfa hay, with the addition of green cabbage leaves and carrots twice a week.

*Blocking substances.* Since our object was to produce physical block of the reticulo-endothelial system limited to its intravascular elements, the blocking substance of choice was a coarse, non-toxic, chemically inert, dispersed colloid which would not pass through endothelial walls, thus avoiding block of extravascular reticulo-endothelial cells or penetration into parenchymatous cells of glandular organs. During the early part of our work we used one part of Higgins' Black American India Ink diluted with two parts of distilled water as a substance thought to answer these requirements (8, 9). Later an article by Victor, Van Buren and Smith (10), dealing with the influence of India ink injections on the hepatic excretion of dyes, brought to our attention the fact that India ink may contain some toxic element, possibly camphor. Higgins Company refused our request to name the ingredients of their product, and therefore we repeated our experiments using separately the precipitated carbon and the carbon-free fractions of India ink, prepared according to directions received from Doctor H. P. Smith. Since eight rabbits injected with the resuspended carbon died from embolism following one or two injections, we substituted for carbon a suspension of colloidal graphite\* in gum acacia. In preparation, the directions of Higgins and Murphy (11) were followed.

In attempting to reduce the functional capacity of the reticulo-endothelial system, the so-called Arndt-Schulze law must be taken into consideration. This repeatedly confirmed law postulates that small amounts of a blocking

substance stimulate, and large amounts depress, the function of the storing cells. Frequently errors are committed by giving an insufficient dose. From at least one study (12), thus far unconfirmed, it appears possible that an

Average Increase of Sugar in Mg.

Chart I. Morning blood sugar of 12 rabbits during and of 6 rabbits after a period of daily India ink injections (5 c.c. given 16 hours previously).

overdose may also increase the functional capacity of the reticulo-endothelium. We attempted to avoid both extremes by determining the effect of different amounts of the blocking substance.

**Timing of experiments.** Opinions differ as to the duration of effective block produced by single injections of a blocking substance. According to some authors (13), the effect of multiple injections may last as long as several weeks; others deny the existence of any cumulative effect with prolonged vital staining (7). In view of such disagreement, and because it is possible that different functions of the reticulo-endothelial system may manifest impairment for different periods of time, we tested our rabbits in separate experiments at intervals of 30 minutes, 5 hours, 16 hours and 24 hours following injection of the blocking substance.

**Tests.** In addition to single blood-sugar determinations, two procedures were employed: 1. The dextrose tolerance test, consisting of administration of 2.5 gm. of dextrose per kg. of body weight. The dextrose was given in a 15 per cent solution by stomach tube, and the blood-sugar level was determined at intervals of 30 min., 1 hour, 2 hours and 3 hours. 2. The blood sugar mobilization test, consisting of a subcutaneous injection of 0.05 mg. of epinephrine per kg. of body weight, which was followed by half-hourly blood-sugar determinations over a period of 2 hours.

To check the results obtained with these two tests, a modification of the dextrose tolerance test was used in which 2.5 gm. of dextrose per kg. were given by stomach in a 5 per cent solution, and 0.5 unit of insulin per kg. of rabbit were injected subcutaneously. Epinephrine was given at the end of 3 hours, and the blood-sugar was followed for 5 hours.

The rabbits were not fasted before the tests because, in our experience (14), fasting for even 16 hours affects the carbohydrate equilibrium of these animals.

Blood-sugar determinations were made in duplicate by the method of Hagedorn-Jensen. For glycogen determinations, the rabbits were sacrificed by a blow below the occi-

put. The entire livers and the adductor longus and adductor magnus muscles were immediately removed and placed in boiling potassium hydroxide after the method of Pflüger.

## RESULTS

In the course of this work over 400 blood-sugar curves were obtained, and for brevity the following manner of presenting our data was chosen. For every curve the average blood-sugar was calculated. By subtracting the figure for the initial blood-sugar from that of the average blood-sugar, a single figure is obtained which expresses the result of the test in terms of disposal or of mobilization of sugar. For instance, the average of a blood-sugar curve obtained at 30 minute intervals after an injection of epinephrine and reading 92, 130, 138, 128 and 116 mg. per cent, is 125 mg. per cent. By subtracting the initial blood-sugar of 92 mg. from 125 mg., the result of plus 33 mg. is obtained. This figure expresses the degree of mobilization of sugar following injection of epinephrine in a given rabbit. In general, the peak of the curves paralleled this increase in the average blood-sugar, but was less reliable.

With this method of calculation, even small differences are significant because each figure represents an elevation of blood-sugar for the duration of the experiment. By averaging these figures from all rabbits for each day of the experiment, we can plot a curve that shows at a glance the effect of successive injections of a blocking substance on utilization or mobilization of sugar.

**Experiments with India ink.** 1. An initial injection of 10 c.c. of India ink was given each of 12 rabbits. This was followed by daily injections of 5 c.c. The animals were tested 16 hours after each injection. The average morning blood-sugar as seen in Chart I was lowered for a time, but eventually this effect of the injections wore off. During the dextrose tolerance test the increase in average blood-sugar at first diminished rapidly (see Chart II), but began to rise again after

the fourth injection and nearly reached its normal value after 12 injections. The average increment in blood-sugar was less by about 40 per cent during the first 10 injections. After that the curve became irregular, but the average was still about 13 per cent

## Average Increase of Blood Sugar in Mg.

Chart IV. Results of the dextrose tolerance and epinephrine tests in 4 rabbits receiving 10 c.c. of India ink on alternate days. The tests were performed 30 minutes after injection.

lower than normal for the remainder of the experiment.

Essentially the same is true of the curve showing changes in the increment of the average blood-sugar during the epinephrine test. The maximum lowering of the blood-sugar approximately coincided with the greatest changes in dextrose utilization and blood-sugar mobilization.

Six animals in this experiment were tested at intervals after the injections of India ink were discontinued, but the curves following both tests were so irregular as to preclude interpretation. The only consistent changes were seen in the morning blood-sugars, which at first were increased above normal for several days and later fluctuated around the level observed before the experiment (Chart I).

2. Two rabbits were injected in a similar manner and subjected to the modified glucose tolerance test 16 hours after injection. Chart III shows that, under these conditions of accelerated assimilation of sugar due to insulin, the increase in dextrose tolerance was

## Average Increase of Blood Sugar in Mg.

Chart V. Results of the dextrose tolerance and epinephrine tests in 4 rabbits injected daily with the carbon-free fractions from 5 c.c. of India ink. The tests were performed 16 hours after the injections.

more pronounced than in the first experiment. The decrease in mobilization of blood-sugar after injection of epinephrine was about the same. The morning blood sugar was lowered.

3. Four rabbits were injected on alternate days with 10 c.c. of India ink (twice the usual dose) for four weeks. The animals were tested 30 minutes and 24 hours after injection. At the 24 hour period the findings were similar to those obtained 16 hours after injection (see Chart II) only less marked.

At the 30 minute period, beginning with the second curve, the blood sugar tolerance curves became higher and the mobilization of blood sugar by epinephrine became greater than before the experiment (see Chart IV).

*Experiment with the carbon-free fractions of India ink.* Four rabbits were given daily injections of the combined carbon-free fractions obtainable from 5 c.c.

of India ink, and both tests were performed 16 hours after injection. During the period of injections the morning blood-sugar in this experiment was slightly higher than normal. Chart V shows only a slight change from normal in the rise of blood sugar after dextrose in these animals. Their ability to mobilize blood-sugar was unchanged.

*Experiments with graphite.* 1. Four rabbits were subjected to daily injections of 10 c.c. of a colloidal suspension of graphite for 11 days. The two tests were performed 16 hours after injection.

2. Four animals were treated in a similar way for 4 days, but only the dextrose tolerance test was done. Sixteen hours after the last injection, these rabbits were sacrificed for determination of hepatic glycogen. Four littermate control animals were kept without food in the laboratory for the same length of time as the experimental rabbits from which samples of blood were being taken. They also received the same amount of dextrose by stomach-tube as the animals undergoing the dextrose tolerance test.

Average Blood Sugar in Mg.

Chart VI. Results of the dextrose tolerance test in 10 rabbits and epinephrine test in 4 rabbits receiving daily 10 c.c. of colloidal graphite. The tests were performed 16 hours after the injections.

3. Four animals whose responses to the dextrose tolerance test were normal were subjected to the same regime as the rabbits in the preceding experiment. These animals, with four controls, were also sacrificed on the fourth day for determinations of the glycogen content of the liver and muscles. Tolerance to dextrose was followed in two of the injected rabbits.

The morning blood-sugar of rabbits in these experiments was lowered to the same extent as that in the first experiment with India ink. The average curves after dextrose and after epinephrine are shown in Chart VI. The changes observed following injections of India ink—namely, increased tolerance to dextrose and decreased mobilization of blood-sugar—are seen to be present to a more marked degree. For instance, increment in blood-sugar after dextrose was about 60% less than normal, as compared with the average of 40 per cent less in the experiment with India ink.

Experiments 2 and 3 (Table I, columns 1 and 2) show that hepatic glycogen was decreased in the rabbits injected with graphite. The same was true of the

glycogen content of the muscles (Table II, columns 1 and 2).

4. Four rabbits were fasted for 3 days while receiving, in the morning, graded injections of 4, 8 and 16 c.c. of colloidal graphite. Blood-sugar determinations were made in the morning and 5 hours after injection. A like number of control animals were treated

injections of 0.5 c.c. and 1 c.c. of this material and were subjected to the epinephrine test after the same interval. On the following morning all animals received 4 c.c. of colloidal graphite, and were sacrificed 5 hours after injection for determination of glycogen in the liver (8 rabbits) and in the muscles (4 rabbits).

Chart VIII shows that the effects of a small dose of our blocking substance on dextrose tolerance and on blood-sugar mobilization were opposite to those of larger doses. The blood-sugar was raised in most instances. Tables I and II (columns 3) show that the glycogen content of the liver and muscles was reduced.

In none of the experiments with India ink or with graphite were toxic symptoms observed. Except in the experiment in which the rabbits were fasted, they

maintained their weight or continued to grow during the period of injections.

### COMMENT

Partial block of intravascular reticulo-endothelial cells, as shown by our data, produces five phenomena in the realm of carbohydrate metabolism: 1. Depression of the blood-sugar under conditions of normal food intake (Chart I) and during fasting (Chart VII). 2. Lowering of the blood sugar curve following ingestion of dextrose (Charts II and VI), which was accentuated by administration of insulin (Chart III). 3. Decreased mobilization of blood-sugar by epinephrine (Charts II and VI).<sup>\*</sup> 4. Reduction in hepatic glycogen (Table I). 5. Diminution in the glycogen of the muscles (Table II).

We believe that these changes are due to physical block and not to a toxic effect of India ink, because colloidal graphite gave results similar to those obtained with India ink (Charts II and VI). On the contrary, the combined carbon-free fractions of India ink failed to produce such changes (Chart V). We ascribe the observed metabolic deviations to impairment in function of the reticulo-endothelial system because a small dose of graphite which, according to the accepted view, should have caused irritative hyperfunction of the reticulo-endothelial cells raised the blood-sugar and produced higher blood-sugar tolerance curves and increased mobilization of blood-sugar (Chart VIII). These effects are the reverse of those observed after larger doses of our blocking substances. An independent study by one of us (B.E.B.) on immunity reactions in experimental Brucella infection following similar doses of India ink resulted in the death of half

*Blood Sugar in Mg.*

Chart VII. Blood sugar of 4 fasting rabbits injected on successive days with 4, 8 and 16 c.c. of colloidal graphite and of their fasting controls (4). Specimens were obtained before and 5 hours after each injection.

of the rabbits. The surviving animals showed more pronounced toxic symptoms than the infected controls among which there were no deaths (15). This indi-

<sup>\*</sup>We assume that the lower curves after injection of epinephrine are not in the main due to increased tolerance of mobilized sugar, because in individual animals they did not necessarily correspond in time or degree to changes in the dextrose tolerance test.

cated that at least one other function of the reticulo-endothelial cells was depressed under the conditions of our experiment.

Our data on the effect of reticulo-endothelial block on carbohydrate metabolism were, we believe, obtained

*Average Increase of Blood Sugar in Mg.*

Chart VIII. The effects of small doses of colloidal graphite on the dextrose tolerance (4 rabbits injected on successive days with 1 c.c. and 2 c.c.) and on the epinephrine test (4 rabbits given similarly 0.5 c.c. and 1 c.c.) 5 hours after injection.

from a large enough number of rabbits studied over a sufficient length of time to minimize the significance of individual variations. Our interpretation of these findings rests in part on conjecture, and therefore is subject to revision.

The phenomena enumerated may be caused directly by interference of accumulated carbon particles with the function of the affected reticulo-endothelial cells, if we assume with other writers that these cells in the aggregate act as a distinct metabolic organ producing intracellular chemical changes in fats, proteins and carbohydrates. On the other hand, it is possible that block of reticulo-endothelial cells may produce these changes indirectly by influencing other organs of metabolism with which these cells are in close anatomical relationship.

In considering the second possibility, we know from the literature (9, 11, 16) and from our own histological observations, that deposition of particles after injection of India ink or of colloidal graphite takes place chiefly in the reticulo-endothelial cells of the liver, and to a lesser degree in those of the spleen and bone-marrow. Since the spleen and bone-marrow have no established function in the metabolism of carbohydrates, we have confined our attention to the liver.

The deviations observed in carbohydrate metabolism cannot be explained by irritation of the hepatic parenchyma with resulting hyperactivity of the liver, be-

cause previous experience (17) has taught us that hepatic hyperfunction is manifested by *increased* tolerance to dextrose and by *increased* mobilization of blood-sugar after injection of epinephrine. Nor can the characteristic changes following block be accounted for by hepatic insufficiency which would result in *decreased* tolerance to dextrose and in *decreased* mobilization of blood-sugar by epinephrine (5, 6).

The combination of *increased* tolerance to dextrose and of *decreased* mobilization of blood-sugar following epinephrine could be due to an insufficient production of sugar in the liver. This organ normally converts sufficient amounts of non-carbohydrate substances into glycogen to fill the gap between the intake of carbohydrates and the energy requirements of the body. In the case of man the liver thus supplies from its own resources about half of the daily internal need for sugar (18). Interference with this function of the liver would lead to an internal deficiency of sugar, thus accounting for lowering of the blood-sugar in blocked fed rabbits and for greater lowering of the blood-sugar in blocked fasting animals than in fasting controls. On the same basis, increased sugar tolerance would be explained partly by an increased sugar vacuity in the tissues and partly by greater inhibition of hepatic gluconeogenesis after administration of dextrose. The latter explanation rests on a demonstration by Soskin (19) that administration of dextrose inhibits gluconeogenesis in the liver and that the degree of inhibition is inversely proportional to the extent of gluconeogenesis. Diminution in the glycogenolytic response to epinephrine is explained by decreased gluconeogenesis and consequent lowering of the glycogen content of the liver. Reduction in the glycogen content of muscles logically follows diminished production of sugar by the liver, with consequent depletion of carbohydrates in the body.

The mechanism of reduced production of sugar on the part of the liver is explicable if it can be shown that the Kupffer cells, which together with ordinary endothelial cells line the hepatic sinusoids, act as a transmitting agent of molecular substances from the blood to the liver. In such a case, block of these cells would curtail the supply of materials from which the liver makes sugar. Evidence that the Kupffer cells have the function of transmitting certain substances to the liver, is furnished by the work of Grossmann (20) and of Radt (21) who showed that previously injected India ink decreases the toxic action of chloroform on the hepatic parenchyma. Jungeblut and McGinn (22) demonstrated that reticulo-endothelial block retards the absorption of arsphenamine from the blood and at the same time reduces the arsenic content of the liver. Higgins and Murphy (11) state that in hemosiderosis iron is transferred directly from the Kupffer cells to the liver.

The Kupffer cells take a similar part in at least some phases of carbohydrate metabolism. Koster, Goldzieher and Collens (23) described changes indicative of enhanced functional activity in the Kupffer cells following administration of dextrose. Gaessler (24) showed that reticulo-endothelial block retards the utilization of injected lactic acid which normally is promptly taken up by the liver and transformed into sugar. *This is a specific instance of failure on the part of a precursor of glycogen to reach the liver in blocked animals.* Finally, Freund (25) found that preliminary fasting leads to increased deposition of in-

jected colloidal particles in the Kupffer cells, while an abundance of glycogen in the liver leads to lessened deposition of such particles in these cells. The last work is of great significance to us because it indicates that *the glycogen content of the liver is a determining factor in the absorptive activity of the Kupffer cells*, which according to our hypothesis furnish the liver with precursors of glycogen from the blood.

Starvation and reticulo-endothelial block have in common lowering of the blood-sugar, reduction in hepatic and muscle glycogen, diminished mobilization of blood-sugar following injections of epinephrine, and decreased threshold for the appearance of acetone bodies in the blood (26). Depletion of carbohydrates, common to both conditions, determines these similarities.

Starvation differs from block in causing decreased instead of increased tolerance to dextrose. This difference is explained by the fact that in starvation the organism is cut off from exogenous carbohydrates\*, but the liver has free access to the fat and protein stores of the body, with a resulting increase in gluconeogenesis which according to Soskin it is difficult to inhibit by administration of dextrose. In block, a normal food supply reaches the blood from the alimentary tract, but there is a partial barrier separating the liver from substances with which to manufacture sugar. Decreased gluconeogenesis which is readily inhibited by giving of dextrose is the result. This explanation is supported by our observation that block brings about an additional lowering of the blood-sugar in fasting rabbits (Chart VII). The additional lowering of the blood-sugar would probably be more marked in a species which, unlike the rabbit, does not have in its alimentary canal considerable amounts of food residues to draw upon even after remaining without food for three days. Our theory on the action of reticulo-endothelial block falls in with the experiments in the preceding papers of this series, showing the influence of hepatic changes on dextrose tolerance; and with those of Soskin, Allweiss and Cohn (27) which prove that the liver and not, as previously thought, the pancreas is essential to the metabolic reactions which determine the normal dextrose tolerance curve.

Can the conception of the Kupffer cells as a transmitting agent be applied to the metabolism of fats and proteins? A complete review of this subject is beyond the scope of the present paper. Moreover the all too frequent use of insufficient amounts of blocking substance, of toxic substances, and of insufficient numbers of animals precludes the possibility of ever fitting the mass of contradictory findings into one conception. However, our hypothesis is consistent with several recent investigations. Outstanding among these is the work of Leites showing that neutral fats and fatty acid are changed to cholesterol in the liver (28), and that reticulo-endothelial block decreases the amount of cholesterol in the blood which leaves the liver through the hepatic veins (29). Hypocholesterinemia in the systemic circulation after block was observed by Leites (30), by Klein and Levinson (2), and by Goebel and Gnoinski (31). Jaffé (11) demonstrated that the Kupffer cells may engulf large quantities of lipid from the blood-stream, and subsequently transfer it to the adjacent hepatic cells.

\*Decreased tolerance to dextrose does not depend on lack of nutrition *per se* because it also follows exclusive fat or protein diets.

In the realm of protein metabolism, Chrometzka (32) found that injections of India ink markedly interfere with the hepatic function of converting uric acid into allantoin in dogs. As would be expected, with depression of several functions of the liver due to shortage of materials for its "metabolic mill," the respiration of hepatic cells was found by Jungeblut and Berlot (33) to be markedly impaired after block.

Against the concept of reticulo-endothelium playing a distinct metabolic role, we wish to offer its histological appearance. The cells of this system possess so little cytoplasm that it is difficult to visualize them performing intracellular chemical transformations in the metabolism of carbohydrates, fats and proteins in addition to their functions of phagocytosis and formation of immune bodies.

There is little additional comment required by our experimental data. Since the effect of multiple injections

Fig. 1. Liver of a rabbit subjected to daily injections of 5 c.c. of India ink for 3 weeks. The section shows a great increase in the number and size of Kupfer cells. By focusing the microscope at different levels the black masses in the dilated sinusoids are seen to consist of up to 20 mononuclear cells. The cytoplasm of these cells is filled with carbon particles while the nucleus is usually pushed to the periphery. A number of multinucleated forms are observed. X 250.

tions of a blocking substance is in dispute, it is interesting to note that the curves representing utilization of dextrose and mobilization of blood-sugar after block (Charts II and V) indicate that the first few injections had a cumulative effect. Subsequent injections caused progressively diminishing changes. The explanation of this lies in increased proliferation of the reticulo-endothelial cells after block, described by Aschoff and others (34-37). Under such conditions, Derman (38) observed particularly active multiplication in the Kupfer cells of the liver, which we were able to confirm from our microscopic studies (see Figure 1).

The irregular response of rabbits to the dextrose and epinephrine tests after injections of India ink were discontinued has its parallel in a similar irregularity during recovery from experimental chloroform poisoning observed by one of us (T.L.A.) (6). The recovery from block is expressed by consistent changes in the morning blood-sugar which, at first, indicate increased hepatic activity and later a return to the level

maintained before the beginning of injections (Chart I). Temporary hyperfunction of organs recovering from injury or following a period of unusual activity associated with hypertrophy, is a well-known phenomenon.

The reduced tolerance to dextrose and increased mobilization of blood sugar after epinephrine in rabbits injected with India ink 30 minutes previously (see Chart IV) is another example of this. The higher than normal blood sugar curves in these animals are due to lessened inhibition of gluconeogenesis by dextrose because gluconeogenesis was more active 48 hours after the preceding injection due to hyperactivity of the regenerated Kupfer cells in supplying precursors of glycogen to the liver. This explanation is supported by the fact that the first 30 minute curves were not higher but lower than normal, because there was no preceding 48 hour injection.

### SUMMARY

Partial block of intravascular reticulo-endothelial cells causes lowering of the blood-sugar, increased tolerance to dextrose, decreased mobilization of blood-sugar by epinephrine and reduction in the glycogen content of the liver and muscles.

These findings are interpreted as indicating that one of the functions of the Kupfer cells is the transmission of precursors of glycogen from the blood stream to the liver. Block of these cells interferes with such a transfer and results in decreased gluconeogenesis and consequent internal deficiency of carbohydrates, which explains the observed abnormalities.

A review of available experimental data on the effects of reticulo-endothelial block in the metabolism of fats and proteins also suggests that this system acts as a transmitting agent of intermediary metabolites from the blood to the liver and perhaps to other organs rather than as a separate metabolic organ.

# DISCUSSION:

DR. LAY MARTIN (Baltimore, Md.): This paper, as you are well aware, is an extremely interesting one, especially, since the reticulo-endothelial system does not readily lend itself to investigation.

It is generally conceded that the reticulo-endothelial cells are strongly phagocytic and have much to do with the breakdown of hemoglobin into bilirubin, beyond this, there is little, if any, knowledge of their function. Dr. Althausen has well described the complex and uncertain state of conjecture that surrounds their other metabolic activities and I congratulate him, not only for his temerity in treading on this unpromising field, but also for his open minded attitude.

The Kupfer cells of the liver are bathed by serum in the hepatic sinusoids and it is difficult to see how there can be any direct passage from them to liver cells. Any product from them would be as apt to be swept into the general

circulation as into the hepatic cells. The question of direct transfer from these cells into hepatic cells is quite unproven physiologically and difficult to understand from their anatomical arrangement.

From the data presented, Dr. Althausen has drawn certain conclusions as to the rôle of the reticulo-endothelial system in carbohydrate metabolism. The data are collected from the results of sugar tolerance tests and epinephrine produced blood sugar responses in rabbits which had previously received repeated intravenous injections of India ink and graphite. The injections were made with the idea that the reticuloendothelial cells, once filled with the material, would be, in part or wholly, removed from normal functional activity.

My first criticism of the paper is in reference to control determinations. Little mention is made of them in the article and, judging from the figure, I take it that only one estimation of sugar tolerance and of epinephrine response was made on each animal. I feel it most important that as many tests be made before the intravenous injection of the blocking material as after. It seems likely to me that in this case, the controls might show the same variations as the test animals.

My second criticism centers on the question of the interpretation of the increased sugar tolerance and the decreased epinephrine response which are described.

When sugar is absorbed by the body, it may be disposed of in several ways.

- I. changed into glycogen in the liver or muscles;
- II. stored in the tissue fluids;
- III. oxidized;
- IV. excreted in the urine.

If there is any lowering of the ability of the body to handle sugar, it will at first accumulate in the blood. Dr. Althausen has presented no evidence that there is any increased storage of sugar in the tissue, nor that the oxidative processes are heightened nor that there is glucosuria. If the liver cannot change glucose to glycogen, it should pile up in the blood. If the reticulo-endothelial system is blocked and it is responsible for the transfer of glucose to the liver again, blood glucose should increase. However, according to Dr. Althausen's figures, it decreases. I do not see that Soskin's experiments to which Dr. Althausen refers, are germane to the points under discussion.

The figures show a decrease in epinephrine response which the investigator believes to be due to decreased liver and muscle glycogen; this decrease being secondary to lowered carbohydrate metabolism following the block of the reticulo-endothelial cells. As epinephrine causes a breakdown of muscle glycogen into lactic acid, there should be an increased amount of blood lactic acid. Furthermore, if Gaessler's interpretation of his own experiments are correct and the reticulo-endothelial cells also control the transfer of lactic acid to the hepatic cells, there should be an even greater increase of blood lactic acid. The present investigations do not attempt to go into this point but it seems to me worthy of study.

The authors figures on the determination of liver and muscle glycogen are worthy of consideration. You will note that in each instance there is a tremendous variation in the liver and muscle glycogen storage in both the control and test determinations.

As Dr. Althausen has mentioned, the work is still in its early stages and much remains to be determined in this very interesting field.

DR. RALPH C. BROWN (Chicago, Ill.): It seems to me that Dr. Althausen and his associates have presented some very interesting data in this paper. They have apparently shown that there is an increased sugar tolerance with a decreased response to epinephrine after the blocking of the reticulo-endothelial system with carbon pigment. As they and many other workers have pointed out, the individual variations in the response of the experimental animals and the opposite effects produced by small and large doses of blocking substances make interpretation of results difficult. Dr. Althausen has shown in some of his curves that, despite continued administration of the blocking substance, a return toward normal occurs, suggesting, perhaps, a proliferation of the reticulo-endothelial system more rapid than the block. It would have been interesting to have followed and correlated the histologic hyperplasia with the return of normal metabolic function. The very great proliferative capacity of the cells of the reticulo-endothelial system has been shown by Weiss and Sümegi of Buda Peste in their extensive series of experiments designed to demonstrate the rôle of the reticulo-endothelial system in the production of bilirubin.

This work adds further evidence to the steadily gaining conception of the importance of the rôle of the liver in carbohydrate metabolism. The work of Soskin and his associates with normal, depancreatized, and hepatectomized dogs has suggested that the form of the dextrose tolerance curve is in the main dependent upon the liver. They stress the importance of the regulatory mechanism whereby a certain level of hyperglycemia causes the liver to cease gluconeogenesis. It seems probable to these workers that a condition of high metabolic activity in the liver results in a less sensitive response, a failure on the part of the liver to cease gluconeogenesis, and a consequent high sugar tolerance curve. On the contrary, in a liver wherein the metabolic activity is proceeding slowly, the regulatory mechanism is sensitive, gluconeogenesis ceases promptly with even mild hyperglycemia, and a lowered sugar tolerance curve is obtained.

The correlation of this work with the present experiments is possible. An explanation in this light would imply the following possible train of events. As a result of the block of the reticulo-endothelial system, fewer precursors of glucose are available to the liver. The liver operates at a lower metabolic level than normal. As a consequence there is a low sugar tolerance curve. The authors have suggested that there is a glycogen debt in the tissues which is responsible for the low tolerance. They have shown this by glycogen determinations upon the muscles. It is possible, however, that this may not be the operating factor in depressing the tolerance curve since in those conditions where there is a marked depletion of muscle glycogen, such as the state following violent exercise, the tolerance curve is distinctly high.

The failure to respond fully to epinephrine following block, coupled with the low glycogen content of the liver make Dr. Althausen's suggestion that gluconeogenesis fails because of an insufficient supply of the precursors of glycogen very plausible. This blockade not only affects the precursors of glucose but, as the authors have stated, other substances such as chloroform, arsphenamine, and injected

lactic acid. Necessarily the suggestion that the Kupffer cells act as transfer agents in the liver can remain only a suggestion. It seems, however, that it is a very possible explanation of the phenomena which are observed.

The method of computing mean changes in the level of blood sugar will necessarily give rather crude approximations. With the many other variables which are almost impossible of control, however, it seems certain that the results are significant. The same criticism could be made of the methods of glycogen determination. In any experiment of this type the use of more control animals is highly desirable.

This work has further established the importance of the liver in the metabolism of the carbohydrates and in particular the importance of the reticulo-endothelial system in hepatic carbohydrate metabolism.

DR. T. L. ALTHAUSEN (San Francisco, Calif., in closing): I am afraid that Dr. Martin and I cannot at present compose our differences of opinion. Dr. Martin thinks that the Kupffer cells lie within closed capillaries of the liver. I believe with the German School that the Kupffer cells form a part of the endothelial wall of the sinusoids and, therefore, are in direct contact with the hepatic parenchyma. The Germans are so much impressed by the intimate relationship of the Kupffer cells with the hepatic cells proper that some of them speak of these two types of cells as forming a functional unit, the "hepaton." I don't want to go that far, but I do think that there is a close relationship between these structures, and I fail to see any difficulty in the transfer of substances from the Kupffer cells to the liver. Moreover, such a transfer as mentioned in our paper has been demonstrated by other workers to take place in regard to chloroform, arsphenamine, iron, and lactic acid.

The second question on which we seem to differ is the conditions governing gluconeogenesis. I am glad that Dr. Brown brought Soskin's work into this discussion, because on my way to this meeting I had a talk with Dr. Soskin, which brought us to the conclusion that his latest work in this field and the here reported experiments fit like pieces of a jig saw puzzle. According to Soskin's theory, gluconeogenesis from non-carbohydrate substances normally occurs in the liver. Administration of sugar tends to inhibit this gluconeogenesis. When this process is active, it is difficult to inhibit. When gluconeogenesis is proceeding at a slow rate, it is early inhibited.

Our finding of low blood sugar curves after the dextrose tolerance test in blocked animals we at first explained, solely by an increased sugar vacuum in the tissues, due to a deficiency of carbohydrate in the body. After learning of the latest work of Dr. Soskin, we agree with him that the low blood sugar curves are at least in part due to the fact that fewer precursors of glycogen reach the liver and that gluconeogenesis, therefore, is proceeding at a slow rate and is easily inhibited by administration of sugar.\*

As for controlling our experiments: The large number of curves obtained and our method of computing results by spreading the peak of the curve over the two or three hours of the experiment, eliminate to a large extent chance variations. The experiment with the carbo-free fractions of India ink also serves as a control.

\*After the meeting, Dr. A. C. Ivy informed Dr. Day that workers in his laboratory obtained low sugar tolerance curves in dogs with an Eck fistula. This is another case where fewer precursors of glycogen reach the liver due to diversion of the portal blood from the liver.

# Studies on Crystalline Vitamin B<sub>1</sub>: Observations in Diabetes\*

By

MARTIN G. VORHAUS, M.D.

ROBERT R. WILLIAMS, M.S.

and

ROBERT E. WATERMAN, B.S.

NEW YORK CITY, NEW YORK

## INTRODUCTION

FOR some time, there has been considerable speculation upon a possible relationship between the carbohydrate metabolism and a deficiency of vitamin B<sub>1</sub>. It has been observed that when a deficiency of any vitamin is induced experimentally in animals, there may be a concomitant disturbance in the utilization of carbohydrates. Some commentators hold that this is a non-specific effect; but the bulk of accumulating evidence (1, 2, 3, 4) indicates that the carbohydrate metabolism invariably is deranged to a marked extent in B<sub>1</sub> avitaminosis.

## PREVIOUS EXPERIMENTS IN ANIMALS

Abderhalden and his workers (5, 6) demonstrated a rise in the blood sugar and glycogen content of the liver and tissues in animals which had been deprived of vitamin B<sub>1</sub>. These aberrations of the carbohydrate metabolism were most marked at the beginning of the convulsive stage of the deficiency and could be intensified by a diet rich in carbohydrates. To prevent them, not only carbohydrates but protein and glycerin had to be eliminated from the diet. It was frequently possible to abolish convulsions in animals on the usual diet by the administration of small amounts of B<sub>1</sub>, such as 0.2 grams of dried yeast daily. When the diet was rich in carbohydrates, however, the addition of this amount of B<sub>1</sub> was not sufficient to prevent the appearance of convulsions. In general, adequate quantities of B<sub>1</sub>, in the form of dried yeast, resulted not only in the disappearance of symptoms but in the return of the blood sugar and glycogen levels to normal.

The influence of insulin in vitamin B<sub>1</sub> deficiency (7) has been remarked. Although Kauffmann-Cosla and his collaborators (8) at first believed that the action of insulin reproduced the effects of the vitamin in this condition, subsequently they found (9) that its only results were to modify the blood sugar and blood carbon dioxide levels. In spite of the administration of insulin, the typical manifestations of experimental beriberi continued to develop and their animals died; but they did not, at death, show the high blood sugar values usually found.

Working along somewhat different lines, Braier (10) demonstrated that dogs which had undergone hypophysectomy previously did not present the usual increase in blood sugar when brought to a state of vitamin B<sub>1</sub> deficiency. In this respect, these dogs showed a similarity to the insulin-treated animals.

Development of the B<sub>1</sub> deficiency state in animals is accompanied by a progressive and proportionate diminution in the carbohydrate tolerance (8). Large amounts of glucose in the diet modify the course of the deficiency state to the point where their intake is followed by severe toxic manifestations, convulsions and death (11).

## CHEMICAL OBSERVATIONS

In addition to experimental studies in animals which indicate a relationship between vitamin B<sub>1</sub> and the carbohydrate metabolism, some highly significant chemical observations have been reported. Peters and his collaborators noted certain striking dissimilarities between the tissues of normal pigeons and those deprived of vitamin B<sub>1</sub> (12). According to their experiments, minced brain tissue of the avitaminous animal *in vitro* has not so great a capacity to utilize oxygen as that of the normal: the oxygen take-up is less. Upon the addition of crystalline vitamin B<sub>1</sub> to the test tube, however, there was a significant increase in the oxygen take-up of the avitaminous tissue as compared with the normal. The addition of lactates known to be formed from glucose enhanced this effect, which reached its maximum at a pH of 7.3. Pyrophosphate and α-glycerophosphate produced a further increase; while cyanide and fluoride, on the other hand, abolished the augmented take-up of oxygen resulting from the vitamin B<sub>1</sub> crystals.

Further studies (13) indicated that this effect was independent of malnutrition since the capacity of minced brain from a normal pigeon to take up oxygen was not modified by the addition of crystalline vitamin B<sub>1</sub>. Experiments with the skeletal muscle, heart muscle and liver of the avitaminous pigeons failed to produce the effect *in vitro* noted in the minced brain (14); but the minced kidney tissue from the same animals, under the same conditions, did show a statistically significant increase in the oxygen take-up. No studies have been reported as yet of the effect of vitamin B<sub>1</sub> upon minced pancreatic tissue.

Careful chemical analysis (15) of the minced brain of the avitaminous pigeon demonstrated the presence of pyruvic acid, absent in the normal minced brain. This disappeared, concomitantly with the increased oxygen take-up, upon the addition of crystalline vitamin B<sub>1</sub>.

These workers conclude (16) that the state of vitamin B<sub>1</sub> deficiency is accompanied by derangement of the lactate system of cellular metabolism, at least in the brain and kidney cells, and that the addition of

crystalline vitamin B<sub>1</sub> to these tissues acts as a catalyst in the lactate pyrophosphate system.

#### ORIGINAL EXPERIMENTS

In the spring of 1934, the chemical studies of Williams, Waterman and others opened the way to clinical investigation of the relationship of vitamin B<sub>1</sub> to the carbohydrate metabolism by placing large amounts of crystalline vitamin B<sub>1</sub> at our disposal. It became pos-

sible to study the effects of the pure antineuritic component of the old vitamin B complex.

A group of eleven cases, proven diabetics according to present standards, was selected for study. There were ten adults, five males and five females, and one child, in various stages of the disease. All of these patients were hospitalized for a period of control observation and when they were as well stabilized as

possible the oral administration of vitamin B<sub>1</sub> was begun. The usual daily dosage was ten mgms., continued for twenty-eight consecutive days. Toward the end of this period, a highly potent concentrate of known B<sub>1</sub> content, proven by biological assay, was substituted in some of the cases for purposes of economy. The patients were kept under observation for some time after the administration of the vitamin was stopped, at first, in the hospital and, subsequently, by fol-

low-up study. Detailed reports of the individual cases follow.

increase in the utilization of carbohydrates was lost as soon as administration of the B<sub>1</sub> was stopped. Case III maintained the gain for two months after cessation of the vitamin. An increased utilization is still in evidence in case II (after five months) and in case I (after ten months). In case VI, there was a diminished intake of insulin while the vitamin was given and an increased utilization of carbohydrates thereafter during a follow-up period of six months.

low-up study. Detailed reports of the individual cases follow.

## RESULTS

It will be observed that six of the eleven cases (I, II, III, IV, V, VI) showed increased carbohydrate utilization of varying degree during the period of administration of the vitamin, as evidenced by the diminished blood sugar and urinary sugar. The remaining five cases (VII, VIII, IX, X, XI) failed to present any such phenomena, either during the administration of the vitamin or thereafter.

In two of the six favorable cases (IV and V), the

Since discontinuing the vitamin, the insulin requirement in this case has risen but not to the previous level.

One of the cases (III) showing an accelerated carbohydrate utilization died, subsequently, of uremia. Post mortem examination of the pancreas showed fatty infiltration and interstitial fibrosis.

Every student of diabetes understands the necessity for careful consideration of the effects of dietary restriction on the clinical course of this condition. This factor must be borne in mind in evaluating the results of the study presented herewith.

## PROTOCOLS

Case No. I: L. D., hospital No. 48362, colored male, age 37, a known diabetic for three years. Admitted to the hospital June 7, 1934, complaining of polyuria, polydipsia, loss of ten pounds during the last eight months, weakness, pruritus. He was treated by diet, without insulin. There was no history of diabetes in the family. The patient was born in the British West Indies but has lived in the United States for the past seventeen years.

*Physical examination* revealed a well developed, fairly well nourished patient. Except for large tonsils and some cervical adenopathy, no abnormal findings were noted.

*Laboratory findings:* Wassermann negative; hemoglobin 85%, r. b. c. 5,760,000, w. b. c. 4,600, normal differential; urea nitrogen 11.8 mgm.; creatinine 1.6 mgm.; cholesterol 216 mgm. The electrocardiograph was normal except for slight left axis deviation.

*Analysis*—This patient was stabilized readily. Within 48 hours after the vitamin was begun there was a noticeable and progressive drop in the blood sugar and urinary sugar. On the 7th day the vitamin was doubled. There was no change in the rate of decline. On the 17th day, the urine was free of sugar. Increasing the diet by 25 gms. of carbohydrate had no effect. After 27 days the vitamin was discontinued. Diet was increased up to full diet. There was a loss of 2 pounds during the administration of the vitamin. Patient was followed for 10 months after discharge on a full diet and without vitamin. During these 10 months he gained 17 pounds in weight, and at last observation the blood sugar was normal and the urine was free of sugar.

Case No. II: I. G., hospital No. 50105, white male, age 47, a known diabetic for two years. He was treated with insulin originally for a short time and was an active patient in the out-patient department, diabetic clinic, where he was treated by diet alone. Admitted to the hospital October 15, 1934, complaining of weakness and pain in the lower extremities, loss of fifteen pounds in the past four months, and general fatigue. There was no history of diabetes in the family.

*Physical examination* revealed a well nourished patient. The positive findings were emphysematous chest, slight cardiac enlargement, moderate thickening of the peripheral arteries and a smooth palpable liver one and one-half fingers' breadth below the costal margin. The oscillometric readings showed a diminished pulsation equally in both legs.

*Laboratory findings:* Wassermann negative; hemoglobin 95%, r. b. c. 5,152,000, w. b. c. 11,200, normal differential; urea nitrogen 16.6 mgm. creatinine 1.6 mgm. The electrocardiograph was normal except for low voltage.

*Analysis*—This patient became sugar free spontaneously. The diet was then increased by adding 50 gms. of carbohydrate. Following this, for 7 days he seemed fairly well stabilized. 15 gms. of protein were added. On the 14th day after admission the vitamin was started, in 6 mgm. doses for 4 days, and thereafter in 10 mgm. doses for 24 days. Immediately after starting the vitamin, the urine became free of sugar, and remained so except for 3 isolated days. The blood sugar varied slightly between 127 and 143. There was a loss of 6 pounds while taking the vitamin.

Patient has been followed for 5 months in the O. P. D. during which time his weight has been constant. There was a slight rise in the blood sugar four weeks after discharge, but thereafter blood sugar levels were comparable to that observed during his hospital period. At the last observation the blood sugar had risen to 160.

Case No. III: M. I., hospital No. 50152, white male, age 60, a known diabetic for over six years. He was treated with insulin constantly for the past three and a half years, taking about twenty units daily for the past five months. Admitted to the hospital October 18, 1934, complaining of severe pains in both legs and feet, numbness and tingling of the feet and toes, swelling of the ankles at night, morning cough, dyspnoea on moderate exertion, polyuria, dysuria and impaired vision. There was no history of diabetes in the family.

*Physical examination* revealed a sallow complexioned, obese, elderly patient, appearing older than stated age. The positive findings were bilateral *arcus senilis*, teeth missing, coated tongue, emphysematous lungs, enlarged heart with sounds of poor quality, A<sub>2</sub> loud and ringing, blood pressure 176/106, enlarged firm prostate, tortuous hardened arteries, and pitting oedema of both lower extremities. The oscillometric readings showed diminished pulsation, more marked in the left leg.

*Laboratory findings:* Wassermann negative; hemoglobin 65%, r. b. c. 4,000,000, w. b. c. 8,200, normal differential; urea nitrogen 43. mgm.; creatinine 3.3 mgm.; uric acid 5.1 mgm.; sedimentation time 42 mm. in 45 minutes. The electrocardiograph showed left axis deviation and noticeable Q.R.S.

Case No. III: M. I., readmitted to the hospital February 27, 1935, complaining of weakness, attacks of dizziness and syncope, cramp like pains in legs and loss of thirty pounds in the past two months.

*Physical examination* disclosed evidence of impending uremia and advanced arteriosclerosis.

*Laboratory findings:* Urine showed albumin ++, sugar — trace; urea nitrogen 57.6 mgm.; creatinine 5.6 mgm.; sugar 210 mgm.; uric acid 6.2 mgm.; cholesterol 230 mgm.

Death was due to uremia—March 9, 1935.

Only the body and tail of the pancreas were secured for *pathologic examination*. There was a large amount of fatty infiltration and a moderate degree of interstitial fibrosis.

Islets of Langerhans are seen microscopically; they have a somewhat disintegrated appearance, but are not greatly fibrosed. There is cystic dilatation of some of the ducts.

*Analysis*—This patient was stabilized only by reducing his insulin. On the 11th day, the blood sugar began to increase. The following day the vitamin was started, in 6 mgm. doses for 4 days, and then for 24 days in 10 mgm. daily doses. The urine sugar declined shortly after the administration of the vitamin, and thereafter fluctuated between 0 and 5½ gms. The blood sugar showed an irregular decline which was more marked after the 5 units of insulin was discontinued on 11/16/34. At the conclusion of the study, the blood sugar was 150 which was less than one-half of the level before beginning the vitamin, even though 5 units of insulin were being administered at that time.

The patient left against advice, and when re-admitted three months later in uremia, his blood sugar was 210, although he had had no insulin nor dietary supervision during those three months.

Case No. IV: J. K., hospital No. 50169, white male, age 52, a known diabetic for two years. Active in the out-patient department, diabetic clinic where he was treated by diet alone. Admitted to the hospital October 18, 1934, complaining of intermittent precordial pain, severe in nature, radiating up to the left shoulder, aggravated by exercise, dyspnoea, weakness and pains in both legs. One son died of diabetes.

*Physical examination* revealed a well nourished patient. The positive findings were cardiac enlargement to the left, sounds of fair quality, A<sub>2</sub> accentuated, blood pressure 130/74, liver one finger's breadth below the costal margin,

absent pulsations in popliteal, posterior tibial and dorsalis pedis arteries on both sides. The oscillographic readings showed markedly diminished pulsation in both lower extremities.

**Laboratory findings:** Wassermann negative; hemoglobin 90%, r. b. c. 5,250,000, w. b. c. 10,400, normal differential; urea nitrogen 15.4 mgm.; creatinine 1.5 mgm.; sedimentation time 17 mm. in 45 minutes. The electrocardiograph showed notched P, and P<sub>2</sub>, inverted P<sub>2</sub>, notched Q.R.S., low T, left axis deviation.

On the forty-third day of the study, the patient had an attack of acute coronary closure with typical pain, fall in blood pressure, friction rub and positive electrocardio-

graph. He remained in the hospital for six weeks and made a satisfactory recovery.

The patient was discharged January 15, 1935, weighing 134 pounds. Blood sugar 168 mgm., urine no sugar.

**Analysis**—This patient was not well stabilized. After 19 days of preliminary study and after an increase of 160 calories in his diet the vitamin was begun on November 7th. Within 3 days the sugar disappeared from the urine and remained absent except for 5 isolated days. The blood sugar increased slightly, fluctuating between 137 and 170. During the course of the vitamin administration the diet was increased by 25

gms. of carbohydrate, with little effect on the blood or urinary sugar. There was a loss of 2½ pounds during the period of vitamin administration.

On the 22nd day after the administration of the vitamin, the study was discontinued because of the occurrence of an acute coronary closure. During the

polyuria of six months duration, a loss of ten pounds in the last six months, generalized pruritus. She had been receiving ten units of insulin daily. There was no history of diabetes in the family.

Physical examination revealed a well nourished patient. No abnormal findings were noted.

treatment of this cardiac disease, carbohydrates were freely given.

He was discharged on January 15, 1935, and has been followed in the O. P. D. for 3½ months. During this time he has gained 10 pounds in weight, and his blood and urinary sugars are markedly higher than during the time of the vitamin administration.

Case No. V: T. K., hospital No. 51534, white female, age 43, a known diabetic for three months. Admitted February 4, 1935, complaining of polydipsia, polyphagia and

*Laboratory findings:* Wassermann negative; hemoglobin 85%, r. b. c. 4,640,000, w. b. c. 6,800, normal differential; basal metabolism minus five; sedimentation time normal; urea nitrogen 16 mgm.; creatinine 1.5 mgm.; uric acid 4.0 mgm.; cholesterol 288 mgm. The electrocardiograph showed slurred Q.R.S.s. and left axis deviation.

*Analysis*—This patient was fairly easily stabilized. After 11 days the vitamin was begun in 10 mgm. doses. There was an immediate drop in the urinary sugar output, to about ½ of the previous level. No

further decline in the urinary sugar was noted even though the vitamin intake was doubled after 14 days. The blood sugar declined very little. During the 11 days of observation the weight was constant. During the 28 days of vitamin administration there was a loss of 6½ pounds. After the vitamin was stopped, there was an immediate rise in the urine sugar to its former level, as well as in the blood sugar.

This patient has been followed in the O.P.D. for 6 weeks after discharge from the hospital. At her last observation the weight and urinary sugar and blood sugar were approximately at the same levels as upon admission.

Case No. VI: D. S., hospital No. 49281, white female, age 18, a known diabetic for ten years. Admitted to the hospital August 9, 1934, without any symptoms other than slight weakness. She had been receiving seventy-five units of insulin daily for several years. There was no history of diabetes in the family.

*Physical examination* revealed an obese patient with no abnormalities other than those resulting from her marked obesity.

*Laboratory findings:* Wassermann negative; hemoglobin 80%, r. b. c. 5,700,000, w. b. c. 16,900, poly. 68%, lymph. 30%, bas. 1%, metamyelocyte 1%; cholesterol 240 mgm.

*Analysis*—This patient was easily stabilized on her usual diet and usual intake of 75 units of insulin. On the 5th day, 20 mgms. of vitamin were administered. For the first 3 days a series of moderate hypoglycemic reactions occurred and the patient insisted upon reducing her insulin intake, even though there was only a slight decrease in the urine and blood sugar levels. On increasing the vitamin to 40 mgms. additional severe reactions occurred, and the patient rapidly reduced her insulin to 25 units, 1/3 of her previous level. Further increase of the vitamin intake to 90 mgms. daily was not attended with additional hypoglycemic reactions. The blood sugar level remained fairly constant during the study, but the urinary sugar output was 4-5 times larger than that before the vitamin was administered and the insulin was reduced. During the period of vitamin administration she lost 11 pounds in weight.

On discharge from the hospital on 9/15/35, she was maintaining her same diet with only 25 units of insulin. Follow up studies continued while this patient was away at college. Reports showed an increasing demand for insulin up to 60 units. During this time the weight increased to the level on admission to the hospital. The blood sugar levels were markedly downwards and the urine sugar was reported negative.

On April 5, while at college, a second course of vitamin therapy was instituted. 10 mgms. daily were given. A very similar series of events occurred during the second administration, as were noted during the first, namely: hypoglycemic reaction, a reduction of the insulin intake from 60 to 42 units, a doubling of the blood sugar, and a urinary sugar output of 91½ gms. (last report) although during all this time the diet remained identical.

Case No. VII: M. W., hospital No. 50199, white male, age 55, a known diabetic for three years. He has been receiving from 20 to 30 units of insulin daily for three years. Admitted to the hospital October 20, 1934, complaining of weakness, pains in the feet, coldness and loss of sensation in the feet, and attacks of fever, chills, pain and swelling of the right foot. There was no history of diabetes in the family.

*Physical examination* revealed a thin, pale, undernourished patient. Positive findings showed poor heart sounds, accentuated second aortic, liver enlarged one finger breadth below c.m., bilateral ptosis of the lids, absent k.j.'s and a.j.'s, equivocal left Babinski, suggestive Romberg, diminished sensation over both feet and legs up to the knees. Oscillometric readings show slightly diminished pulsations in both lower legs.

*Laboratory findings:* Blood and spinal Wassermann's negative, hb. 78%, r. b. c. 4,640,000, w. b. c. 7,600, differential normal; urea n. 21.6 m.g.m., creatinine 1.7 mgm., uric acid 3.4 mg. E.C.G. showed slurred Q.R.S., notched P, and left axis deviation.

*Analysis*—This patient was stabilized fairly readily. On the 7th day, 6 mgms. of vitamin were given and one week later was increased to 10 mgms. for 6 days, and then increased to 20 mgms. for 18 days more. Following the administration of the vitamin, there was a marked, although irregular increase in the urinary sugar output, which seemed to bear some relationship in time, to the increase in the amount of vitamin given. The blood sugar level increased somewhat, but not in proportion to the urinary sugar level. During the period of vitamin administration, he lost 5 pounds in weight. Upon discharge from the hospital, the blood sugar level increased, and he was finally placed upon insulin. He is still under observation in the O.P.D. and at last observation 5 months after discharge he was taking 60 units of insulin and had gained 8 pounds.

Although the studies reported in this communication are confined entirely to observations relating to the carbohydrate metabolism, the clinical picture of this patient underwent such a marked change immediately after receiving the vitamin, that it is worthy of recording. There was complete disappearance of the pain and paresthesia in both lower extremities, and the patient was able to walk easily without the use of a cane. This improvement was noted within the first week of the vitamin administration. It continued for two months after discharge. In the last 3 months there is a slight recurrence of pain.

Case No. VIII: P. D., hospital No. 50335, white female, age 6, a known diabetic for 2½ years. She has been receiving 40 units of insulin daily. Admitted to the hospital October 20, 1934, with no complaints. One maternal uncle has diabetes.

*Physical examination* revealed a well nourished young child who seems to be in good health. No abnormal findings were noted.

*Laboratory findings:* Wassermann and Kahn negative. Hg. 78%, r. b. c. 4,800,000; w. b. c. 9,800; differential normal, sedimentation time 4 mm. in 45 min., urea N. 15 mgm., creatinine 1.4; E.C.G. normal except for sinus arrhythmia.

*Analysis*—This patient could not be brought to a state of stabilization. After 12 days of preliminary observation, the vitamin was begun, at first in 2 mgm. doses (because of her age) and then in increasing doses up to 24 mgm. The period of vitamin intake covered 27 days. There was an increase in both urinary and blood sugars while taking the vitamin, but the increase was irregular. There was some suggestion of a relationship between vitamin increase and increase in urinary and blood sugar. Shortly after the vitamin was begun a questionable hypoglycemic reaction occurred with a low blood sugar. The insulin was reduced 5 units daily for 9 days and then increased 3 units for 11 days. There was little change in the levels

associated with the insulin variation. The patient lost 2 pounds during the experimental period.

No follow up studies have been possible in this patient, but reports by mail state that her condition is the same as when first seen.

Case No. IX: B. R., hospital No. 51244, white female, age 58, a known diabetic for over four years. She has been receiving insulin for the four years, taking 40 units daily. Admitted to the hospital January 11, 1935, com-

vitamin feeding. When the vitamin was stopped the urine and blood sugar levels remained unaltered, and since discharge for a period of 2 months follow up has shown very little change. There has been a gain of at least 6 pounds since discharge.

Case No. X: D. H., hospital No. 51241, white female, age 48, a known diabetic for over eight years. She has been taking 30 units of insulin per day for the past seven years. Admitted to the hospital on January 11, 1935, com-

plaining of polyuria, polydipsia, genital pruritis and generalized joint pains. One aunt has diabetes.

Physical examination revealed a slightly obese patient. No pertinent abnormal findings were noted.

Laboratory findings: Wassermann and Kahn negative. Hb. 85%, r. b. c. 5,240,000, w. b. c. 8,700, differential normal, urea N. 11.2, creatinine 1.4 mgm. cholesterol 300 mgm.; B.M.R. plus 21, E.C.G. showed inverted T 3, and left axis deviation.

Analysis—This patient was fairly well stabilized after 13 days of hospitalization. Following the administration of the vitamin, in 10 mgm. doses, there was little, if any change in either urine or blood sugar levels. Patient lost 7 pounds during the period of

plaining of slight weakness, and occasional nocturia. One brother and one sister have diabetes.

Physical examination revealed a well nourished patient. Positive findings showed poor heart sounds, pulse rate 58, blood pressure 92/56.

Laboratory findings: Wassermann and Kahn negative; hb. 75%, r. b. c. 4,640,000, w. b. c. 8,600, normal differential; sedimentation time normal; urea nit. 12.9 mgm., creatinine 1.5 mgm., cholesterol 242 mgm., B.M.R. minus 15, E.C.G. showed inverted and notched P<sub>2</sub>, inverted T<sub>2</sub> and left axis deviation.

Analysis—This patient was extremely difficult to stabilize. After 27 days of preliminary hospitalization the insulin was stopped and the vitamin begun. Very

little change was noted during the period of experimental study. The blood and urinary sugar levels increased. This increase occurred simultaneously with the withdrawal of the insulin, and appears to be in proportion to the amount of insulin withheld. After 28 days of vitamin administration, the vitamin was stopped. The patient was observed in the hospital for 9 days more and in the O. P. D. for almost 2 months.

for the past 4 years. Admitted to the hospital February 5, 1935, complaining of genital pruritis, precordial pain radiating to the left arm, dyspnoea, ankle oedema at night, polyuria, cramps in both legs at night. There is no history of diabetes in the family.

Physical examination revealed a slightly obese patient. Positive findings showed cardiac enlargement to the left, accentuated A<sub>2</sub>, blood pressure 156/90, thickened peripheral arteries.

vitamin B<sub>1</sub> was begun. For 28 days 10 mgms. first, and later 20 mgms. were administered daily. During this period of time no change in the blood or urine sugar levels was noted. The patient lost 6 pounds in weight during the time of the vitamin administration. She has been observed for about 6 weeks since dis-

worse at the time administration of the vitamin was begun. This was particularly true of those whose intake of insulin had been reduced.

The brevity of the interval between the administration of the vitamin and the lowering of the blood sugar and urinary sugar also argues for a causal relation-

charge from the hospital with practically no change in the urine or blood sugar level.

#### RECAPITULATION

Analyzing these cases, the conclusion is inescapable that there is a direct causal relationship between the intake of the vitamin and the subsequent drop in the blood sugar and glycosuria. The elements of coincidence and dietary control may be rejected since all of the cases were fairly well stabilized. As a matter of fact, several of the patients were definitely growing

ship. Usually, the drop took place within two or three days, never after more than seven. If this effect did not manifest itself in a very short time, it did not occur throughout the entire period of the experiment.

Complementing this observation is the rapidity with which the aberration returned in two of the cases, *i. e.*, the blood sugar and glycosuria increased, when the administration of B<sub>1</sub> was discontinued. All of this points to a causal rather than coincidental relationship be-

tween the ingestion of the vitamin and the increased utilization of carbohydrates.

Additional substantiation of this theory is furnished by some of the negative cases in which administration of the vitamin not only failed to increase the utilization of carbohydrates but was followed by an aggravation of the diabetic state. This result, although adverse, confirms the influence of vitamin B<sub>1</sub> on the carbohydrate tolerance.

Once we concede the causative relationship, the question arises as to the *nature of the interaction*. Previous experiments in animals indicate that B<sub>1</sub> acts as a catalyst. This hypothesis provides a plausible explanation of the rapidity of the reaction to the vitamin. It also accounts for the fact that once an effect appears, it is not heightened by augmenting the dosage. In other words, the reaction is at its maximum as soon as it is established, and an increase in the amount of the vitamin does not produce additional consequences. In one case, the quantity necessary to bring about a positive result was multiplied nine times without intensifying the effects. This is convincing evidence that we are dealing with a catalyst rather than with a substance like insulin whose influence is proportional to the amount used.

It is interesting to speculate on the character of the reaction in those negative cases which seemed worse after ingestion of the vitamin. Bearing in mind experiments in animals in which glycogen in the liver and muscles was broken up by the addition of B<sub>1</sub>, the possibility is suggested of some irreversible chemical reaction which arrests the catalytic function of the vitamin but permits it to flood the blood stream with available carbohydrate. This theory, admittedly mere conjecture, might account for the increase in blood sugar and urinary sugar in some of the negative cases when the vitamin intake was increased.

In the course of our investigation, a careful search of the literature was made to determine whether or not other work in this field had been described. In 1928, Mills (17) reported a study of seven diabetics to whom he had administered a crude acid alcohol extract of a variety of plants, which he believed to be rich in vitamin B<sub>1</sub>. All of his cases experienced a diminution in urinary sugar. In 1933, Labbe, *et al.* (18) published the results of administration of a vegetable powder, said to possess a high vitamin B<sub>1</sub> content, to twelve cases of diabetes. Nine of these showed beneficial results. Unfortunately, neither of these reports contains detailed observations and there is no indication of adequate controls.

Minot (19), in 1929, observed two cases of diabetes associated with peripheral neuritis and achylia gastrica whose symptoms improved slightly upon taking large amounts of a yeast concentrate. Wohl (20) also reports a case of diabetes, with symptoms of beriberi, whose diabetic and neuritic manifestations improved on insulin and yeast.

In previous studies of the effect of crude extracts, containing unknown quantities of vitamin B<sub>1</sub>, upon the clinical course of diabetes mellitus, although the number of cases investigated was small and results were questionable, benefits of varying degree were reported. Our group of eleven patients, observed over a period

of months under careful controls, showed an increased utilization of carbohydrates in 54.6% of the cases upon an average daily intake of ten mgms. of vitamin B<sub>1</sub> for four weeks.

The clinical syndrome of diabetes mellitus has many features of a nutritional disturbance whose etiology is not yet known. It has been suggested that a vitamin deficiency may be conducive to its incidence, and influence its clinical course. Proceeding on this hypothesis, there is evidence that vitamin B<sub>1</sub> may be the substance in question. In view of the results of experimental work in animals, of biochemical research, and the clinical studies reported herewith, it is urged that further investigations be conducted to determine the effects of large amounts of this vitamin in diabetes mellitus.

### SUMMARY AND CONCLUSIONS

1. Experimental deficiency of vitamin B<sub>1</sub> causes a disturbance of the carbohydrate metabolism characterized by a rise in the blood sugar and in the glycogen content of liver and muscle. Although a diminished carbohydrate tolerance is encountered in other forms of avitaminosis and aberration from the normal state, it is most consistent and marked in experimental B<sub>1</sub> deficiency.

2. The clinical syndrome of diabetes mellitus is suggestive of a nutritional disturbance and there is reason to think that a deficiency of vitamin B<sub>1</sub> may be a factor in the production and clinical course of this condition.

3. In a series of eleven cases of proven diabetes mellitus (according to present day standards) to whom an average of ten mgms. of vitamin B<sub>1</sub> were administered daily for twenty-eight consecutive days, six (or 54.6%) showed an increased carbohydrate utilization. Five cases (45.4%) showed no increase. Two of the six positive cases lost the gain in carbohydrate utilization as soon as the administration of vitamin B<sub>1</sub> was stopped. In four cases, the increase continued for periods ranging from two to ten months. Two of these four are still maintaining the gain.

4. Further study of this problem is merited.

### DISCUSSION:

DR. JOSEPH T. BEARDWOOD, JR. (Philadelphia, Pa.): Through the courtesy of Dr. Vorhaus, I was able to try this vitamin on three patients on my service at the Hospital of the Graduate School of the University of Pennsylvania. My experience, therefore, has been very limited and possibly the choice of cases not altogether so great as one might wish, but from these cases, the histories of which I will briefly detail, we fail to find very marked alteration in the carbohydrate metabolism which we would attribute to the action of the vitamin alone.

There were three cases in which we used the vitamin: First, a man of thirty-five, who had known that he had diabetes for about four years. He was admitted and placed on a 2100 caloric diet, consisting of 140 grams of carbohydrate, 70 grams of protein, and 140 of fat, and his blood sugar varied to 243 from 220, without insulin. He was placed on the vitamin for a period of ten days, at which time his blood sugars ran from 200 to 210, and we then placed him on insulin. He was standardized readily on 57 units a day, and on discharge he required 16 units a day.

The second was a case of a woman of fifty-three, also on a maintenance diet ran sugar between 112 and 160

without vitamin and over a period of ten days with the use of vitamin, the sugar varied between 144 and 153. She showed no urinary sugar at any time.

The third case was a case which had a blood sugar of about 145 to 150 on a normal maintenance diet. She had a B.M.R. of plus twenty and had some gall bladder disease. With the use of vitamin her blood sugar varied between 110 to 122. This was the only case which showed any marked change, that we felt could be attributed to the vitamin, although the blood sugar started to come down before vitamin was administered.

I should like to emphasize that on a maintenance diet, we normally often find a decrease in the blood sugar over a period of time. This drop sometimes may take ten days or two or three weeks before it is made manifest, but it does occur in practically all diabetics except severe ones, and we must bear this in mind in evaluating any method of treatment. The type of diet is of importance. We feel that the amount of carbohydrate in the diet, if it be high enough, has relatively little to do with the amount of insulin that is required; in other words, with the higher carbohydrate diet, it is probable that diabetics, none of whom are total diabetics, as experimental animals are, are stimulated to secrete a certain amount of insulin of their own, the most important thing is to keep the total calories relatively low.

It is interesting in Dr. Vorhaus' group of cases to notice the marked change in the urinary sugar which did not always keep pace with the blood sugar.

In analyzing his cases, they all showed relatively high blood cholesterol which, of course, is a common finding in uncontrolled diabetics, but it would be interesting to note any change in the blood cholesterol as the cases were followed, because from work of Rabinowitz, it is apparently the blood cholesterol which determines to some extent the amount of insulin required to control the diabetes.

The cases in which the vitamin was active in all these series were all rather stout and from the protocols of the cases, well nourished individuals. Those in whom the vitamin had little effect were thin and underweight, except in two cases.

The average thin diabetic is a severe diabetic. One would be justified in the conclusion that possibly there are several types of conditions which produce the syndrome of diabetes mellitus.

I am probably somewhat out of order when speaking to this Association, in saying that from recent work it is apparent that many cases of diabetes are not due to pancreatic disease. Metabolists feel that the number of cases of diabetes which are due to actual demonstrable diseases of the pancreas is relatively small, and it would seem logical, therefore, that if further work by Dr. Vorhaus and others show any consistent effect of the vitamin or carbohydrate metabolism that vitamin deficiency might be one factor which would produce a syndrome of diabetes mellitus. Dr. Vorhaus has been modest in his claims and I think the work merits further investigation and further report.

DR. J. EARL THOMAS (Philadelphia, Pa.): Dr. Vorhaus' paper deals with two quite distinct problems: namely, the relation between vitamin B<sub>1</sub> and carbohydrate metab-

olism; and the possible relation between Vitamin B<sub>1</sub> and diabetes mellitus.

The relationship between the vitamin and normal carbohydrate metabolism appears to be a fairly well established fact; whether that is the primary function of the vitamin in metabolism is another question, but there doesn't seem to be any doubt that deficiency of vitamin B<sub>1</sub> results in an excess of blood sugar and an excess of liver glycogen.

Considering diabetes, although there is an increase in blood sugar, there is a deficiency of liver glycogen, whereas the opposite condition develops in vitamin B deficiency. The deficiency of liver glycogen in diabetes is well known to biochemists and physiologists, and I assume also to members of the medical profession.

There is a very close and intimate relationship between all the different metabolic processes that go on in the body, and the mere fact that the administration of a vitamin in a particular disease condition improves the condition of the patient and causes an alleviation of the symptoms, doesn't in itself establish any relationship between that vitamin and the disease in question.

Now, it seems logical to suppose that many diabetics suffer from vitamin B deficiency. Vitamin B occurs mostly in cereals. Diabetics have a restricted carbohydrate diet, and unless their diet is watched carefully to see that there is a sufficiency of the vitamin, Vitamin B is likely to be deficient. Deficiency of vitamin B would almost certainly aggravate the symptoms of diabetes. It might even cause a latent diabetes to become active. If that should occur, the administration of vitamin B would unquestionably alleviate the condition to some extent though it would not cure the disease; however, such an observation would not establish a causative relationship between vitamin B deficiency and diabetes.

The most logical conclusion that I can draw from these most interesting and valuable studies is that vitamin B deficiency is likely to be an accompaniment of diabetes, and in the treatment of diabetes such condition should be looked for and, if present, treated appropriately.

DR. MARTIN G. VORHAUS (New York City, in closing): I want to take this opportunity to thank the discussants, particularly Dr. Beardwood for his efforts in studying some of these cases. It has been interesting to speculate on the points brought up; namely, as Dr. Thomas so well put it, whether or not the relationship is coincidental in diabetes, or causative.

In a small series of cases which we have shown, no definite deductions can be made. The future may answer the question.

Dr. Beardwood's observation is in accordance with ours, that perhaps some of the milder cases of so-called diabetes according to the present-day standards may turn out not to be diabetes mellitus as we understand it, but that the diabetic manifestations may be signs of a vitamin B<sub>1</sub> deficiency. That question cannot be answered at the present time.

It is significant that in a certain percentage the patients show some improvement based on chemical studies, and in addition there is an improvement in the general state, which may be either non-specific or specific.

The question of blood cholesterol is being studied, but for such a short length of time that reports have not been included in the study.

## Gastro-Intestinal Manifestations of Hyperinsulinism \*

By

SEALE HARRIS, M.D.  
BIRMINGHAM, ALABAMA

**H**YPOGLYCEMIC symptoms are found not infrequently in patients who suffer from the various manifestations of disorders of the stomach and other abdominal viscera. This is particularly true of patients ordinarily classed as neurotics, who go from one specialist to another for relief of "nervous indigestion." Hyperinsulinism has been found associated with peptic ulcer and gall bladder disease in a number of cases; and it may be a manifestation of both acute and chronic pancreatitis, and adenomas of the pancreas, so that the patient with a proved abdominal lesion may suffer also from the bizarre manifestations of hypoglycemia. Careful history taking in gastro-intestinal patients will elicit the information that in many of them the symptoms occur most frequently before breakfast, one or two hours before meals, and during the night. Blood sugar studies during the attacks, or when fasting, and dextrose tolerance tests carried out for six hours will reveal not infrequently the hypoglycemia that is the *sine qua non* in the diagnosis of hyperinsulinism, which may be relieved or prevented by the proper dietary management.

Cambridge, (1) in one of the most valuable contributions to the literature on "chronic hypoglycemia," reported 200 cases in which blood sugar readings of below 0.070 per cent were found. Cambridge said: "Comparatively few cases of hypoglycemia are free from gastro-intestinal disorders; long-standing constipation is common, but frequent and offensive stools are not unusual, especially in children; and some patients have distension, flatulency and heart-burn." Cambridge believes that there is an etiologic relation between inflammatory lesions of the upper intestines and "chronic hypoglycemia." He said: "Since a chronic catarrh of the upper intestines is generally associated with an infection of the bile and pancreatic ducts, the consequent disturbance of the liver and pancreas may contribute to the low blood sugar in that type of case." He adds: "I find that patients with chronic hypogly-

cemia do not improve satisfactorily unless the bowel condition is successfully treated."

Cambridge's study of his 200 cases revealed that 32 children in whom "cyclic vomiting" was a manifestation of hypoglycemia, 84 per cent had "chronic catarrh of the intestinal tract." Thirteen of his adult patients complained of severe recurrent attacks of "bilious" vomiting, including 6 cases of pernicious vomiting of pregnancy. There were "recurrent headaches" in 25 cases; and in the 11 cases he classified as "neurasthenia," "all suffered from intestinal disturbance." Seven of Cambridge's hypoglycemics had "convulsive attacks, 4 of which were believed to have mild epilepsy." In the cases in which "lack of energy" was the principal complaint, "75 per cent had evidences of infection in the upper part of the abdomen." Twenty-two cases of "chronic hypoglycemia" were found in patients who had been rejected for life insurance on account of sugar in the urine; and in "75 per cent of these there were evidences of intestinal trouble."

Cambridge found 48 patients with abnormally low blood sugars during the course of routine examinations. Of these "the majority had obscure disturbances of digestion or metabolism." Six were obese; 4 had gall bladder disease; 2, pernicious anemia; 1, cancer of the pancreas; and in 1 child there was delayed development. Cambridge's analysis of his 200 cases of "chronic hypoglycemia" proves the value of routine blood sugar studies on gastro-intestinal patients.

Cambridge (2) in another article on the chronic hypoglycemia as an operative risk said: "Several chronic hypoglycemics had previously been operated upon for duodenal ulcer with unsatisfactory results. In others the removal of the appendix was followed by serious vomiting and ketoses which were relieved by intravenous injections of glucose."

There were symptoms referable to the gastro-intestinal tract in 18 of the 25 cases of "hypoglycemia" which Sippe and Bostock (3) of Brisbane, Australia, reported in 1933. The following is a brief review of the gastro-intestinal symptoms in the 18 cases reported by Sippe and Bostock:

\*Read before the 38th Annual Session of American Gastro-Enterological Association, Atlantic City, New Jersey, June 10, 1935.  
Approved by the Publications' Committee of the Association.

Case 1. Woman, aged 31 years. "Sick feeling accompanied by prostration." Blood sugar 0.062 per cent. Relieved by dieting.

Case 2. Female, aged 26 years. Headaches, relieved by taking food. Blood sugar 0.068 per cent. Symptoms relieved by dieting.

Case 4. Female, aged 35 years. Recurring attacks of severe vomiting, accompanied by "tight feeling around abdomen." Fasting blood sugar 0.080 per cent. Relieved by frequent feedings.

Case 5. Male, aged 33 years. "Feeling as if stomach were gripped by a knot" preceding attacks of unconsciousness, which came on when stomach was empty. Blood sugar 0.079 per cent. Improved by dieting.

Case 7. Male, aged 27 years. Epileptiform convulsions accompanied by intermittent vomiting. Blood sugar 0.077 per cent. Symptoms controlled by dieting.

Case 8. Severe pains in right iliac fossa, accompanied by hysteria. No abdominal rigidity. Pain was relieved by taking food. Blood sugar 0.069 per cent.

Case 9. Female, aged 37 years. Recurring headaches, relieved by taking food; but symptoms accentuated when patient eats "rich" foods. Fasting blood sugar 0.052 per cent. Much improved by dieting.

Case 10. Female, aged 19 years. Sudden severe headaches, followed by dizziness coming on before breakfast. Fasting blood sugar 0.052 per cent. Patient improved, but not completely restored to health, by giving glucose between meals.

Case 11. Male, aged 30 years. Recurring bilious attacks. Gastric discomfort, vomiting, headaches. Fasting blood sugar 0.063 per cent. Patient lost sight of, and results from treatment not known.

Case 13. Female, aged 32 years. History of severe vomiting of pregnancy. Attacks of unconsciousness and vomiting. Not related to meals. Fasting blood sugar at the time of an attack was 0.068 per cent. No attacks since glucose given between meals.

Case 14. Female, aged 37 years. "Forced to eat often to relieve frightful empty feeling." Could work for 2 hours then be "knocked out" and lie down. Could go back to work after eating. Fasting blood sugar 0.077 per cent. Much improved by taking glucose between meals.

Case 15. Female, aged 35 years. Intense hunger, following attacks of weakness, nervousness, and trembling. Relieved by taking food. Fasting blood sugar 0.081 per cent. Symptoms relieved. Can do a full day's work by taking barley sugar between meals.

Case 16. Female, aged 52 years. "Uncanny, hollow feeling" and marked weakness when fasting, relieved by food. Smothering sensation. Fasting blood sugar 0.065 per cent. Improved but not entirely relieved by dieting.

Case 17. Female, aged 36 years. Complaint: "Awakens at 4:00 A. M. every morning with an empty feeling. A headache then commenced, and increased until food was taken when it gradually disappeared. History of "bilious attacks." Fasting blood sugar 0.063 per cent. Frequent feedings. Orange juice and glucose at bedtime. No recurrence of symptoms.

Case 18. Female, aged 25 years. Complaint: Feels tired on awakening, but is relieved by eating breakfast. After working for an hour or two feels faint and has become unconscious on several occasions. Precordial distress, worse after exertion. Fasting blood sugar 0.070 per cent. Result of treatment not given.

Case 21. Female, aged 22 years. Complaint: Emotional depression, nervousness, irritability, epileptiform convulsions. Diagnosis of dementia precox considered. Anorexia, periodic vomiting, with low food intake considered cause of hypoglycemia. Fasting blood sugar 0.082 per cent. Frequent feedings relieved symptoms for a year when patient stopped dieting and symptoms returned.

Case 23. Female, aged 11 years. Complaint: Bilious attacks, vomiting and prostration coming on early in the

morning. Relieved by being given glucose between meals and increased carbohydrate diet. Blood sugar not given.

Case 25. Female, aged 21 years. Complaint: Migrainous headaches once a week. Recurring "bilious vomiting." "Glucose tolerance test showed a low curve." Headaches less frequent and less severe. General condition much improved one year after treatment.

The class of patient as reported by Sippe and Bos-tock is seen frequently by gastro-enterologists. These two Australian clinicians estimate that hypoglycemia is as frequent as the opposite condition, diabetes mellitus, in which hyperglycemia is a manifestation. In their general practice the percentage of hypoglycemia was 0.47 and that of diabetes 0.51.

Moore, O'Ferrell and Mariority (4), of Dublin, Ireland, reported a case of severe hyperinsulinism in which they attributed the hypoglycemia as partly due to "faulty amylaceous digestion":

A woman, aged 27, poorly nourished, was brought into the hospital in semi-conscious state; the following morning she was completely unconscious, limbs rigid, positive bilateral Babinski. Her blood sugar was 0.035 per cent. Ten grams of glucose were injected intravenously. Immediately afterwards she became quite conscious and rational. Had frequent dizzy spells, and always felt better after eating. Examination of her stomach contents showed an achlor-hydrin, and repeated examinations of her feces showed much undigested starch. The patient was much improved by diet.

Maxwell (5), an English physician, reports an unusual type of hyperinsulinism:

A female, aged 22, who about an hour after meals had a peculiar "sinking feeling in abdomen as if she were hungry." She then felt faint, and trembled. The patient associated the attacks with eating, and though she felt hungry, was afraid to eat. Her fasting blood sugar was 0.095 per cent. In half an hour after the ingestion of 50 grams of glucose her blood sugar was 0.116, succeeded by a sharp fall to 0.065 at the end of an hour, at the time when her symptoms usually appeared. At the end of two hours her blood sugar had risen to 0.097. The symptoms in this patient were controlled by eating barley sugar or chocolate as soon as the premonitory symptoms appeared. The drop in blood sugar one hour after the ingestion of glucose in a carbohydrate tolerance test is unusual, but several other similar cases of hyperinsulinism have been reported.

A very excellent review of reported cases of hyperinsulinism and hypoglycemia was made by Wauchope (6) in the English "Quarterly Review." Wauchope's article is a valuable contribution to the literature on a subject that seems to be of world interest to the medical profession.

#### FRENCH, GERMAN, AND ITALIAN CASES

Several cases of hyperinsulinism in which there have been gastro-intestinal manifestations have been reported by the French. Labbé (7), reported a case which he called "alimentary hypoglycemia":

A woman, aged 38 years, experienced abdominal pain after meals at which time there were muscular weakness, vertigo and intense hunger, which persisted for half an hour to disappear spontaneously. The patient, thinking that eating brought on the pain, ate sparingly and lost 26 pounds in two years. In this case the ingestion of carbohydrate paradoxically reduced blood sugar when her symptoms appeared, then there was a spontaneous rise in blood sugar and the hypoglycemic symptoms were relieved. Her recorded fasting blood sugar was 0.115 per cent, but in one hour after the ingestion of 50 grams of glucose fell to 0.046 per cent.

A number of other French clinicians have given excellent descriptions of their cases of hyperinsulinism. The interest of the French in hyperinsulinism is shown by the fact that the first book on the subject, "La Hypoglycémie," was written by a Frenchman, Jean Sigwald (8). In this excellent monograph of 300 pages Sigwald reviews the literature on hyperinsulinism and hypoglycemia and reports his studies on experimental hypoglycemic states induced by giving laboratory animals varying doses of insulin.

German clinicians likewise have reported a number of cases of hyperinsulinism in which there were gastro-intestinal manifestations; and some of the most important contributions to the literature on this recently recognized disease entity have been published in German medical journals. Indeed, one of the most comprehensive papers that has been published on hyperinsulinism was by Rosenberg (9) of Berlin. Krause (10), another German, made a thorough study of one case in which abdominal pain was associated with recurring attacks of unconsciousness. A diagnosis of an insuloma was made, but operation was refused. Another thoroughly studied case of hyperinsulinism was reported by Frank (11), the pathological report of which was prepared by Tërbrucken. This case, one of multiple islet adenomas, was similar in many respects to the classical case reported by Wilder, Allen and their associates (12) in 1927.

Reports of cases of hyperinsulinism and a number of excellent articles on the subject have appeared in medical journals of many other countries. A few of these cases having gastro-intestinal manifestations will be reviewed.

Theohara and Angelesco (13) of Italy reported the case of a man 27 years of age with a history of 5 years of gradually increasing severity of the symptoms which they described as follows:

"The illness started slowly with epigastric heaviness and eructation after meals, eased by the horizontal position. Later, the patient experienced epigastric emptiness which developed into ravenous hunger before meals, and great agitation—desire to pace the floor, had difficulty to fix his attention on his work—finally unable to add sums. The patient devours his food, the act of eating is a violent impulse. These crises before meals are of variable intensity. If the patient is quiet or isolated, the attacks are milder, at times almost unnoticeable. But as the attacks hinder him at his work, the patient decided to go to the clinic for treatment."

Glycemia: Determined several times in the morning on empty stomach: 0.060; 0.083; 0.075; 0.068 per cent.

Diagnosis: Crises of bulimia with agitation. Moderate hypoglycemia.

Treatment: Regime—meat once a day, vegetables, fruit, milk, predominance of macaronis, rice and pastry. Alkaline bromide, and belladonna 0.01 grain 2-4 times per day.

The patient has not had attacks in the clinic. When he was discharged from the clinic, he continued the belladonna at home, alternating it with suprarenal capsular extract."

Guido Lami (14), another Italian physician, reports an interesting case of "functional hyperinsulinism":

"A macaroni maker, aged 20, gave a history of never having felt a sense of satiety even after heavy meals. His diet consisted largely of macaroni and bread of which he ate 2250 grams a day, but his hunger was never satisfied. When his stomach is empty, he feels cramp like epigastric pains from which he gets relief by eating. Frequently he has to get up at night to eat for the relief of abdominal pain. His fasting blood sugar readings were 0.035 and 0.042 per cent. He also had a severe attack of urticaria.

He was relieved by dieting, peptone 1 gram doses and gluconate of calcium endovenously on alternating days for the relief of the urticaria."

Federico Peco (15), in Santiago de Chili, reported 3 cases of mild hyperinsulinism in a medical journal published in Spain. One patient, a woman aged 23, who had to take food 10 to 12 times a day to prevent attacks of "faintness." Another patient, a merchant, age 42 years, had attacks of unconsciousness during the morning. He had observed that if he ate a good breakfast the attacks did not occur. The attacks had been coming on almost daily for a year. "An alimentary regimen rich in carbohydrates was sufficient to make the crises disappear." Peco's third case was a writer, age 26 years, who had observed that following an attack of "flu" he had a faint, weak feeling a few minutes before eating, especially if his meals were delayed. He became unconscious at a dance. His friends believed him drunk and carried him home. After taking a cup of sweetened coffee, he felt perfectly well and assured his friends that he had not been drinking. The patient had no recurrence of symptoms on a diet rich in carbohydrates and with the use of epinephrine.

Maranos (16) called attention to the fact that acidosis may occur in hypoglycemia as well as in hyperglycemia (diabetes mellitus). The gastro-intestinal symptoms of acidosis which he describes as having occurred in his patients with hypoglycemia are loss of appetite, vomiting and diarrhea. Cammidge likewise called attention to the fact that acetone, diacetic acid and glycosuria may be found in patients who have hypoglycemia.

#### RUSSIAN CASES

It is interesting to note that while cases of hyperinsulinism have been reported in nearly all the European nations, and a number of cases have been reported in Central and South America, the only country in the world, except the United States (about 40 cases) and Canada (1 case), in which surgery has been resorted to for the relief of hyperinsulinism has been Russia. Federoff (17) in Metchinkoff's Clinic in Leningard has performed one partial resection of the pancreas—the patient, an obese boy 16 years of age died—and an exploratory operation, finding in the latter case an inoperable tumor of the caudal end of the pancreas. It is also interesting to note in studying the literature on hyperinsulinism in the medical journals of many countries that all over the world progressive physicians are practicing the same kind of scientific medicine as in the United States. It is pleasing to note that physicians in every country in reporting cases of, or in reviewing the literature on, hyperinsulinism are familiar with the work that has been done on this recently recognized disease entity by American clinicians.

One of the Russian cases operated on by Federoff should be of interest to gastro-enterologists:

A physician, aged 40. The earliest symptom was pain in the region of the stomach; and like a number of American cases of hyperinsulinism, it was first diagnosed ulcer of the stomach. An operation was performed but no ulcer was found. There is no record of an examination of the pancreas at the first operation. A gastro-enterostomy and an appendectomy were performed with only temporary benefit. The abdominal pain continued and in addition there were attacks of fainting preceded by numbness of the tongue and profuse sweating. The attacks recurred generally before meals and were relieved by eating. The patient found that the attacks could be prevented by eating

Case 1—Fig. 1

sugar, and he always carried a lump of sugar to prevent or relieve the attacks. The pains increased in intensity and there was a sense of heaviness in the stomach after meals. The blood sugar rose to 0.282 per cent in one-half hour after taking glucose, and then fell rapidly to 0.055 per cent when the patient complained of a sensation of suffocation, then sweating and trembling. In another half hour the patient became comatose, when the blood sugar level was 0.027 per cent. After administering 15 grams of glucose intravenously, consciousness returned when the blood sugar had risen to 0.065 per cent. An exploratory laparotomy revealed an enlarged hard pancreas with a tumor of the caudal end reaching to the right lobe of the liver. The report does not state how long the patient lived after the operation, but adds that the autopsy showed a large tumor of the tail of the pancreas, cancerous nodes in the omentum and an enlarged liver, presumably from metastases.

#### ABDOMINAL SYMPTOMS IN AUTHOR'S REPORTED CASES

It is not possible to review the literature of all of the many cases of hyperinsulinism in which there were gastro-intestinal manifestations as reported by American clinicians; but brief reports of a few personal cases, in which there have been abdominal symptoms, will present some of the problems incident to the diagnosis and treatment of hyperinsulinism that may interest gastro-enterologists.

In the October (1934) number of this Journal in an article on "Clinical Types of Hyperinsulinism" (18) I reported 15 cases. A brief review of some of the cases reported in that article will bring out some of the prominent abdominal symptoms of hyperinsulinism:

Case 1. Hypoglycemic symptoms, i.e., extreme hunger, weakness, nervousness and profuse perspiration in addition to recurring attacks of abdominal pains. Undoubtedly chronic cholecystitis (non-visualization of the gall bladder Graham-Cole test). Tenderness over pancreas, chronic pancreatitis suspected. Low blood sugar, 0.050 per cent. Hyperinsulinism symptoms controlled by dieting, but has occasional attacks referable to the gall bladder and pancreas. Operation refused.

Case 2. A case of proved duodenal ulcer in addition to hypoglycemic symptoms. Blood sugar 0.060 per cent. Both the ulcer and the hyperinsulinism were relieved promptly by dieting. No symptoms for 3 years.

Case 3. Hyperinsulinism with ulcer symptoms. Sent in with diagnosis of duodenal ulcer because of abdominal discomfort between meals, relieved by taking food. No filling defect in duodenum on X-ray examination. Achlorhydria. Blood sugar, 0.060 per cent, 4, 5, and 6 hours

Fig. 1. A. Blood sugar curve in dextrose tolerance test. At the end of 4 hours when blood sugar level fell to 0.040 per cent, he became very dizzy and weak, fearing fainting. Pulse rate, 40. He felt better after lying down, and his blood sugar rose within an hour to 0.066 per cent, in 2 hours to 0.092 per cent when symptoms were relieved without taking food.

after taking food. Symptoms relieved by taking food between meals and the use of dilute hydrochloric acid (1 oz. or 4 c.c.) mixed with milk at meals and 3 hours after meals.

Case 4. Paroxysmal tachycardia with pains and soreness in the upper part of abdomen. Normal fasting blood sugar (0.100 per cent); but in one attack when pulse was about 200 she complained of "gas on stomach pressing around heart"; her blood sugar was 0.056 per cent. Relieved in a few minutes from taking 50 grams of glucose. A dextrose tolerance test showed low readings, 0.060 per cent at the end of 5 hours. Has been much improved on a low carbohydrate, high fat diet with feedings between meals, though she has had an occasional paroxysm of tachycardia.

Case 5. Hysterical attacks in a woman 56 years of age, who complained of hunger, numbness, tachycardia, (gas in stomach pressing on heart), gaseous eructations 2 or 3 hours after breakfast. Insomnia—gets up to eat several times a night. In her dextrose tolerance test at the end of 5 hours when her blood sugar fell to 0.048 per cent, she had a hysterical attack, which was relieved by taking a glass of malted milk. Symptoms prevented by dietary management and patient was in good health when last heard from a year after having begun treatment.

Case 6. Hyperinsulinism and neuro-circulatory asthenia in a woman who complained of nervousness and weakness between meals. In 1923 she had symptoms of a duodenal ulcer and was improved by rest and ulcer diet. Her abdominal discomfort and weakness began 2 hours after meals when her blood sugar fell to 0.070 per cent. Five hours after a dextrose tolerance test her blood sugar was 0.048 per cent. Frequent feedings of a low carbohydrate, high fat diet relieved her.

Case 7. Hyperinsulinism induced by reducing diet. This case illustrates the dangers of reducing without the direction of a physician. A woman reduced 75 pounds in a year and became very irritable, nervous, emotionally unstable, and actually psychotic, having had delusions of persecution. She also had upper abdominal pains. She was relieved by frequent feedings. No symptoms in 3 years.

Case 8. Hyperinsulinism and recurring attacks of abdominal pains and unconsciousness. Referred with diagnosis of gall stones or peptic ulcer. History of taking 15 or 20 glasses of coca-cola a day. Had been operated upon for appendicitis following an attack. Low glucose tolerance curve, 0.070 per cent after 2 hours and at 6 and 7 hours blood sugar was 0.050 per cent. On a low carbohydrate, high fat diet he has had no abdominal pain or unconscious attack in 3 years.

Case 10. Dysinsulinism associated with abdominal pain and tenderness in upper part of abdomen, nausea, vomiting and a low grade fever, followed pelvic infection 6 months

Case 2—Fig. 2

Fig. 2. A. Dextrose tolerance curve. Note: When blood sugar dropped to 0.060 per cent, she was so weak that she had to go to bed. She complained of palpitation and tachycardia. Test was continued for one hour longer and at the end of five hours blood sugar was 0.050 per cent when the tolerance test was discontinued. She was relieved in a few minutes by taking a glass of malted milk.

previously. Fasting blood sugar 0.062 per cent, at which time her pulse rate was 108, and she was quite uncomfortable. She received almost immediate relief and her pulse rate fell to 72 from taking 100 grams of dextrose. Her dextrose tolerance curve was distinctly diabetic, having risen to 0.200 per cent in 3 hours after the ingestion of the dextrose. A diagnosis of sub-acute pancreatitis was made. She was improved by rest and frequent feedings.

Case 11. Dysinsulinism associated with recurring attacks of pain and tenderness over the pancreas, nausea and vomiting. Appendix had been removed 2 years before without relief of symptoms. Had "spells" of weakness and fainting before breakfast and when stomach is empty, relieved by eating. Her fasting blood sugar was 0.060 per cent. One hour after dextrose it rose to 0.200 per cent and then fell to 0.050 per cent 5 hours later. Dietary management for 5 months gave no relief. Resection of the pancreas resulted in a clinical cure—no symptoms in more than a year.

Case 12. Hyperinsulinism and epilepsy apparently resulting from trauma of the pancreas. Following an abdominal injury, after a month in bed suffering from pain, nausea and vomiting, a high school girl began having epileptic attacks. The convulsions now occur only during menstruation. In a dextrose tolerance test when her blood sugar fell to 0.050 per cent, she had a light epileptic convulsion. She had no attacks for several months, but gave up dieting and her attacks have recurred.

Case 13. Narcolepsy and recurring attacks of abdominal pain. Appendix had been removed without relief a year before. Fasting blood sugar was 0.050 per cent. Hypoglycemic symptoms, including abdominal pain, were controlled while in the hospital, but he could not carry out diet properly at home, and the symptoms recurred. He therefore was operated upon with complete relief of symptoms for 3 years. Glucose tolerance test 2 years after operation was normal.

#### ADDITIONAL CASES WITH GASTRO-INTESTINAL SYMPTOMS

The following reports of additional cases hitherto unpublished present symptoms and syndromes that may be involved in making a diagnosis of hyperinsulinism:

*Hyperinsulinism and "Nervous Indigestion."* Case No. 1. August 14, 1934. Formerly merchant, now on government relief roll. Age 44. Height 6 feet. Weight 154 pounds.

*Symptoms:* Attacks of gaseous eructations, dyspnoea, nervousness, twitching of muscles of hands and face.

Fig. 4. Dextrose tolerance test. Note: At the end of 4 hours when the patient's blood sugar was 0.060 per cent, he complained of hunger and weakness and felt as if he would faint. He was so uncomfortable that the test was concluded at the end of 4 hours. Was given a glass of malted milk and obtained relief from symptoms in a few minutes.

Fig. 3. A. Dextrose tolerance test.

When hungry he has pains in abdomen, is nauseated and sometimes vomits. Feels better after eating. If he misses a meal, he becomes weak and prostrated. Constipation. At times his mind becomes "inactive" so that he cannot work. Physical examination, negative. About 3 hours after breakfast, while waiting in the clinic office for examination, he became very weak, complained of "gas on stomach," and hunger. His blood sugar at that time was 0.058 per cent. He was relieved in a few minutes from taking a glass of malted milk.

*Treatment:* On a low fat, high carbohydrate diet with food 3, 4, and 5 hours after meals has been quite comfortable and able to do some work. Improvement has continued for 8 months, though on account of financial conditions he has not been able to get proper food at all times.

*Comment:* This patient had been examined by a number of physicians, some of whom had told him there was nothing the matter with him, and others diagnosed his case as hysteria. An over-dose of insulin (induced hyperinsulinism) in one of our patients caused a drop in pulse rate to 40 when his blood sugar fell to 0.055 per cent. Since this man's pulse rate dropped to 40 when his blood sugar fell to 0.040 per cent, it appears that spontaneous hyperinsulinism may be one of the causes of bradycardia.

*Hyperinsulinism, Abdominal Pains, Hunger Spells and Psycho-neurasthenia.* Case No. 2. April 18, 1932. Housewife. Age 38. Height, 5 feet 3 inches. Weight, 148 pounds.

*Symptoms:* Fatiguability and weakness; becomes exhausted from slightest exertion. Nervousness, trembling, profuse perspiration—"hunger spells"—relieved by taking glass of milk or other food. Abdominal pains and backache. Constipation. Symptoms more pronounced during menstruation. Twenty pounds underweight. Occasional trace of sugar in urine. She was given barium with malted milk for gastro-intestinal series. When she returned for the six hour examination, she was very weak, nervous and pale. On fluoroscopic examination her heart was observed to be beating rapidly, 96 per minute. A blood sugar at that time was 0.050 per cent. Gastric analysis showed total acidity of 30 and free hydrochloric acid, 20. Blood pressure 126 over 82. Her basal metabolic rate was plus 12 per cent. Wassermann, negative.

*Treatment:* Was very much improved by rest and frequent feedings. Marked tendency to obesity. Is regarded as a potential diabetic.

*Comment:* This patient came for relief of symptoms which she attributed to "indigestion." The hypoglycemic symptoms were so pronounced during an X-ray gastro-intestinal series, six hours after the barium and malted milk, that a blood sugar test was made and found to be 0.050 per cent. She was then given a glass of malted milk, and the nervousness and weakness subsided in a few minutes. The next day she was given a dextrose tolerance test which con-

Case 5—Fig. 5

firmed the diagnosis of hyperinsulinism. We have had a number of other cases in which during the fasting period of a gastro-intestinal X-ray study the patients complained of weakness, nervousness and tachycardia five or six hours after the morning barium and malted milk meal. Blood sugar tests proved that the symptoms were due to hypoglycemia. If gastro-enterologists and roentgenologists will question patients regarding their suggestive symptoms during the X-ray examination, they may find the clue for the diagnosis and treatment that will relieve the patient.

*Hyperinsulinism, Ulcer Symptoms, Nervousness and Insomnia.* Case No. 3. January 1, 1927. Rural mail carrier. Age 26. Height, 5 feet 8½ inches. Weight, 153½ pounds.

*Symptoms:* Heartburn, eructations of gas and sour liquids. Abdominal pain occurring 3 hours after eating and relieved by food. Nervousness. Gastric analysis showed total acidity 25, free hydrochloric acid 10. No occult blood in stools. X-ray examination showed orthotonic stomach with no filling defect but slightly irregular duodenal cap. No residue in stomach six hours after barium meal. Case considered suspicious at that time of duodenal ulcer and hyperinsulinism was not suspected. Patient returned on May 24, 1932, with much the same symptoms but complained particularly of nervousness and restlessness. Dreaded for night to come because of insomnia. Tires easily and complained of weakness and trembling at times.

*Treatment:* On a moderately low carbohydrate, moderately high fat diet with frequent feedings during the day, food at bedtime and every 3 hours when awake at night the patient's symptoms were relieved.

*Comment:* In this case the ulcer symptoms were pronounced and there was a filling defect in the duodenum before the hypoglycemic symptoms were pronounced. The irregular duodenal cap probably was not due to a lesion but to a spasticity probably from the nervous irritability resulting from the hypoglycemia. It is difficult to differentiate between hyperinsulinism and duodenal ulcer from the symptoms alone. A hypoglycemic curve as in this case may decide the diagnosis but it should be remembered that patients may have duodenal ulcer and hyperinsulinism.

*Hyperinsulinism Associated with Gastric Neurosis and Syphilis.* Case No. 4. March 23, 1932. Baker. Age 44. Height, 5 feet 7 inches. Weight, 116 pounds.

*Symptoms:* Frequent attacks, 20 or more in a month, of dizziness, mental lapses and tight feeling in chest, smothering sensation, difficult breathing, palpitation, gaseous distention, "gas pressing on heart," abdominal discomfort. Attacks usually occur between 11 and 12 o'clock in the morning and at about 5 o'clock in afternoons. Feels better after eating. Gastric analysis showed total acidity of 50, free hydrochloric acid of 40. X-ray showed a hypo-

Fig. 5. Dextrose tolerance test.

tonic stomach with no filling defect but the duodenum did not fill regularly and there was 15 per cent residue in the stomach 6 hours after the barium meal. Routine blood Wassermann was 4 plus. A repeated test the following day was also 4 plus and the Kahn test was positive. He denied an initial lesion or any history of syphilis. Fasting blood sugar was 0.080 per cent. Basal metabolic rate was plus 3. Blood pressure 112 systolic over 65 diastolic.

*Treatment:* Patient was placed on a low fat, high carbohydrate diet with frequent feedings between meals and when awake at night. Was given arsphenamine and bismuth (Kixel-Moore treatment for syphilis) by his home physician. The hypoglycemic symptoms were relieved almost immediately by dieting and 2 years later he states that he had had no recurrences of his hypoglycemic symptoms.

*Comment:* In this case a routine Wassermann in a patient without luetic history was positive. The diagnosis of syphilis was confirmed by repeated Wassermann and Kahn tests. The fasting blood sugar was the low normal but the symptoms were so suggestive of hypoglycemia that a glucose tolerance test was made, and it showed unquestionably hypoglycemia. The fact that the gastric and cardiac neuroses were relieved by dieting seemed to prove that the syphilis had nothing to do with the hypoglycemia.

*Hyperinsulinism and Psycho-neurasthenia with Gastric Symptoms:* Case No. 5. February 16, 1932. Housewife. Age 32. Height, 5 feet 5 inches. Weight, 132 pounds.

*Symptoms:* Duration 8 years. Five years ago was in bed for almost a year because of varied gastro-intestinal and nervous symptoms. Has no energy. Dreads work. Excessive hunger associated with nervousness and weakness. Feels normal after meals. Eats frequently in order to work. Has had varied digestive symptoms including abdominal pains, choking sensation, sour stomach. Symptoms more pronounced from work like sewing.

*Treatment:* Greatly improved on low carbohydrate diet with orange juice or tomato juice every hour between meals and frequent rest periods during the day. Fasting blood sugar 0.068 per cent, January 26, 1933, after one year's dieting; and in June, 1935, fasting blood sugar was 0.075 per cent.

*Comment:* This is a pronounced case of psycho-neurasthenia with gastric neuroses. She was almost a confirmed invalid when the treatment was begun. She has had 3 years of comparative comfort on a diet consisting largely of fruits, 5 and 10 per cent vegetables, meat once a day and a slice of bread with meals, with frequent feedings intended to maintain blood sugar levels within normal limits. Rest also played an important part in keeping this patient comfortable. In making dextrose tolerance tests we have observed several patients when the blood sugar level fell to 0.060 per cent or lower, hypoglycemic symptoms developed that subsided on lying down.

Case 6—Fig. 6

Fig. 6. A. Blood sugar curve in dextrose tolerance test.

*Hyperinsulinism and Psychasthenia.* Case No. 6. December 29, 1934. Teacher, unmarried. Age 54. Height, 5 feet 8 inches. Weight, 139 pounds.

*Symptoms:* Extreme fatigability. Feels well on arising but 2 or 3 hours after breakfast becomes extremely tired. Feels better after luncheon but about 3 P. M. becomes exhausted mentally and physically. Feels better after supper but is unable to concentrate her mind to read or study at night. Has a heavy uncomfortable feeling in abdomen, sometimes actual pain, in the upper left quadrant 2 or 3 hours after meals. She was referred because of gastric symptoms.

*Treatment and Results:* A low carbohydrate, high fat diet with feedings every 2 hours between meals and until bedtime gave almost immediate relief. She has had no gastric or psychasthenic symptoms in 5 months. She says that she feels like a different person.

*Comment:* The mental depression, abdominal discomfort and inability to work from 3 hours after meals and until after the next meal; and the euphoria for 3 hours after meals, when blood sugar levels are within the normal range parallel one of Powell's cases of a child who, when her blood sugar levels were within the normal range, learned readily, and for the 2 or 3 hours before noon meals and in the afternoon when the child could not learn the blood sugars were below 0.060 per cent. The dramatic results in this case of simple dieting has transformed a teacher into an efficient happy woman, whereas she had been miserable and in failing health, as she thought, for a year previous.

*Hyperinsulinism, Headaches and Gall Bladder Symptoms.* Case No. 7. July 15, 1932. Housewife. Age 36. Height, 5 feet 6 inches. Weight, 142 pounds.

*Symptoms:* Pain in epigastrium, extending to the left side of the abdomen, and weak spells about 11 A. M. and 4 or 5 P. M. and at night about 1 or 2 A. M. Discomfort and pain continues and is unable to get back to sleep for the rest of the night. Also complains of pains and soreness in shoulders and arms. The pain is not relieved by eating—feels better when stomach is empty and pain is worse from eating solid food. Eructates food after meals and occasionally vomits. She feels well for weeks at the time and usually has the spells in the spring and fall. Fatiguability, irregular menstruation, nervous headaches, more frequent during menstruation. Her case had been diagnosed as gall bladder trouble and an operation had been advised by her local surgeon. Her brother had been operated on a few weeks before for gall bladder trouble and died following the operation. The physical examination was practically negative except the general tenderness

Fig. 7. Dextrose tolerance curve.

over the abdomen, more in right and left lower quadrants. Her urine, blood and feces were normal. Wassermann negative, basal metabolic rate plus 1.9 per cent. Gastric analysis showed total acidity of 110, free hydrochloric acid 70 one hour after the Ewald test meal. The X-ray showed a hypotonic stomach, no filling defects in stomach or duodenum. Duodenum slow in emptying. Graham-Cole test showed normal gall bladder which was slow in emptying.

*Blood sugar findings:* August 15, 1932, 10 A. M., 0.060 per cent and 4 P. M. 0.060 per cent. The following morning her fasting blood sugar at 8:30 was 0.060 per cent and at 10 A. M., 0.055 per cent. A dextrose tolerance test was not made because she could not remain in Birmingham long enough.

*Treatment:* On a relatively low carbohydrate, high fat diet her headaches, abdominal pains and other symptoms subsided. Letters from her stated that she was very much improved.

*Comment:* This patient came to this Clinic after diagnosis had been made of gall bladder disease and an operation advised. Her brother had been operated upon for gall bladder trouble a few weeks previously and had died following the operation. She came to us for advice as to whether or not she should have the operation. The Graham-Cole test showed a practically normal gall bladder that emptied slowly. There was hyperchlorhydria but no evidence of ulcer. Apparently her symptoms were caused by hypoglycemia, because she was relieved by a low carbohydrate, high fat diet with frequent feedings. The periodicity of symptoms, with euphoria for weeks at a time, followed by periods in which her symptoms came on at about 11 A. M., 4 P. M. and 5 P. M. and 1 or 2 P. M. suggested an ulcer. The patient was not placed on an ulcer diet but was given frequent feedings and the symptoms subsided. Apparently her pain and attacks of weakness were due to the hypoglycemia of hyperinsulinism.

*Abdominal Pain in Hyperinsulinism with Glycosuria. Potential Diabetic.* Case No. 8. March 3, 1933. Student nurse. Age, 22. Height, 5 feet 5 inches. Weight, 135 pounds. (Referred because sugar found in urine).

*Symptoms:* Weakness, nervousness, irritability, dizziness ("staggers") and mental lapses 3 or 4 hours after meals. Trembles, perspires, has difficult breathing, and becomes very pale in attacks. Relieved in a few minutes after eating. Abdominal pains between meals and at night. Relieved by taking orange juice or other food. Had similar but more severe attacks in 1928 when 3 or 4 times she fell and became unconscious when stomach was empty. Is excessively hungry before meals. When she sees food and has to wait her turn in hospital cafeteria, she becomes very weak, and on one occasion became unconscious.

Fig. 8. A. Dextrose tolerance test May 22, 1935, (Folin-Wu Method). At the end of 4 hours when blood sugar was 0.035 per cent, had typical insulin reaction—prostration, marked weakness, nervousness, trembling, sweating and extreme hunger—asked that test be stopped and food given him, but agreed to continue it. After rest and dozing in a chair, in 1 hour blood sugar had risen to 0.050 per cent and in 2 hours to 0.100 per cent—2 plus sugar in urine 2 hours after luncheon.

Case 9—Fig. 8

Case 10—Fig. 9

**Treatment:** On a weighted and measured diet, 120 Ch., 75 P., and 180 F., with orange juice or tomato juice and cream every 1 or 2 hours between meals and until bedtime all her symptoms were relieved. She has had no symptoms for 2 years. The fats were reduced as symptoms subsided.

**Comment:** In spite of admonitions against overeating this patient is becoming obese. She is regarded as a potential diabetic. Glycosuria is seen frequently in hyperinsulinism. Twenty-five per cent of Cambridge's 200 cases of "chronic hypoglycemia" had glycosuria. May not the so called "low renal threshold" be of pancreatic origin?

**Dysinsulinism with Abdominal Pain and Diarrhoea.** Case No. 9. May 22, 1935. Physician. Age, 42. Height, 5 feet 3½ inches. Weight, 146 pounds.

**Symptoms:** About 3 hours after eating becomes faint, weak, restless, irritable, has a sensation of extreme hunger, trembles and is in profuse perspiration. Has aching and soreness in the abdomen ("low grade colic"). Obtains immediate relief from eating. If food is delayed 5 or 6 hours, he has almost total collapse, but obtains relief very quickly after eating. Symptoms exaggerated after taking soluble carbohydrates. Has "hungry pain," a feeling of pylorospasm, on awakening in the morning, from which he gets immediate relief by eating. Extreme fatigability. Has abdominal cramps and diarrhoea after the ingestion of fats. Glycosuria in afternoons but none in mornings. Has precordial pain and dyspnoea on exertion at anytime. Symptoms have grown progressively worse. Has been in hospital twice—once for 5 weeks and at another time for 1 week. Is improved by rest, but symptoms recur on returning to work.

**B. Dextrose tolerance test (Schaffee-Harman-Samogyi Method)** Barnes Hospital, February 20, 1935.

**Treatment:** Patient hospitalized and is comfortable on a diet of 120 C., 60 P., 120 F. with food every 2 hours between meals. Because of the rapid course and increasing severity in symptoms so that this patient is a semi-invalid, an adenoma of the pancreas is suspected. An operation will be advised if improvement does not continue.

**Recurring Attacks of Headache, Vomiting and Unconsciousness Due to Brain Tumor Involving Hypophysis.** Case No. 10. September 27, 1934. Teacher. Age, 39. Height, 5 feet 8 inches. Weight, 138 pounds.

**Symptoms:** Following an attack of what was called flu, patient had attacks of drowsiness and slurring of speech late in the afternoons. Two or 3 months later he began having attacks of headaches, vomiting and unconsciousness during which time he was very restless but had no convulsions. Intervals of euphoria between attacks. Physical Examination: Negative. Blood count, normal. Wassermann, negative. Ophthalmoscopic examination revealed choked discs in the right and left eye with few small hemorrhages around and over the discs. Vision normal on June 25, 1934. In October, 1934, vision was 25—50 plus. Stereoscopic film of skull showed marked broadening of the sella tursica. Diagnosis of brain tumor involving the hypophysis was made.

**Comment:** Even though this patient had a brain tumor involving the hypophysis, on low carbohydrate,

Fig. 9. A. Dextrose tolerance test September 28, 1934. B. Dextrose tolerance test 3 months after being on low carbohydrate, high fat diet.

high fat diet with frequent feedings between meals, his hypoglycemic symptoms were relieved temporarily. After a few weeks his headaches became more intense and patient was in stupor at times. Operation for brain tumor urged, but refused. He died at his home in the country. No autopsy; but the choked discs, enlarged sella tursica shown in skull picture, the headaches, vomiting and unconscious attacks make certain the diagnosis of a tumor involving the hypophysis.

### OBESITY AND HYPERINSULINISM

Wilder (19), who with his associates, Allen and Robertson (12), reported the first case of convulsions and unconsciousness due to hyperinsulinism, and who proved the pathological basis for this new disease entity, in a valuable summary of the present knowledge of hyperinsulinism states that gastro-intestinal symptoms are "fairly frequent"; and he mentions "flatulency, epigastric burning and constipation. Two patients were operated on for undiscovered ulcers. One had gall stones."

Wilder mentions Winans' (20) two cases of obesity in which the first symptom of hyperinsulinism followed efforts at reduction of weight by dieting. My first case of dysinsulinism reported in 1924 was an obese woman who had diabetes and her first hypoglycemic symptoms followed marked restriction in her food to control the diabetes. My first 2 cases reported in 1923 (21) was in an article on the etiology of diabetes in which the suggestion was made that the hunger and the overeating associated with hyperinsulinism may be the cause of the obesity which is so frequent in diabetes. Wilder cites Winans as sharing Falta's opinion that "overstimulation of the pancreas may lead primarily to obesity and later to diabetes." Wilder also mentions that "in several instances a diabetic state of metabolism has come first and hypoglycemia later," mentioning the case of "a woman 40 years of age who formerly required large doses of insulin to control glycosuria and now presents the clinical picture of hyperinsulinism, with blood sugar as low as 40 mg. for each 100 c.c."

### HUNGER IN HYPERINSULINISM

The hunger and the abdominal discomfort that are frequently but not invariably associated with hyperinsulinism, induced from overdoses of insulin or that occurs spontaneously in non-diabetics in some cases, may be accounted for by the gastric peristalsis which usually accompanies a falling blood sugar—not necessarily associated with hypoglycemia (John) (22). Graham (23) states that in hyperinsulinism the sensation of hunger may be extreme or agonizing. Graham cites Carlson and his associates as having shown that "hypoglycemia is associated with violent contractions of the stomach." Wilder (19) says that "a feeling of intense hunger is usually but not always present." He cites Quigley, Johnson and Solomon (24) as accounting for the hunger in hyperinsulinism by excessive gastric peristalsis, but adds that Heinz and Palmer (25) have found that gastric mobility from hypoglycemia is frequently absent in man. Wilder also cites LaBarre and Destree (26) as having found that "hypoglycemia of about 75 mg. in each 100 c.c. provoked gastric contrac-

tions, whereas with still lower depressions, about 45 mgs. in each 100 c.c. gastric atony developed." My clinical experience seems to confirm the last statement, because in the mild type of hyperinsulinism, with blood sugar readings from 0.075 to 0.050 per cent, the hunger and gastric distress are more severe than in the most severe cases in which there are lower blood sugar readings. In the latter cases, as Wilder (19) has pointed out, occasionally there has been a disgust for food, and sometimes actual sitophobia, because the patient erroneously regards the attacks as being due to eating.

#### THE VALUE OF ROUTINE BLOOD SUGAR STUDIES ON GASTRO-INTESTINAL PATIENTS

Routine Wassermanns and routine examination of the urine and feces are accepted procedures in the examination of every patient who consults a gastro-enterologist. The high incidence of hyperinsulinism, or chronic hypoglycemia, in gastro-intestinal patients as reported by clinicians all over the world indicates that routine blood sugar studies on patients who complain of symptoms referable to gastro-intestinal and other abdominal diseases may in some cases give the gastro-enterologist information that will be helpful in prescribing diets and other remedial measures which may relieve or cure the sufferer of his complaints.

This new disease entity may simulate peptic ulcer, irritable colon, cholecystitis, appendicitis, pancreatitis, and particularly the group of cases now classified as neuroses of the stomach, intestines and other abdominal viscera. Certainly in some cases in order to differentiate between gastro-intestinal, gall bladder diseases, or other intra-abdominal disease or functional disturbances and hyperinsulinism, blood studies are necessary. Even when there is a positive diagnosis of an intra-abdominal lesion, hyperinsulinism may exist as a complicating factor which may be the cause of some of the most disagreeable symptoms of which the patient complains.

It adds but little to the laboratory work of the gastro-enterologist to make routine blood sugar studies on every patient whom he examines. The technician can get enough blood for a blood sugar determination when a venepuncture is made for the Wassermann and Kahn tests. It is best to obtain such specimens before breakfast on the second day of the examination; and if indicated, enough additional blood may be drawn from the vein for calcium, non-protein nitrogen, urea, and creatinin determinations. Cammidge (2) says that "accurate determinations of blood sugar may be made in less than half an hour by the micro-method from a finger prick."

A low fasting blood sugar suggests, but is not proof of, hyperinsulinism, because hypoglycemia may also be due to dysfunction of the liver or the pituitary, thyroid and adrenal glands. It, therefore, is necessary to exclude disease, or disorder, of the liver and the endocrine glands before assuming that the hypoglycemia found in any case is due to the hyperactivity of the internal secretory glands (islands of Langerhans) of the pancreas.

The diagnosis of hyperinsulinism may be suspected, or even assumed, in the patient who complains of weakness, nervousness, anxiety, trembling, sweating and inability to concentrate on work one or two hours before meals; symptoms that are relieved by eating

only to recur when the stomach is empty; but the diagnosis is confirmed only by finding hypoglycemia at the time when the symptoms occur, i.e., the fourth, fifth, or sixth hour of a glucose tolerance test. Occasional cases have been observed when low blood sugar readings are found in the second and third hours of the glucose tolerance tests, but there may be no abnormally low blood sugar readings until the fifth or sixth hours. Four hours is sufficiently long to carry out a glucose tolerance test for diabetes; but in a suspected case of hyperinsulinism, the tests should be made hourly for six hours. Sometimes the hypoglycemic symptoms may be reproduced during the glucose tolerance test. If so, in order to relieve the symptoms, it may be best to give the patient food.

A low fasting blood sugar obtained in the routine examination of a patient may be the clue for making a six hour glucose tolerance test that will prove hypoglycemia as the cause of some or all the gastro-intestinal symptoms of which the patient complains. It, therefore, seems that routine fasting blood sugars are of as much value in the diagnosis of gastro-intestinal cases as are Wassermanns or the routine examination of the urine and feces.

Already gastro-enterologists, more than other medical specialists, are finding cases of hyperinsulinism; and since the mild and moderately severe types of hyperinsulinism usually can be relieved by dietary management, it is important to use routinely a simple laboratory procedure that will remove many cases from the realm of the make-shift diagnosis of gastro-intestinal neuroses to the domain of an accurately determined and well known disease entity that usually is amenable to treatment.

#### CONCLUSIONS

1. Reports of cases of hyperinsulinism by clinicians in many countries show that the gastro-intestinal manifestations of this new disease entity are protean and important.

2. Abdominal pain between meals and during attacks of unconsciousness has been pronounced in several reported cases so that a number of hyperinsulinism patients have been subjected to needless operations in which an erroneous diagnosis of appendicitis, duodenal ulcer or cholecystitis had been made.

3. Hyperinsulinism has occurred frequently in patients who have had proved abdominal lesions, including duodenal ulcer, cholecystitis, pancreatitis and tumors of the islands of Langerhans.

4. Dietary management usually controls, or cures, hyperinsulinism in intelligent, cooperative patients.

5. Resections of the pancreas and the removal of insulomas have produced clinical cures in hyperinsulinism patients who were not relieved by dietary management.

6. Fasting blood sugar studies, dextrose tolerance tests, and glycemia determinations during attacks in gastro-intestinal patients, particularly those who think they have "nervous indigestion," may reveal hypoglycemia as the underlying factor in many cases.

## DISCUSSION:

DR. JULIUS FRIEDENWALD (Baltimore, Md.): Great credit is due Seale Harris who, as early as 1923, recognized hyperinsulinism as a distinct disease entity and pointed out that symptoms identical with those noted in diabetes from overdoses of insulin occurred in non-diabetics as well. Since then, numerous important observations concerning this condition have been recorded in which to a large measure the work of Seale Harris has played an important rôle.

He has pointed out 3 types of hyperinsulin, the mild, moderately severe and severe forms, ranging from mild symptoms of a nervous character often classed as forms of anxiety neuroses to extreme prostration—with short periods of unconsciousness, lapses of memory, irritability and finally to prolonged and recurrent attacks of unconsciousness and even convulsive seizures.

Among these symptoms those relating to the digestive tract play an important part. It is not uncommon to observe for example hyperinsulinism mimicking the symptoms of so-called ulcer, chronic gastritis, cholecystitis, nervous indigestion and even mucous colitis.

In the ulcer type of hyperinsulinism hunger pains followed by the relief from food is frequent. In some instances a definite epigastric painful area may even be present. The symptoms are not, however, always entirely typical of ulcer. Physical weakness and nervous symptoms are usually prominent and the Roentgen-ray signs of ulcer are absent as is likewise the presence of occult blood in the stools. However, actual duodenal ulceration may occur in association with hyperinsulinism. Harris has reported such instances and we have had a similar experience.

In those instances in which hyperinsulinism simulates chronic cholecystitis the attacks of weakness and sweating occur on an empty stomach and are relieved by food; and in addition are associated with recurrent abdominal pain in the gall bladder region with tenderness in this area. As a rule but little or no direct evidence of cholecystitis can be

discovered; but occasionally a definite associated lesion in the form of gall stones may be demonstrated.

In a single instance of chronic alcoholic gastritis a high degree of hyperinsulinism was noted on arising in the morning previous to and subsequent to such symptoms as nausea, excessive vomiting in association with weakness, faintness, tremor and nervousness, which was entirely overcome as soon as food could be retained.

Certain types of so-called gastrointestinal neuroses may likewise be due to an underlying hitherto undetected hyperinsulinism. The symptoms of excessive weakness, bulimia, tachycardia together with abdominal distention, fullness and aerophagia, so common in these cases are not infrequently associated with spastic colitis and other functional digestive upsets. The fasting blood sugar may be extremely low and proper dietetic regulation is usually followed by entire relief.

In some instances of hyperinsulinism definite chronic pancreatitis may be demonstrated by means of a study of the pancreatic secretion obtained through the duodenal tube, while in others pancreatic tumors have been shown to occur. It may be of interest to note that in a series of experiments on dogs in which sugar metabolism and blood studies were made following vagotomy, Feldman, Samuel Morrison and I observed that symptoms of hyperinsulinism, especially in the form of nausea and vomiting were more apt to manifest themselves following the administration of insulin than in non-vagotomized animals.

In conclusion, the impression gained from the observations of Seale Harris and others is that in all instances in which gastrointestinal symptoms are prominent when associated with those commonly manifested in hyperinsulinism even though these be quite mild, the diagnosis must be promptly established by means of blood sugar investigations.

DR. FRANK SMITHIES (Chicago, Ill.): Naturally, I came here to learn. Inasmuch as Seale Harris was going to deliver this address, it seemed to me an opportune time to learn of this syndrome from the fountainhead.

There are other accidental factors which come in this type of ailment, but it appears to me that frequently when one partakes of an abnormal or unbalanced diet, not only do we have the steaming up of the secretion of the pancreas with the production of extraordinary secretion, but in association with that we have variations in the production of hydrochloric acid and pepsin. We have, in other words, stimulated a link in the digestive system before we reach the pancreas. When we have normal gastric secretion, then we can expect normal pancreatic secretion and normal biliary tract secretion.

Out of curiosity I went through a number of patients who had duodenal ulcer and other ailments. We found that in the duodenal ulcer patients, 9½% of them had blood sugars lower than 100, but none lower than 70; gastric ulcer, 7%; gall bladder ailments 11½%; so-called nervous indigestion, 4½%; epileptic cases in the young individuals, 38 cases (of course, I don't see many epileptics), 5+% had blood sugars lower than 100, and not any lower than 70. Of feeble people, especially older people who had lost the habit of eating either through finickiness or failure of appetite from inertia (if we can use that term), in 17% there was a blood sugar lower than 100, but not lower than 70.

Now, putting the horse into the shafts, (I have given you the cart here before the horse)—it may be interesting to note that while I have seen to a certain degree manifestations of hypoglycemia similar to those described by Dr. Harris, and to those described by the Mayo Clinic, yet in individuals in whom I suspected that I had typical instances and watched the blood sugars for a week or ten days, I was vastly disappointed to find I didn't have lowered blood sugar readings. These patients were secre-

ting normally, provided they ate with any degree of rationality.

I am not here to deny the syndrome that may be due to hypoglycemia. Far be it; yet, on the other hand, I believe that unless we are very careful, we are going to pay too much attention to blood sugars. In estimating them there are possibilities for many sorts of error. We are going to pay too much attention to that observation alone and not enough to noting other disturbances which the patient manifests: disturbances due to disease, or disturbance in function which may be traced to something more definite than hypersecretion of the pancreatic gland.

DR. MAX EINHORN (New York, N. Y.): If I am allowed to say a few words, some years ago I described a condition in which the pancreas secreted too much, gave too much juice. I called it *hyperchylia pancreatica*.

The way I found it was that people who had intense diarrhea, were run down a great deal, and then tried to ascertain how much secretion would run up from the duodenum—if you had the tube in, there would be pancreatic juice in several minutes, and I measured it with regard to the normal and found in those cases I had about three or four times as much; I described such patients as having *hyperchylia pancreatica*.

I am sorry to say that I did not take the blood sugar, but in these cases I surmised that there would be found also probably too little, a small percentage of blood sugar would be present.

I think we are all very grateful to Dr. Harris for bringing up that topic and I would only add that in my cases atropine helped a great deal; I had cases where the pancreas was at fault due to too much action, and by giving atropine and treating in that way, we could bring on quite some improvement.

In this connection I would also say that Boldyreff, the associate of Pavlov, was of the opinion that insulin was a secondary product which is formed in the blood after the pancreatic juice is secreted, so here would be a connection between hyperinsulinism and *hyperchylia pancreatica*.

DR. SEALE HARRIS (Birmingham, Ala., closing the discussion): I predict that within the next year most of those present will have had one case, or a number of cases, of hyperinsulinism. In other words, when gastro-enterologists become "hyperinsulinism conscious," they find the

cases; because such patients usually connect their symptoms with their stomachs.

Three years ago I delivered an address on hyperinsulinism at Shreveport. Since then, Dr. Powell, a Louisiana doctor, has reported twenty-five cases. Incidentally, this general practitioner was the first to suggest that cerebral malnutrition is the cause of the symptoms in hypoglycemia. He noted in an editorial of the Journal of the A. M. A., a statement by Ziegler to the effect that the brain derives its nourishment entirely from glucose circulating in the blood. Heimwich, of Yale, says it is lactic acid that is metabolized in the brain, a product of glucose; but at any rate, Powell observed that when one of his patient's blood sugar went down to 60 or 50, the child could not learn anything, was irritable and below par mentally; whereas, when the child's blood sugar was over 70, she learned her lessons easily and was happy and contented.

Careful questioning of patients who come to gastro-enterologists with suspected gastric ulcer or duodenal ulcer, will in many cases bring out that in addition to the pain three or four hours after eating, they are weak and nervous, and perspire freely until they are relieved by eating. If at the time a blood specimen is obtained for a routine Wassermann enough blood is drawn to make a blood sugar test, low fasting blood sugars will be found more frequently than positive Wassermans. All cases of hyperinsulinism, however, do not have low fasting blood sugars, but where there are symptoms, if the dextrose tolerance test is carried out for six full hours, hypoglycemia, often reproducing the symptoms, will occur in four, five or six hours.

Abdominal pain between meals and during attacks of unconsciousness has been pronounced in several reported cases, so that a number of hyperinsulinism patients have been subjected to needless operations in which erroneous diagnoses of appendicitis, duodenal ulcer, or cholecystitis have been made. Hyperinsulinism has frequently occurred in patients who have proved abdominal lesions, including duodenal ulcer, cholecystitis, pancreatitis, and tumors of the islands Langerhans. Dietary management usually controls or cures hyperinsulinism in intelligent cooperative patients; but resection of the pancreas and removal of insulomas have produced clinical cures in hyperinsulin patients who were not relieved by dietary management.

## ABSTRACTS

FRANK H. LAHEY, M.D., AND G. E. HAGGART, M.D.

*Hyperparathyroidism. S., G., and O., Vol. 60, No. 6, June, 1935.*

In this paper the authors present an excellent review of the subject of hyperparathyroidism together with a report of five new proven cases with the significant findings which led to the diagnosis. The operative exposure for removal of a parathyroid adenoma is illustrated, with particular emphasis upon the possible atypical location of parathyroid bodies—and so these tumors.

The diagnosis of the clinical entity, hyperparathyroidism, depends primarily upon (1) An analysis of the chemical findings and (2) A careful survey of the roentgenograms, including not only those of the bones of the skeleton (especially plates of the skull, spine, pelvis and femora) but also X-rays of the kidneys. The latter plates are taken to demonstrate the presence or absence of calculi. In very early cases of hyperparathyroidism, or in the presence of severe renal damage, study of the chemistry and X-ray findings may be misleading, and the diagnosis not arrived at.

The authors classify cases of hyperparathyroidism clinically into three groups, i.e.:

(1) Classical—The osteitis fibrosa cystica of von Recklinghausen's. Skeletal X-ray of these patients are quite characteristic showing not only the diffuse granular osteoporosis, but also the presence of multiple cysts.

(2) Hyperparathyroidism with osteoporosis—these cases are an early stage of group one and rarely show cyst formation. The decalcification of the bone is not as advanced as in group one, but there is present the characteristic osteoporosis.

(3) Cases in which renal pathology, due to the precipitation of calcium phosphate, is the significant finding. In these cases X-rays of the skeleton are often negative.

The majority of the reported cases have occurred in females between 30 and 50 years of age. From an analysis of 115 proven cases, Gutman, Swenson and Parsons state that pain in the back or extremities was the major initial symptom in 72 per cent, while 22 per cent primarily complained of muscle weakness. The possibility of hyperparathyroidism must always be considered in patients who complain of relatively diffuse "neuritic" or "arthritic" pains, made worse by motion. This is particularly true if the symptoms exhibit localized or general bone tenderness, and if there is a history of pathological fracture.

### The Treatment of Amoebiasis With Iodoxyquinolin Sulphonic Acid \*

By

F. W. O'CONNOR, M.R.C.S.

and

C. R. HULSE

NEW YORK CITY, NEW YORK

IN 1930 the writers reported the results of treatment with iodoxyquinolin sulphonic acid (anayodin) in fifty-one cases of *Entamoeba histolytica* infection. Since our experience has, on the whole been satisfactory, this form of treatment has been continued in 102 additional cases with the results to be described. These may well be considered in *four groups*.†

In the *first group* are thirty cases of acute amoebic dysentery in the stools of each of which actively motile trophozoites, some containing red blood cells, were found. The high percentage of acute cases is due to the advent of the Chicago outbreak in 1933-34 when twenty of these patients definitely attributed the infection to their sojourn in two hotels in that city. These cases were particularly severe and some of them were fulminating in type.

In the *second group* are thirty-eight missionaries either suffering from subacute dysentery, diarrhea, or general ill health with or without histories of dysentery, in whose stools cysts or pre-cystic forms and occasionally, trophozoites of *E. histolytica* were found. The foreign mission fields from which these patients had returned were: Africa 11, Brazil 8, China 6, East India 3, Mexico 1, Philippines 3, Persia 2, Peru 1 and Chosen 3 respectively. In this group two families showed a high incidence of infection with the parasite. In one family from West Africa *E. histolytica* cysts were found in the stools of both parents and four children, while in another family from Brazil the mother, father and two children were found to be infected.

In the *third group* are nineteen *E. histolytica* carriers amongst locally born American citizens who had not traveled outside the northern United States. They were examined for various indispositions and the parasites were found during routine examinations. Some of these patients gave histories of diarrhea with or without the passage of blood and mucus.

In the *last group* are fifteen foreign born residents or United States citizens who had traveled in various,

(including tropical and subtropical), countries. Most of these gave a history of diarrhea or dysentery.

In the whole series *liver abscess* was diagnosed six times. The condition occurred in two of the acute cases originating in Chicago and in two of the local cyst carriers who had never been to Chicago or traveled outside the United States. Neither of these patients gave a history of diarrhea or dysentery. In the sixth case, the patient, a citizen of this country, had lived for some years in the West Indies. He had not suffered from dysentery. *E. histolytica* cysts were found in the stools as confirmation of the diagnosis of hepatic abscess.

#### TREATMENT

All the cases suffering from acute intestinal amoebiasis and all the carriers were treated with anayodin, four pills three times daily with meals for eight days. For those persons in whom the diarrhea was increased by treatment the dosage was reduced to three or two pills, three times a day, but in all cases treatment was continued until the full course of ninety-six pills had been taken.

One patient affected with cardiac disease and very acute dysentery failed to react to treatment. Despite several courses of anayodin and later, courses of carbarsone, vioform, ipecachuana by duodenal tube, emetine alone, or in combination with the other treatments, there was throughout no diminution in the numbers of free phagocytic amoebae and the patient continued to pass blood and mucus. This patient, despite her condition with extensive ulceration of the rectum as seen by proctoscope, complained of neither pain nor local tenderness. Eventually, she developed auricular fibrillations and died suddenly of heart failure. There was one other case of hyposensitiveness amongst the acute cases. This case recovered. He had noticed blood and mucus for several weeks before the condition was discovered but stated that he had not experienced pain, tenesmus or discomfort. Both of these patients were stout types.

With the exception of the fatal case described all the other cases (95) not complicated with liver abscess made an uninterrupted recovery following treatment with iodoxyquinolin sulphonic acid (anayodin) treatment. In their stools, re-examined at intervals during

\*From the Department of Medicine, Presbyterian Hospital, Columbia University, New York City.

Read before the Pan American Medical Association at sea, 7-22-35.

†Note: Complete protocols of these cases are at the Presbyterian Hospital or in the possession of the writers but for purposes of brevity are not given here.

Submitted September 12, 1935.

periods varying from a minimum of six months to several years, *E. histolytica* in any form has not been discovered.

One patient with advanced diverticulosis (demonstrated by roentgenogram) required three courses of treatment with the drug before amoebae disappeared permanently from the stools. In the other cases only one course of treatment was found to be necessary.

The treatment of the liver abscess cases required separate consideration. In one case the patient developed lobar pneumonia during treatment with anayodin for acute dysentery. Anti-amoebic treatment was stopped owing to the gravity of the latter condition. Subsequently convalescence was interrupted by rapid enlargement of the liver, local tenderness and all the other classical clinical, roentgenological and hematological signs of hepatic abscess. Cysts of *E. histolytica* were then found in the stool. The patient was treated with a full course of emetine hydrochloride,  $\frac{1}{2}$  grain twice a day hypodermically for twelve days together with the usual course of anayodin. Signs and symptoms of liver involvement disappeared and the patient made an uninterrupted recovery.

One patient had been treated with anayodin but subsequently died of pre-existing aortic disease. At autopsy a large liver abscess was found in the right lobe of the liver. In the walls of this abscess *E. histolytica* were found in microscopical sections. No amoebae were found in the healing intestinal ulcers.

In two cases operation was performed to evacuate from the liver pus in which amoebae were found and these patients were treated with combined courses of anayodin orally and emetine hydrochloride hypodermically.

In two other cases after hepatic abscess of amoebic origin was definitely diagnosed treatment with emetine and anayodin as already described, was followed by disappearance of symptoms and subsequent recovery.

### SUMMARY

From six years experience, during which one hundred and fifty-two cases of *E. histolytica* infection have been treated, there seems reason to believe that in intestinal amoebiasis iodoxyquinolin sulphonic acid (anayodin) is a very useful drug. It is now shown to be as effective in stopping severe symptoms rapidly and curing acute cases as it is in curing carrier cases. It will not cure all cases any more than any other drug known for the treatment of this infection.

During or following its administration no toxic symptoms have been observed by the writers or their colleagues. In some cases the full dosage increases the diarrhea and causes a scalding sensation during defecation. These symptoms may be eliminated by reducing the dosage without discontinuing the treatment.

Anayodin alone is useless in the treatment of hepatic amoebiasis. When liver abscess is diagnosed present experience suggests that treatment with emetine hydrochloride hypodermically promptly carried out with the necessary precautions may stop further abscess extension. In such cases the administration of a full course of anayodin at the same time seems warranted to prevent later reinfection of the liver from the intestine.

## ABSTRACTS

CALLENDER, C. L.; RUSH, G., AND NEMIR, A.

*Mechanism, Symptoms, and Treatment of Hernia Into the Descending Mesocolon (Left Duodenal Hernia). A Plea for a Change in Nomenclature.* S., G., and O., Vol. 60, No. 6, pp. 1052-1071, June, 1935.

The authors report a case of left duodenal hernia giving an explanation of its occurrence in embryology, and some reasons for changing the nomenclature of this lesion. The hernia reported contained the entire small bowel in a sac formed by the descending mesocolon; it was discovered accidentally at necropsy. The anterior wall of the sac contained the inferior mesenteric vein.

The embryology of the intestinal tract is reviewed and it is pointed out that the fossae about the duodenum may be shallow with strong walls or they may be very deep with relatively weak walls. During fetal life, before the descending and transverse mesocolon have undergone agglutination, the fossae about the duodenum are deep; their walls are thin and entrance into their depths is readily accomplished. The authors feel that a portion of the small bowel falls behind a portion of descending mesocolon and becomes incarcerated there. As the bowel increases in length, the body of the cavity enlarges while the continued rotation of the bowel and its agglutination with the pos-

terior parietal peritoneum fixes the opening into the sac. The position of the vascular channels strengthens the free margin of the sac.

The authors propose naming the herniae according to the structures which form the anterior wall of the sac, such as "hernia into the descending mesocolon," "hernia into the ascending mesocolon."

Such herniae frequently do not cause any symptoms; they are usually discovered during laparotomy or necropsy. They should be suspected in a patient who has had repeated attacks of intestinal obstruction. If a large ovoid or globular, doughy or soft mass is visible or palpable filling the upper left part of the abdomen this type of hernia should be suspected.

The treatment of hernia into the descending mesocolon may be very difficult or very easy. If the hernial sac may be emptied manually that should be done. The neck of the sac may be enlarged upward or downward as far as the dissection may be made without injuring any of the vascular trunks around the neck of the sac. As a last resort, the anterior wall of the sac may be incised in an avascular area and the sac explored. The rent in the sac should be repaired after the obstruction has been released.

N. M. Percy, Chicago.

## SECTION VII—*Surgery of the Lower Colon and Rectum*

### The Specificity of the Frei Test in Lymphopathia Venerea\*

By

HARRY E. BACON, B.S., M.D., F.A.C.S.  
PHILADELPHIA, PENNSYLVANIA

THIS fascinating disease entity — lymphopathia venerea or lymphogranuloma inguinale—is of particular interest to us as proctologists by virtue of its interrelationship with various anorectal syndromes, especially stricture of the rectum and esthiomene which now are to be considered the most important sequelae of L.V. The subject is such a massive one and the literature so voluminous that in this brief space we will confine our remarks to but one phase of the disease, namely the specificity of the Frei reaction.

Many are prone to question the existence of such an affection as lymphopathia venerea as well as the value and reliability of the Frei test (42). We earnestly entreat our colleagues, however, to judge unbiasedly by the writings and experimentations of pioneer workers in this field of research. In a recent article by the Author (10) the ubiquity of this disease was cited in reports by 158 investigators representing twenty-one different countries of the world. Each of this number had confirmed the Frei test as a diagnostic aid. Surely the authenticity of the reports offered by such scientists as Levaditi, Hellerstrom, Wassen and Bensaude is not to be derogated. Is not the fact that in patients with a positive Frei test, experimental transmission of the unknown virus by inoculation with pus from an unopened bubo (106) and tissue from a rectal stricture (66, 86) through guinea pigs into monkeys, with the production of a typical meningoencephalitis which histologically corresponds to the lesion in the human, to be considered a conclusive proof? Further evidence may be cited in that the lesion so produced in the monkey, when prepared according to Frei's technic, gave a positive reaction when injected intradermally into the forearm of patients known to be affected with this disease. Leadrich states that "The experiments prove in a striking manner the specific value of Frei's intradermo-reaction and at the same time the incontestable etiologic role of Nicolas-Favre's disease in stenosing proctitis." Fischer (37) remarks "the intradermal test of Frei shows rather conclusively that stricture of the rectum and chronic granulomatous ulceration of the anus and vulva are due to the specific virus of L.V." Cole (20), who has observed a large number of these cases, mentions that the Frei test has

been of particular value in the diagnosis of the so called "anorectal syphiloma of Fournier." Bensaude (14), in describing the value of the Frei test remarks "The obscure and much discussed etiology of rectal stricture seems to be finally explained by the knowledge of lymphogranulomatosis inguinalis and which must now be added to the list of venereal diseases." Martin (75), who was the first to call our attention in Philadelphia to this interesting disease remarks, "the causative factor of stricture of the rectum, esthiomene and certain other anorectal infections which particularly appear to be an affection peculiar to the Negro race, has been we feel finally solved by the work of Nicolas, Durand, Favre and Frei." In an excellent article on the subject, Bloom (17) declares, "the problem of inflammatory stricture is inseparable from esthiomene." We believe, as others, that in a large percentage of cases this affection is part of L.V. A series recently tabulated by Hellerstrom (54), with their Frei reactions, is as follows:

#### ESTHIOMENE

| Authors                     | Number of Cases | Frei Positive |

\*From the Departments of Proctology, Graduate Hospital, University of Pennsylvania, Temple University and St. Luke's Hospitals.

\*Read at the thirty-sixth annual meeting of the American Proctologic Society, Atlantic City, June 10th and 11th, 1935.

Submitted August 5, 1935.

It is interesting to note that Ravaut, Levaditi, and Cachera (86) upon inoculating a guinea pig with ulcerated growths from the anus of a patient with a positive Frei test, observed that a typical lesion of L.V. was produced by transmitting the disease directly to monkeys. Later Meyer and Rosenfeld (79) injected the excised tissue from an esthiomene patient into a guinea pig which subsequently showed a process similar to that of L.V. Loehe (71) and Lutz (73) not only support the interrelationship between esthiomene and L.V. but state that this evidence must be considered conclusive. In four instances we have excised a portion of the esthiomene tissue, which when prepared according to Frei's technic, gave positive intracutaneous reactions in known cases of L.V. Well worth mentioning is the experiment of Nicolas, Favre and Charpy (81) who obtained a positive Frei test in a known L.V. patient with an antigen prepared from the pus of an anorectal fistula. This we have confirmed in a series of six cases.

Many workers in this field have referred to the Frei test as specific for this disease. (99, 87, 9, 52, 55, 33, 92, 85, 97, 18, 84, 82, 65, 64, 63, 62, 59, 47, 45, 61, 56, 38, 40, 35, 23, 7, 8, 11, 15, 13, 68, 31, 32, 43, 108, 104, 36, 76, 4, 5, 70, 103, 2, 19, 110, 112).

A few with their percentage of positive reactions are tabulated as follows:

| Author                               | Bib. | Per-centage | Service | Path-ology Rectal      | Genital |

In order to substantiate the intracutaneous test of Frei, Coutts and Bianchi (26) studied the Bordet-Gengou complement reaction in relation to different

syndromes of L.V. by using an antigen prepared from the lymph nodes as a receptor. After months of research these authors (25) report that this complement fixation is specific for L.V. and supports Frei's intra-dermal test. Another experiment worthy of mention is that by Strauss (93) who found that where the Frei test is strong enough to cause vesicle formation, the content of this vesicle is capable of producing reaction similar to that of the Frei in patients with L.V. In our series of 155 cases, 150 gave a positive Frei test, or 96.7%. Thirty-six different antigens were used, 25 from our cases and the others sent to us by Van Cleve, Hill, Hayden, Strauss, McKenney, Jelks and Reimann in the U. S. and Almanza in Bogota, Hellerstrom in Stockholm, Levaditi in Paris, McDonagh and Stannue in London, and Coutts in Chile. Each test was verified always using a second antigen, usually a third and frequently a fourth. Through the courtesy of Drs. Coca and Roberts, we have utilized the saline suspension of mouse brain prepared by the Lederle Laboratories and find that it compares favorably with our own antigen and those received from others. In order to evaluate the test properly a control antigen obtained from the normal gland of patients not affected with L.V. was used as suggested by Martin (77). In some instances a sterile suspension of leukocytes was injected, while in other cases a control of 0.25 per cent phenol in normal saline solution, as mentioned by Wang (105), was utilized. All controls were negative.

#### TOTAL NUMBER OF CASES SHOWING POSITIVE FREI TEST—150

In an attempt to rule out various diseases such as syphilis, gonorrhea, tuberculosis, and ulcer molle, which may cause or at least have been considered the etiologic factors in L.V., certain laboratory tests were performed. Of the 150 cases herein reported, the blood Wassermann and Kahn, and in some instances the Kolmer and Eagle, were taken in 97 instances. At the suggestion of Dr. Edwin Gault a small series was given provocative doses of neoarsphenamine. Seventeen patients showing a negative Wassermann reaction were injected with 3 mg. after which another test was taken. In each case the report was negative.

| REACTION       | Number      |
|----------------|-------------|
| Negative ..... | 71          |
| Positive       |             |
| / 4 .....      | 22          |
| / 3 .....      | 3           |
| / 2 .....      | 0           |
| / 1 .....      | 1           |
|                | 26 or 26.8% |
| Total          | 97          |

We wish to mention that in our series of 155 cases, 150 of which showed a positive Frei test, three of the five remaining showed a positive Wassermann reaction. During the institution of antiluetic treatment and even after the completion of the course, we failed repeatedly to obtain a positive Frei test. Apparently there exists a reciprocal immunologic reaction between syphilis and L.V. which thus far has not been explained, for it has been observed (39, 16) that in the presence of a recent or an active syphilitic process the Frei test may be rendered temporarily negative.

Smears for the gonococcus were taken in a limited number of cases. Two smears were taken and each stained by the Gram technic. The results were noted as follows:

| Rectal Smears for G. C.  |            |
|--------------------------|------------|
| Negative .....           | 28         |
| Positive .....           | 6 or 17.6% |
| Total                    | 34         |
| Vaginal Smears for G. C. |            |
| Negative .....           | 41         |
| Positive .....           | 13 or 24%  |
| Total                    | 54         |

Reenstierna Test for chancroidal infection (87, 88, 89). Through the courtesy of Almanza of Bogota and Reenstierna of Stockholm, we obtained a supply of Dmelcos vaccine (suspension of *B. culey* and streptococcus) which is considered specific for chancroids (3, 57, 109) termed on the Continent *ulcus molle*. Forty-one cases showing a positive Frei test were injected intradermally with 1-10 c.c. of the Dmelcos vaccine. Thirty-eight gave a negative reaction. Of the three showing a positive Reenstierna test, two of this number presented clinical evidence of chancroidal infection.

| NUMBER         |    |
|----------------|----|
| Negative ..... | 38 |
| Positive ..... | 3  |
| Total          | 41 |

In one instance we attempted to transmit the Ducrey organisms to the forearm of the patient after scarification but without success.

*Tuberculosis.* To determine the presence or absence of tuberculosis is a most perplexing problem especially when applied to the use of tuberculin. Either it is inert in a large percentage of instances or there is considerable chance of falsely interpreting many reactions as positive. The new standard tuberculin termed "Purified Protein Derivative" (P.P.D.), prepared by Seibert (90, 91) and adopted by the National Tuberculosis Association, is considered of greater value than O.T. (49, 72, 80) in that it is free of salts and non-specific proteins and that its potency is reproducible (6). With the assistance of Dr. Gault, Pathologist to the Temple University, School of Medicine, forty-five patients in our series were tested intradermally with P.P.D., using the first dilution (0.00002 mg.). Their reactions were read and measured in 48 hours. The second dilution (0.005 mg.) was injected in cases that were negative to the first. The results were as follows:

| Reaction                                                                           | Number |
|------------------------------------------------------------------------------------|--------|
| Negative                                                                           | 33     |
| Positive 1 reaction shows area of swelling measuring 5 to 10 mm. in diameter ..... | 1      |
| 2 reaction shows area of swelling measuring 10 to 22 mm. in diameter .....         | 5      |
| 3 reaction shows area of swelling exceeding 20 mm. in diameter. .                  | 3      |
| 4 reaction shows area of swelling and definite necrosis.....                       | 3      |
| Total                                                                              | 45     |

Of the 12 cases showing a positive P.P.D. test, five presented clinical and histologic evidence of tuberculosis: pulmonary 2, fistula 1, nodule 1 and anal skin 1. All, however, showed a positive Frei reaction.

In an effort to determine the percentage of positive Frei tests in various affections other than L.V., we solicited the services of our colleagues in allied clinics. Negative Frei tests were obtained in the following cases:

## FREI TEST CONTROLS

|                                           | Number<br>of Cases |

Total 264

In a recent communication to C. F. Martin, Silvers reported a series of 100 control cases from the Atlantic City Hospital in which all gave a negative Frei test.

## CONCLUSION

By repeated testings the Frei test has proven specific and has assisted in the recognition of the heretofore unaccepted therapy of L.V. Over a period of two years we have observed these patients and their Frei reactions in various stages of the disease, and feel that in the presence of clinical evidence one negative test should not be considered as confirmatory that the process is not one of L.V. To a large degree, incorrect readings may be obviated by careful selection of the tissue used, strict adherence to the preparation and preservation of the antigen, its method of administration and time of reading.

We consider the Frei test to be of utmost value in the diagnosis of L.V. judging from our total series of 155 cases bearing a positive percentage of 96.7 that clinically and pathologically presented manifestations of this disease, but we do concur with Guy del Vivo (44) that further and more conclusive evidence should be sought as to its etiology.

## ABSTRACTS

MORGAN, J. W.

*Pectenosis and Minor Maladies of the Anal Region.*  
S., G. and O., Vol. LIX, No. 5, Nov., 1934, pp. 806-809.

The author wishes to call attention to the importance of the variety of lesions found in the anal canal, and to record some personal observations as to their clinical findings and treatment. A consideration of the anatomy of the part is important. Four landmarks are recognized, namely: (1) the ano cutaneous line which marks the lower end of the intestinal tract; no hair follicles are seen cephalad to this line; (2) the white line of Hilton which lies 1.5 centimeters above the ano cutaneous line. It is from six to nine millimeters in width, and, during life, is blue in color; (3) the pectinate line is represented by the lower margins of the sinuses and columns of Morgagni; (4) the ano rectal line is 1.5 centimeters above the pectinate line; it can be accurately identified only with the aid of the microscope. The pectinate line is the important area as it is here that the blood, lymphatic and nerve supply divide. When the anal orifice is closed, the pecten forms the central part

of the floor of the rectum, and it is reasonable to suppose that it should be the seat of special organs whose function it is to regulate the action of the sphincter muscles. Any disturbance of the equilibrium of the sphincters leads to chronic passive congestion, which in turn leads to round cell infiltration, fibrosis, and the production of a condition termed pectenosis. The fibrous deposit, which varies in breadth and thickness according to its duration, encircles the canal, and was called "the pecten band" by Miles in 1918. Passive congestion may result from many causes; e. g.; haemorrhoids, contusions or lacerations of the canal, irritating liquid stools, etc. The resulting pectenosis persists and becomes more marked, aggravating the primary condition until it is corrected. During the last year and a half the author has operated on 83 patients whose lesions could be explained by the presence of pectenosis and a pecten band. In most cases where the pecten band is well defined simple incision of it affords complete relief. The author warns against the practice of division as it is always dangerous.

N. M. Percy, Chicago.

## SECTION VIII—*Editorial*

### THE DIAGNOSIS OF GASTRITIS

**P**ROFESSOR Katsch reviews the subject of gastritis chiefly from a diagnostic standpoint. Like many of his German contemporaries, he feels that gastritis is a frequent disease, supported by an abundant factual material. Nevertheless, in his opinion, the diagnosis of gastritis remains a delicate matter, a fact of which the general practitioner is aware, and confirmed by the clinician attached to a Clinic where he is occupied intensively with mass pathology.

The Author feels that the unsatisfactory state of the situation concerning gastritis lies in the fact that gastroscopy is a diagnostic procedure reserved for the few specially trained physicians and can hardly be made available to the general practitioner. "Moreover, a clear relation between gastroscopic findings and the clinical picture, even excluding everything but the subjective illness, can be established with any degree of certainty only in cases with clear-out findings. Less pronounced pictures of gastritis are found both in patients with severe symptoms and in those with mild complaints. They may also be discovered by chance in persons who feel quite well. Therefore, a diagnosis made exclusively by gastroscopic examination is not only impracticable in many instances for reasons mentioned, but it is furthermore not to be relied on entirely for the general diagnosis of all cases of gastritis" (1).

**Roentgen Diagnosis:** Katsch regards this procedure as considerably less reliable than gastroscopy. At times the diagnosis of gastritis can be made through visualization of the mucosal relief with a small amount of barium. He feels that granulation of the relief is the most certain roentgen sign. This may be of such extent that folds can no longer be recognized. Such findings are relatively rare however. Changes in the folds may give rise to reliable findings, especially when the fold is not only wide, but shows a confused, unusual type of sinuosity, a rigid course, "against the grain" (Berg), or on longer observation, that rigidity and immobility so familiarly seen in the gastroscopic picture. Another sign of some importance, in the Author's judgment, is the presence of smooth surfaces lying between coarse folds. He discusses at length some of the pitfalls in the diagnosis of gastritis from the appearance of the mucosal folds under certain conditions, as brought out by Forssell, Velde, and others.

**Examination of the cellular sediment in the gastric content:** He discusses the work of Loeper, Kauffmann, Westphal, and Kuekkuk. A distinction is made between exudation and the normal desquamation of cells of the gastric mucosa into the lumen of the stomach, the former being of chief diagnostic significance. In the conception of exudation are included the emigra-

tion of leukocytes (leukodiapedesis), and to a less extent the emigration of connective tissue cells (histiodiapedesis). For the present, the most important findings, in the Author's opinion, giving rise to any serious diagnostic consideration, are such cell findings as are notably and crassly abnormal, a leukocytic sediment so marked as to resemble or approach a purulent sediment, a richness in cells so great that one might speak of desquamative catarrh. One must not forget that such findings are also present in cancer.

**The diagnostic role of gastric chemism and functional tests:** It is pointed out that in those cases in which the diagnosis of gastritis has been made on the basis of morphologic findings, it is very seldom that one can predict what the gastric analysis will show as regards the functional capacity of the stomach. The only exceptions are the cases with extensive atrophy of the gastric mucosa. In very high-grade forms of so-called hypertrophic gastritis, and in most cases of erosive gastritis, achylia is also found, at least subacidity in the latter. In the majority of cases functional capacity can be determined only by the functional test. Hence Jaworski and Hayem speak of an anacid, subacid, acid and hyperacid gastritis.

Beyond question a deficiency of gastric juice is the most important functional finding in gastritis. Of course, such finding is present in most cases of carcinoma and in pernicious anemia. The Author also discusses the importance of gastric analysis not only in determining the concentration of the free hydrochloric acid, but the amount of secretion and determination of the total chloride value. The Author describes a simple test for the determination of the latter. The importance of observation, and repetition of the functional tests in cases of gastritis, to determine whether progress or retrogression under treatment is occurring, is emphasized.

**Symptoms:** In patients over forty years of age, who have had infections and alimentary injuries in the past and have been exposed to the action of irritants, gastritis, in the opinion of the Author, is exceedingly common, so that the explanation of even atypical gastric disorders will often come to mind. But even if a diagnosis of gastritis is made, there remains the estimation of the degree of injury to the mucous membrane, the degree of functional disturbance, the nature of the tendency of the chronic inflammatory process, the oscillations of the process between activity and latency, the acute exacerbations and the final defect states; and further, the degree of compensation attained up to the point where digestive processes in the intestine fully make up for the deficiency in gastric digestion. Symptoms, especially intestinal disturbances, appear with gastric decompensation, and the work of Brinck and Gutzeit with reference to gastro-enteritis is mentioned.

The Author discusses briefly some of the variations in the symptom complexes. (1) The patient with a

1. Die Diagnose Gastritis—G. Katsch. Klin. Wehnschr. 14; March 23, 1935, pp. 411-414.

"sensitive" stomach occupies a place close to that of the individual with latent gastritis. The Author has reference to "acidism" (epigastric burning, heartburn, acid eructations) easily occasioned by dietetic error. (2) The pyloric syndrome, closely simulating the symptom complex of duodenal ulcer. The Author, however, points out that in the pronounced chronic cases of this kind, an ulcer of the pyloric region or duodenum is usually found, without exception. (3) The weak stomach which is not equal to more than moderate demands, either qualitative or quantitative, and is not infrequently accompanied by disturbances of taste and appetite, and intestinal disturbances. Cases in which disturbances are primarily intestinal, characterized by diarrhea, constipation, or gaseous distension. (3-a) The hyperchromic anemia of patients with achylia, which react to treatment with iron. (Faber's anemia). (4) Cases of gastric hemorrhage as the result of erosive gastritis in the absence of gross ulcer. This clinical picture has long been emphasized by Konjetzny. (5) Patients with more acutely painful symptoms, the result of acute and subacute stages of gastritis.

The pains are the result, for the most part, of infiltrative inflammations affecting more or less of the gastric wall, and no doubt including the nerve plexuses. This, in the Author's opinion, explains the frequent, almost neuralgic character of the pain. On the one hand, the pain may appear independently of the taking of food and may persist for hours as a constant pain, and on the other hand, the pain may become intensified by the peristaltic movements of the stomach. The Author agrees with Henning, that such pains may be aggravated by anything which distends the stomach and by body movements, such as physical exertion, stooping, the putting on of an abdominal belt, etc. In rare cases the pains of gastritis may be so acute and intense, accompanied by board-hard tension of the abdominal wall, so that perforation is suggested. Konjetzny was the first to call particular attention to these cases. There is an associated lymphangitis extending into the subserosa and into the regional lymph glands. The differentiation from perforated ulcer may be impossible without abdominal exploration.

The writer, as others before him, summarized the knowledge gained by gastroscopy, microscopic exami-

nation of freshly resected material, by roentgen examination, and by experimental research. He emphasizes the importance of intensive study in this field, and as soon as possible, the clarification of our knowledge so that the general practitioner may avail himself of its use. A literal translation of the closing paragraphs is of interest to workers in this field.

"In order to further our therapeutic ability it will be necessary in the future for us not to rest content with the diagnosis of gastritis but to characterize more accurately the individual states and their transformations. We cannot dispense with a certain many-sidedness of nomenclature. We have on the one hand a nomenclature referring to the gastroscopic pictures (gastritis hypertrophicans, infiltrative, atrophicans, granularis, polyposa, erosiva, haemorrhagica, pseudomembranacea, etc.); one also refers to the gastroscopically determined localization (corpus gastritis, pylorus gastritis). On the other hand, the functional test supplies a nomenclature (gastritis superacida, subacida, anacida, achylia absoluta, achylia perniciosa). Thirdly, there is the nomenclature derived from the clinical pictures and course, (gastritis acuta, subacuta, recurrens, exudans, dolorosa, latens, larvata, chronica, progressiva, etc.) Since there is no simple parallelism between gastroscopic pictures, results of the function test, subjective symptom pictures, the disease has to be considered simultaneously from the morphologic, clinical and functional standpoints and we cannot dispense with a mixture of names obtained according to different points of view and used to supplement one another. It is greatly to be desired that we should have an etiologic nomenclature of gastritis. At present, we can use such a nomenclature in some cases only (gastritis infectiosa, corrosiva, alcoholica, uraemica). In other etiologic designations, such as hepatogenic gastritis (Wichels), and peptic gastritis (Buchner), we sometimes run off into the region of hypothesis. It is particularly for the recognition of what is harmful and what is useful in the various forms of chronic gastritis and for the advance of etiology, prophylaxis and therapy that it is necessary to differentiate and characterize the gastritic stages as accurately as possible and to observe the changes and the course with patience over long periods of time."

George Eusterman, Rochester, Minn.

## SECTION IX—*Book Reviews*

*(This section is open to contributions from any medical reader, whether a member of the Editorial Council or not).*

Traite de Gastroscopie et de Pathologie Endoscopique de L' Estomac, by Francois Moutier, Masson et Cie, Publishers, Paris, 1935.

**T**HIS volume represents an elaborate and most praiseworthy attempt to present the subject of Peroral Gastroscopy in thorough going fashion. The volume is complete, beautifully illustrated and represents the first volume in the French language to explain fully this interesting subject. It is presented along similar lines to that of Bensaude, which is a

beautifully illustrated book on sigmoidoscopy and was published by the same Company some years ago.

The time-honored methods of examining the stomach, namely the history, physical examination, gastric analysis and X-ray study have been supplemented within recent years by two methods, both of which have been immensely improved. These are gastroscopy and gastrophotography. Both of these methods have for their purpose a study of the gastric mucosa; in both instances, earlier attempts were

poor but these later attempts are rich in promise. Gastrosocopy has for its purpose the exploration of the interior of the stomach. It necessitates a concept somewhat removed from the ordinary approach. The stomach to the gastroscopist is a different stomach from that of the radiologist, the clinician and the anatomist. The gastroscopist deals in mucosal patterns. He has a highly labile structure to handle. Local contractions, alterations in tension, changes in color and alterations in the gastric rugae or plications present interesting problems apart from the actual appearance of the mucosa.

This volume discusses the various instruments employed and their method of introduction as well as the appreciation of normal and pathological mucosal changes. Two models of instrument have engaged the attention of this author, the flexible Wolf-Schindler and the rigid instrument of Schindler. The Wolf-Schindler instrument is characterized by an optical system with a series of lenses of short focus, sufficiently close together to permit of movement. The peripheral portion bearing illumination and the superior part both are rigid. The inferior rigid segment is 8 cm. long, the flexible portion 27 cm. and the rigid oropharyngeal is 34 cm. There are, of course, some objections to this instrument. Such an instrument must of necessity be somewhat frail and the complexity of its optical apparatus does not give the clear illumination of the rigid instrument. Furthermore, sterilization in the ordinary way is out of the question. Moutier uses a weak solution of oxycyanide of mercury. A discussion of other instruments appears and while mention is made that gastro-photography is possible by means of the apparatus of Henning, the latter is a rigid instrument; we know of no means by which photography can be made part of the study by the flexible instrument.

This volume is a careful *exposé* of all the details of gastroscopy and it bears the additional merit that it is written by a clinician from the clinical viewpoint. No mere gastroscopist could have written this volume and Moutier is fully alive to the restrictions and the difficulties attending this method of examination. The idea that gastroscopy is a simple bedside problem is dispelled by the thoroughness of this volume. One gets the impression that gastroscopy is almost an operating room offense. Certainly, careful previous preparation, thorough local anesthesia and the need for several assistants is desirable. The Author frankly discusses the difficulties as well as the dangers of gastroscopy. The dangers, he feels, are markedly alleviated by the use of the flexible instrument. The contraindications which he recognizes are deformities of the vertebral column as well as the chronic sufferers with pulmonary and cardiac diseases, dyspnea and obesity. Pharyngeal diverticula, esophageal strictures, cirrhosis with esophageal and gastric varices, aortic and mediastinal lesions present almost insuperable obstacles and recent gastric hemorrhage is recognized as a definite contraindication. In fact, Moutier points out that it is well to abstain from all endoscopic examinations of the stomach for at least a month after a hemorrhage. It is likewise desirable to avoid such examinations if there is fever, violent pain or evidence of any acute gastric condition. Pharyngeal and esophageal lesions might be followed by diffuse mediastinitis and death although the use of the flexible instrument apparently has robbed this procedure of much of its danger. This

Author points out that perforation can even follow X-ray examination and quotes Paneek, who claims that 22.2% of gastric perforations followed X-ray study and that 11.1% were unquestionably due to it; a statement that hardly tallies with the facts which we observed. The preparation of the operator and his education as well as the preparation of the patient, the technic in the introduction of the tube and the general appearance of the normal stomach mucosa are considered in great detail.

Perhaps gastroscopy finds its greatest field of usefulness in the much misunderstood chapter of gastric affections, known as chronic inflammations of the mucosa. With the newer interest in gastritis as a precursor of carcinoma and ulcer the evidence yielded on gastroscopic examination is useful even if not final. Certainly the studies of Hayem, Lion, Loeper, Schindler, and Konjetzny have thrown light on the seriousness of chronic mucosal inflammations of the stomach. Moutier recognizes the proliferative form of gastritis showing changes in secretion, hyperplastic inflammation, including the hypertrophic forms going all the way to the so-called "*état mamelonné*," the group which he calls "Gastrites Alteratives" representing changes varying from a simple edema to gangrenous ulceration, in which are included edematous gastritis, hemorrhagic gastritis, ulcerative gastritis and the atrophic forms of gastritis and finally, the form which he calls "Gastrite Segmentaires" all of which are recognized by gastroscopy. This chapter is complete and well worth reading because it includes the clinical approach as well.

The chapter on gastric ulcer is of interest to the clinician; some of the observations are those which only a gastroscopist could make. The larger number of ulcers was clearly gastric and the Author points out that 75% of gastric ulcers are observed along the lesser curvature and the ulcer-bearing area is clearly the lesser curvature and posterior wall. It is surprising to note that the Author has never seen a true ulcer in the antrum. It is true that they are relatively rare, but they do occur. There is an interesting discussion in this chapter on the actual appearance of the ulcer as compared with its radiographic image. An ulcer, on gastroscopy may appear as a lozenge shaped loss of substance, a simple fissure or even star-shaped in form. Owing to the movement of the stomach wall, the tendency for the mucosa to overlap and the crater of the ulcer to become filled, a lesion can be overlooked by this method as well as by X-ray examination. There is no question that small ulcerations, which cannot be revealed by ordinary X-ray study can be demonstrated by both gastroscopy and gastrophotography. We have had this experience on a number of occasions.

We feel that gastroscopy should always be carried out by an expert. If misinterpretations are to be avoided the skilled gastroscopist must have a broad clinical knowledge as well. In our own institution, this work has always been done by the department of esophagoscopy where all the requirements, trained assistants and careful preparation of the patient insures a procedure which is relatively free from risk. There is no question that gastroscopy has come to stay and that it affords an additional diagnostic procedure of the greatest value in certain cases. We believe that in the hands of a tyro, the method can be not only unsafe, but misleading. Those of us who have been interested in gastrophotography have had a somewhat

similar experience. How was it possible to interpret the blurred photographs of several years ago and on that basis submit a patient to operation? At the Jefferson Hospital, after two years with the improved gastrophotographic instrument in the hands of Mr. Falenks, we have changed our minds regarding the value of that instrument, entirely flexible with the exception of the small terminal piece, but the latter procedure consumes less than a minute and is not an operating room procedure. Furthermore, we have gotten excellent photographs of the mucosa representing practically all the types mentioned by Moutier. Gastroscopy, in permitting direct inspection, is even preferable, but on the other hand, a painted picture after gastroscopy is not to be compared with an actual photograph. For that reason, we have used gastrophotography as a routine procedure within the last two years and we have photographs of gastric lesions which were not revealed on X-ray examination. Gastroscopy, when indicated, has been performed by the bronchoscopic department, formerly under Dr. Chevalier Jackson and now under Dr. Clerf's supervision. While biopsies can be performed with a direct vision instrument such as Jackson's, it is out of the question with a flexible instrument (Schindler's) and this is the case with gastrophotography as well.

Moutier's discussion of ulcer evolution is one which will interest the clinician and we are glad to say that this Author is not above using every method at his disposal to make a diagnosis. There are many radiographs in the volume. Contrary to the opinion of Konjetzny and Korbach, this Author believes that the true peptic ulcer and an ulcerative gastritis are essentially different phenomena. The behavior of the active ulcer with its irritable stomach is contrasted with the latent ulcer, a point which is borne out by radiographic examination as well. Moutier maintains that it is possible to determine a cure of the lesion and the degree of activity by this means, both of which are of interest to the clinician.

The chapter on cancer of the stomach is one that concerns all of us. Here again, Moutier is dominated by the findings of the laboratory, but he is strong in his statement regarding the current methods which are to be used. He maintains that X-ray study is not a means of early diagnosis, but rather of late diagnosis in cancer of the stomach. We feel that this statement might be put the other way and that is, that late diagnosis is due to the fact that the disease is so silent and latent in the early stages that in the great majority of instances when the patient reaches us, the lesion already is far advanced. Certainly the need for gastroscopy will not be revealed until the patient presents himself for examination and the same delay will then be apparent. A careful description of the findings of gastric cancer is given, revealing the infiltration, alteration in the plications, tendency to tumor formation and alteration of the normal mucosal pattern as well as ulceration. In the absence of biopsy, it is difficult for anyone to say that the localized alteration in the mucosa is necessarily malignant. Here is where Schindler's "closed instrument" fails us in early lesions. Some years ago, we took motion picture photographs of the mucosa of a large series of cases with carcinoma and the variation in the pictures was so great as to make it difficult to reach a definite conclusion from the superficial mucosal picture alone. The same thing is true of gastrophotography. Carcinoma

reveals many alterations in the mucosal pattern. The suggestion is made here as with other methods of examination that, when in doubt, an examination should be repeated within a few weeks to confirm or to deny the finding.

We do not believe that routine gastroscopy will reveal many early malignant lesions that are not revealed by a careful radiographic study by an expert, although one is intrigued with the possibilities of a direct inspection of the mucosa. We feel that in doubtful cases, every method of diagnosis should be used. We should not hesitate to avail ourselves of all of these methods of examination in given cases; but particularly in the question of gastric carcinoma. Those of us who have had much experience with this problem know how difficult the early diagnosis really is. We know the lesion infiltrates, while it may or may not ulcerate or cause changes of mucosal pattern or interferes with peristalsis. We have a number of gastrophotographs which match the various pictures which adorn Moutier's volume, but the problem of early diagnosis is by no means so simple as it would appear from the discussion. There are many alterations of the gastric mucosa which are suggestive and will bear watching, but except in the advanced lesion there are few pictures which are pathognomonic. The reviewer is convinced that the majority of gastroenterologists who are interested in this problem will agree that at least a large part of the failure to diagnose early gastric carcinoma is due as much to the patient and the curious latency of the disease as it is due to the inability on the part of the gastroenterologist to recognize the lesion. In a great majority of instances, the gastric cancer that we see is well advanced and easily recognized by ordinary clinical means.

There need be no hesitation in recommending Moutier's book to all students of this problem. It is well done, worthy of study and the Author is to be congratulated on the method of presentation and the general excellence of his work.

Martin E. Rehfuess, Philadelphia.

An Atlas on Biliary Drainage Microscopy, by B. B. Vincent Lyon, M.D., Philadelphia, Pa. Issued in Limited Edition and Privately Printed and Assembled by the Author. Thirty-Four Pages of Text Supplementing 110 Original Photomicrographs and Photographs. Subscription Price for Each of the 100 Copies to be Available, \$25.00 (United States funds).

ON May 4, 1920, the afternoon train from Atlantic City to Philadelphia carried a half dozen animatedly vocal members of the American Gastro-Enterological Association. On the previous day, under the modest title, "The Need of Early Diagnosis and Treatment of Cholecystitis and Cholelithiasis," they had heard Dr. Lyon present his initial, public announcement of the fact that, by taking advantage of the results of physiological investigations with solutions of magnesium sulphate (studies made by Prof. S. T. Meltzer) via a properly introduced duodenal tube, specimens of the content of the gall-bladder and bile passages could be secured. With conservatism and restraint, from the standpoint of today,—rather more than fifteen years—Lyon described his epoch-making observations and advanced clinical pointings possible from such. The lapse of time, the prompt

objections—then even scornful and acid—the researches of scores of physiologists—then, extremely incredulous of the work of both Meltzer and of Lyon—clinical studies and a voluminous literature, have added or subtracted little of basic significance from what the proponent of biliary tract drainage, as a diagnostic and a therapeutic procedure, presented in his initial discourse. Indeed, the clinical and laboratory procedure which quite properly bears Lyon's name was, as advanced by him, a clinical method in advance of experimental proof which subsequently—tho' not without much controversy and travail—was to demonstrate the function of Oddi's sphincter, the common duct's internal pressure, the ability of the gall-bladder to exhibit "peristaltic" activity, the relationship of the innervation of the biliary system and that of the stomach and other abdominal viscera.

The acumen of Lyon in adapting a procedure from "pure investigative effort" to clinical use was unique fifteen years ago. Similar adaptations now are not uncommon; in fact, one may say that a chief guiding spirit in investigation at laboratories affiliated with our first grade medical schools is that which plans and carries through researches in an effort to solve problems of a clinical character.

The liveliness of the discussion following Lyon's address, combined with a certain incredulity that specimens from the biliary tract actually could be secured for study, *prior to abdominal section*, explains why that group of physicians travelled from Atlantic City to Philadelphia on that hot, dusty—no "air conditioning" in those days!—train. They wanted to observe Lyon's procedure "at first hand": the technique, the type of patient, the material recovered, to study that material, to appraise its significance, to have exhibited to them the results of "duodenal drainage" as therapy. Briefly, they wished "to look over Lyon's shoulder while he worked, and to be shown!"

As physicians know—and certainly, Dr. Lyon now well has realized—there are limits of time, patience and physical and brain endurance to that sort of thing. In a comprehensive book, as a teacher, by demonstrations and addresses before representative medical societies, Lyon gave to our profession most generously of his time and energy in explaining, qualifying and elaborating "his" method. This not always was a pleasant task, because seldom in our day has a man and his work been so unjustly or viciously attacked. At once, he was subjected to a storm of criticism by investigators and clinicians, often men who were misinformed, had not performed or had not followed closely the procedure or of Lyon's own findings or interpretations, by captious critics of the "set" type who resent being aroused from smugness, by surgeons or by that group of our profession which doesn't know that it doesn't know, but ever is vocal. However, Lyon has weathered the storm most admirably. The method, which he set forth in 1920, in all modern and though-unshakelled clinics, now in an established diagnostic procedure and, in selected instances—as, for example, where the surgeons already have "had their innings" and the patient still is a "duct and liver invalid"—a therapeutic aid of indispensable value.

Now comes the "Atlas" a stupendous piece of original, specialized effort in which Lyon actually allows progressive clinicians and laboratory workers "to look over his shoulder," to observe, with his interpretation, what can be learned—and depended upon—in that most

important field, *microscopy* of fresh material secured at biliary tract "drainage."

In its *physical make-up* the "Atlas" is unique. Its "text" is brief—approximately 34 pages of multi-graphed, condensed data. This is a veritable "Bible" on the subject, axiomatically terse and pointed, from Lyon's own enormous clinical and laboratory experience. Under proper technical conditions and with controls, supplemented by such records as few men or institutions have compiled—nay, of which actually never have they even thought—the Author has recorded his observations. This text is faced by 110 photomicrographs (there is but a scant half dozen or so schemata and roentgen reproductions), each an "original." These photographs admirably are illustrative of what one who is an expert technician, and who knows what it is that he sees, can find when he makes an intelligent and serious effort at the microscopic study of the alimentary and biliary tract contents when such have been secured via the inlying "duodenal" tube in the upper alimentary tract or metapylorically placed. Below each photomicrograph is a crisp, explanatory legend.

Rarely has our profession been favored by a contribution holding this "here is the proof of things as recorded by the microscope and camera" form of instruction. Such photographic demonstrations actually place the burden of *disproving* Lyon's method of diagnosing pathology—particularly *early* departures from the normal—*via* duodenal intubation, squarely upon the shoulders of its critics. Until contrary evidence is submitted by opponents as skilled in technique and interpretation as is Lyon, very definitely, indeed, must stand his method and his deductions from the microscopic study of *freshly* secured and promptly examined material.

The text of this "Atlas" opens by drawing a timely analogy between what, several decades ago, diagnostically, constituted kidney or urinary passage disease from data available at examinations of the urine—*late* disease then—and what, since microscopy (and chemistry) is stressed, *now* constitutes the diagnostic findings—data which give us indications of *early* urinary system disease. Similarly, less than twenty years since, diagnosis of biliary tract disease came from recognition and evaluation only of facts derived from patients' histories and from physical examinations and meant but appreciation of *advanced* lesions. Indeed, apart from the recognition of malignancy and the cirrhosis, until the advent of "explorative" abdominal section and particularly since the introduction of the duodenal tube, as a diagnostic aid, what we now know as biliary tract disease, was regarded as only *gall-bladder* pathology. Those familiar with the subject will recall with this reviewer, that so recent as approximately ten years ago (even after Lyon and others, by employing the duodenal tube as a diagnostic aid some years previously, definitely had shown that but few instances of gall-bladder pathology are unassociated with gall-duct and liver changes) the contribution of Pratt and Stengel stressing how chronic affections of the gall-bladder and ducts are capable of causing such advanced pathology as cirrhosis of the liver, proved an important influence in establishing among internists (tho' not so widely among surgeons) that gall-bladder disease alone—in the presence or the absence of calculi—

rarely exists. This reviewer finds no mention of Lyon's work in Pratt and Stengel's contribution.

Briefly, but succinctly, Lyon discusses—and illustrates—often in the form of *axioms*, the significance, as shown by microscopic study, of what may be present in specimens secured through the duodenal tube. The normal and the abnormal are detailed in a most word-sparing summary. Emphasis is placed upon the recognition of cellular structures, bacteria, food remnants, parasites and crystalline formations in regards to *local* segments of the alimentary and biliary tracts: the oral cavity, the oesophagus, stomach, duodenum, gall-duets, gall-bladder, etc. From an unusual experience, controlled by careful records and made permanent by photomicrographs, the Author is able very decisively to establish certain criteria which, in the form of "axioms," mean to him not alone evidence of pathology but, by his methods, to *localize* that pathology and to gauge its degree in the regions considered. Lyon expresses well his ideas and, at perhaps a slight sacrifice of certain details, from his observations derives such "axioms" as "Excess cellular exfoliation means irritation of the mucous membrane of the zone from which such epithelial cells are derived"; "Increased pus cells mean inflammation"; "No unbile-stained epithelial cells recovered in duodeno-biliary aspirates can be considered derivable from liver, gall-bladder or bile ducts"; "Excess bacteria, freely distributed or in colony formation, mean infection, etc."; "A bacterial colony cannot be considered derivable from the biliary tract unless it is bile-stained"; "Increased mucus means *catarrh*"; "Excess crystals in a biliary tract drainage-sediment mean *formed* or *forming* gall-stones," and so on. Each "axiom" is elaborated upon from the viewpoints of error in observation, in technique, as to its pathologic significance and its diagnostic value. Thus, in very small space, Lyon presents a condensation of what is and has been helpful to him clinically from a systematic, microscopic examination of more than 280,000 "drainage" returns. It is upon this enormous material that the Author has built the foundations of his widely-known clinical and laboratory procedure. That he is justified in his employment of metapyloric, tube "drainage" of the biliary tract, diagnostically and therapeutically, seems well established. Certainly those of Lyon's critics who have worked amateurishly or have condemned his procedure upon second- or third-hand data, secured not alone from few patients but by unskilled or non-medical "assistants," should give pause to their vocalizings in the face of facts and so great a material examined and controlled over more than fifteen years.

Lyon includes in his discussion the very important observations that, in affections of the oesophagus, stomach and duodenum, expert microscopy of "wet," fresh material obtained *via* the duodenal tube, proves of valuable service in the diagnosis of both early and late lesions of those segments of the alimentary tract. Undoubtedly, with less inconvenience to the patient and without the employment of "test-meals" likely to confuse microscopic examination, and without the introduction of annoying, large "stomach" tubes, Lyon's procedure is worthy of wider appreciation and employment than is common. Examination of "fasting" contents for the recognition of cellular structures, bacteria, etc., long has seemed to the reviewer to be of importance far greater than is "tubing" with the object of determining "acidity" and ferments—factors

which now we know widely fluctuate even in digestively sound persons (recently so strongly emphasized by Hellebrandt, *American Journal of Digestive Diseases and Nutrition*, September, 1935, page 402).

The text section of the "Atlas" concludes with a thorough discussion of the recognition and the significance of parasites, crystals and food particles recovered at tube "drainage" and detected by microscopy. The pages devoted to this subject alone are invaluable, particularly as long experience has shown to the reviewer that, all too often, even so-called "experts" pass lightly over the meaning of residues of the class mentioned or they fail entirely to recognize what the residues are!

The *illustrations* constitute, perhaps, the most valuable part of Lyon's "Atlas." Certainly, the collection, grouping, assembling, mechanical effort and the devising of legends to fit both text and pictures must have been a soul-trying task. It is an achievement, technically, which excites one's enthusiastic congratulations to the Author. It was this collection of photomicrographs, when shown in the Scientific Exhibition at the 1935 Convention of the American Medical Association, which is responsible for the issuance of the "Atlas." So great was the interest in Lyon's demonstration and so persistent were the demands by physicians who visited the exhibit that *somewhere, somehow*, what Lyon had accumulated be made available to others for leisurely study and for their guidance, that the "idea" of issuing the photomicrographs with explanatory text, was conceived. That the difficulties to be overcome were formidable was recognized, as also was the fact that since no publisher would undertake such highly specialized work, the Author and his assistants wholly must be relied upon. This meant that, in whatever form these photomicrographs became available, of necessity, the output definitely must be limited—especially if each "print" was to be an "original" and each picture must be placed in any "book" by hand. The required financial outlay seemed prohibitive when it was considered that but few books could be issued.

However, with characteristic ingenuity, patience and hard work, Lyon overcame the seemingly impossible. The result means the issuance of approximately only 100 "Atlases" but assures also that whoever becomes the fortunate possessor of a copy, has at hand, unquestionably, the finest and most complete collection of photomicrographs of material secured from the upper alimentary tract and from the gall-bladder and biliary passages, as yet, extant. So beautiful and instructive are these pictures that we venture to prophesy that, for many years, reproductions of them will appear in standard texts or in books concerned with special phases of gastro-intestinal and biliary tract disease. Apart from the value of these photomicrographs, as they elucidate the text of this "Atlas," each very readily could be reproduced as a lantern-slide and the whole, in such fashion, would form a collection of very great value in the instruction of medical students and of laboratory workers.

It is not possible by words to describe the beauty or the comprehensiveness of these photomicrographs: they must be seen and studied if one is to realize, adequately, their technical perfection in a most difficult field, their instructiveness and too, the tremendous amount of effort which, personally, the Author must have been compelled to give to the selection of the

original specimens, the grouping to serve his purpose, their arrangement in association with legends and text and, finally, to completeness in the field discussed. Although Lyon, himself, has had several hazardous experiences with the abdominal surgeons, one may not contemplate this "Atlas," the latest of his numerous important ventures into medical authorship, without feeling strongly, that whatever the surgeons may have done to him, they did not deprive him of his "intestinal fortitude." The reviewer has scrutinized critically each of the photomicrographs in this unique collection and has been unable to find a "poor" one. What this means will be appreciated by those who have attempted photomicrography with "wet" specimens—mostly unstained—when we mention that the illustrations include epithelia, salivary corpuscles (and of *lecithin liberated from suck!*), myelin threads, pus cells, various bacteria, algae, bile-duct "casts," crystalline formations, protozoa (wonderful groups of giardia), (some perfect at  $\times 1600!$ ), strongyloides, and practically every common form of food cell. Even if there were no "text," Lyon's "Atlas" would be a monumental achievement.

Doubtless, this work will serve as a model for the issuance of similar volumes, particularly in specialized fields of endeavor. To the reviewer, publications of this character sorely are needed, especially by physicians and investigators who have "passed the first grade." More than ever, what is desired (as did the Members of the American Gastro-Enterological Association who travelled to Philadelphia on that hot day in May, 1920, to "look over Lyon's shoulder") is fewer huge textbooks whose contents have been assembled from many sources by the plugging, but rarely brilliant, type of "author," but more and briefer texts which represent

what one clinician or investigator has found he can depend upon—and such books actually planned and written by that person. Our shelves are laden with what purported to be the "latest and most authoritative" and yet, on examination, proved "just another compilation"—hence, remains decorative, perhaps, but rarely used. Our money outlay for that kind of book runs into startling dollar-figures: when we "pass on," the volumes rarely sell for as much as twenty-five cents each, if at all! The crying need in medical literature is for books which bear the stamp of personality, individual effort, first-hand knowledge, pioneering, usefulness, and which do not attempt to cover so much ground that one knows, instinctively, that not even a Nicholas Senn could have been sufficiently versatile as to have been "an authority" on so many varied topics.

Lyon has given us a "path finding" book, every page of which bears the stamp of personal effort, careful and controlled clinical and laboratory experience and conservatism, yet sufficiently daring to venture into what, seemingly, will be common knowledge a decade or two hence and, above all, a series of illustrations which demonstrate the unquestionably valuable discoveries of his pioneering.

Whatever may be the cost of this type of book, always it will be worth what one pays. The regrettable feature is that an "Atlas" such as that of Lyon's must be an issue limited as to number available. Fortunate, indeed, is he who secures a copy!

Frank Smithies.

N. B. The reviewer paid the full price: he would have felt it an imposition had he accepted an "Atlas," gratis, "for review." Also, he would have regretted that by so securing a copy, one person would have lost the opportunity of buying one.

## SECTION XI—*Societies, Programs and Proceedings*

### Report on the First International Congress of Gastro-Enterology Held at Brussels, Belgium

THE Belgian Society of Gastroenterology has been in existence for some years; likewise the periodical the "Journal Belge de Gastro-Enterologie." About a year ago, largely through the activities of Dr. Georges Brohée, a gastroenterologist in Brussels and the Editor of the Journal, the interests of these were pooled and the International Congress was born. The officers and Honorary Presidents representing the various countries were selected and contacts were made with prominent men throughout the world. The Presidents of the different gastroenterologic societies, 22 in number, were appointed as "Patrons." As part of Belgium's activity in connection with the national exposition, the occasion was propitious for congresses of various kinds to be held in Brussels. Dr. Brohée was

the moving genius and organizer to establish one on gastroenterology, which was held in Brussels, August 8th to 10th inclusive under the presidency of Dr. Jan Schoemaker of The Hague.

With the exception of nearby France, the largest delegation from any foreign country came from the United States. Most of these came from the Eastern part of the country, the South and West not being represented. In this country propagandic work for the Congress had been going on for some months. At the last moment, the United States appointed a committee of 9 all of whom were members of the American Gastroenterological Association headed by a retired Army Medical man who was an otolaryngologist. Representing the two national gastroenterological or-

ganizations here, there were 17 from the National Society for the Advancement of Gastroenterology, 5 from the American Gastroenterological Association, 3 who belonged to both organizations, and 10 who belonged to neither of them: all together 32 Americans.

The Committee of Organization consisted of five members. These met with committees of like kinds from different countries, formed a permanent organization, adopted statutes, and selected Paris, France, as the place of the next Congress to be held in 1937. The official languages selected were English, French and German.

At Brussels no American had been selected for the main papers; 5 entered into the discussions. The subjects considered were Gastritis and Ulcerative Colitis. It being the first congress, run without a permanent organization and with no guiding experience, there were omissions in the way of arrangements for exhibits, unbalance in representations, absence of interpreters, etc., but no doubt these will be provided for in future Congresses. The enthusiasm and spirit however ran high and the Belgian medical men displayed themselves as excellent social hosts to the visiting medical men and their ladies as well. The American authorities most mentioned in the papers read and the discussions were Doctors W. Beaumont, W. J. Mayo, M. E. Rehfuess, M. Einhorn, H. Bockus, A. Basler, J. Bank, F. D. Ackerman, E. B. Benedict, W. Allen, R. H. Cheney, C. C. McClure, B. Crohn, E. S. Judd, G. W. Nagel, A. B. Rivers, I. W. McRoberts, M. E. Steinberg, W. Alvarez, Lynch and Felsen, M. Paulson, A. Bagen, M. Rosenou, and S. Flexner.

In this country with the advent of abdominal surgery, roentgenology, bacteriology, etc., we have gotten away from an interest in gastritis as a subject. This has not been so with the European gastroenterologists, and since Minot and Murphy's work, attention to deficiency disorders, and the possible connection of gastritis with ulcer and carcinoma, real attention to gastritis has been reestablished here. The use of the Wolf-Schindler flexible gastroscope has added stimulus to this.

Dr. A. F. Hurst of England, drew attention to the exceptional frequency of chronic gastritis, the inflammatory changes seen in ulcerated stomachs, suggested that chronic gastritis may be an underlying cause of carcinoma, the importance of alcohol and the continuous use of purgatives as particularly important in the causation of chronic gastritis, the significance of "elimination gastritis" from products administered outside of the stomach, the relationship of gastritis in the production of diseases of the liver and gall-bladder, and the significance of gastritis occurring after gastric operations due to invasion of bacteria into the anacid remaining portion of stomach.

Prof. H. H. Berg of Hamburg, brought out the limited value of the X-ray in the diagnosis, in which relief changes, severe and deformed, plastic thickness due to hypertrophy and oedema and non-malignant neoplastic rigidities were important. Hypertrophy of the rugae, he believed, was only of value when accompanied by consistent changes, that spasms were largely the result of swelling states, and that great care and considerable experience were necessary so as

not to suspect a carcinoma when only a gastritis was present.

Dr. Francois Moutier's of Paris, contribution on the anatomic pathology of gastritis was exceptionally able especially in the micro-pathology. He showed the frequency of the acute, subacute and chronic processes existent at the same time in various parts of the same stomach, the occurrence of epithelial erosions, the differing pathology of the glands, and the associated degeneration of all the structures that make up the stomach as an organ. He held that hypertrophic reactions of the epithelial cells of the lining or acini are less common than believed, that the mucosa tends to change by localized necrosis and fibrosis, that the gross appearance of the mucosa in diagnosing hypertrophy or atonic states should not be made without histological study and this ruling in the use of test meals as commonly studied, the X-ray and the gastroscope.

Prof. Lion of Paris, discussed the value of test meal examinations from the standpoints of the volume of secretion and concentration abilities especially in connection with the hormone excitants of gastric secretions and enzyme values in diagnosis. He scheduled the values in functional and syndrome states and the ease by which the chemism can be altered by various agents such as medications, various functional and emotional disturbances even for long periods of time.

Prof. G. E. Konjetzny of Hamburg, presented the surgical aspects of the subject. In this he drew attention to the symptom-complex of gastro-duodenitis being non-recognized and often diagnosed as ulcer and that gastro-duodenitis requires distinctly more study and attention than is being paid to it. He believed that surgery in chronic gastritis should be confined to localized polypoid swelling of the mucosa in which there is suspicion of malignancy and to the various forms of non-malignant hypertrophic stenosis which in the large majority of cases are sequelae to chronic gastritis. Another paper on the surgery of the subject was presented by Dr. H. Paschoud of Lausanne, which summarized the entire subject of gastritis.

Prof. F. G. Mones of Barcelona, presented the pathology in connection with Prof. P. Domingo Sanjuan who added the bacteriology of ulcerative colitis. Their beliefs were that this disease was toxic-infectious in etiology in which the most important offender is the streptococcus. While attaching importance to the Rosenow-Bagen so-called "diplostreptococcus," which they found commonly in healthy intestines, from its action on haemoglobin, cultural characteristics and bio-chemical qualities, they claim is identical to the *streptococcus mitis*, it being only a secondary variety according to the classification of Brown's. While these organisms and the majority of the diplostreptococci found in ulcerative colitis have a pathological effect on rabbits, in healthy individuals they are innocuous. It was claimed that, when in the very occasional human, they produced lesions it was by effect on the mucosal chorin, the lesions not being in any way characteristic of the disease. Currettings of the mucosa of patients with ulcerative colitis and the intravenous inoculations of salt solution filtrates made with a Chamberland L (3) filter produced a disease in rabbits similar to the inoculations of pure cultures. They therefore felt, as

Bassler had drawn attention to, that a filterable virus may be the cause of the disease, a virus that may at times be found in healthy individuals. They stated that their experiments very much diminished the value of the conception that the diplostreptococcus is the only cause of the disease. Judging by analogy of *B. tuberculosis* injections in Guinea pigs, the anaerobic organisms are enhancers of virulence. They concluded their presentation with the following statement: "The treatment is not very successful and until now we cannot do much more than work against the symptoms; a specific treatment does not exist." Prof. I. Snapper of Amsterdam, claimed that the causative agent was unknown even though a typical clinical picture of the disease exists. He felt that any form of treatment, including the biologic, should not be viewed optimistically, rest in bed, strengthening, and easily digestible diets with heat on the abdomen being the most worth while. He cautioned against believing in the curative effect in the use of drugs, lavagings and vaccines, and that almost all cases in which the ulceration is limited to the rectum and descending colon have a good prognosis under any form of treatment—thus the cure of such a case cannot be regarded as proof of the efficacy of any particular drug or method. When the right colon is definitely involved no method has much effect, this explaining why the collaboration of the surgeon is so often required.

The paper of Dr. Dall'Acqua of Milan, was an excellent presentation of the X-ray diagnosis of ulcerative colitis especially in the roental studies of the early cases, for only in this way can the inflammatory alterations of the colon in the mucosal substratum be revealed. In this the reactional contractions of the muscular layers and the auto-plasticity of the mucosa occur in a way which gives definite roentgen patterns. He brought forward that different radiological pictures are seen in the same case at different times and different in various parts of the colon and different in the same part according to the influence of functional changes; this explains why one may have anything from the absence of classic pictures to the different characteristic pictures met with in the certain cases. He felt that characteristic pictures meant serious involvement.

Dr. B. Vintrup of Copenhagen, stated that the disease was first described by Wilck and Moxon in their lectures on pathological anatomy (London, 1875) and but little has been added to their original description of it. He drew attention to the denuded coats of the mucosa and submucosa being replaced by naked granulation tissue and claimed that the disease is primarily an affection of the mucosa involving chiefly the blood vessels and the connective tissue with masses of leucocytes at the edges of the ulcers, a zone of fibronoid necrosis, congested tissue containing polyblasts, and the mucosa rich in fibrocytes and fibrils but no conspicuous sclerotic processes. In the slow and chronic case the *muscularis* remains well preserved for a long time, but in the fulminating case it becomes quickly involved.

Prof. R. Goiffon of Paris, advanced that blood in the movements was the first stool finding and that modifications of the blood and urine are secondary and are the result of complications rather than due to the ulceration itself.

Prof. M. Donati of Milan, made the point that there were different forms of the disease, and that infectious and surgical conditions in different parts of the body (teeth, sinuses, gall bladder, etc.) should have attention in these cases. He felt that the various types of direct surgery were dependent upon the study of the case at hand and that total colectomy should be rejected. He believed in conservative surgery if it sufficed and that one should not be partial to any standard way or a single surgical procedure for all cases, some not doing well with ileostomy but far better with colostomy on the ascendans, transverse or even the left side. He preferred doing a right colectomy in one stage but using several stages on other parts of the colon.

These papers were discussed by 130 persons. Because of the small time possible, each discussion was so short that it was unsatisfactory especially so with the mixture of languages spoken. Since French was the dominant language of the Congress the discussion was rendered further unsatisfactory by the poor and hesitant French that most of the foreigners struggled with. The writer suggests to those who attend the future Congresses that they be familiar with French but speak at the medical meeting in their native tongue. Generally it was true that those who attended this Congress understood English and were anxious to hear it spoken. They would far rather have this, than be treated to a poor quality of their own language some of which must have been far more difficult for them to understand than would have been English. It should be stated that the Europeans deeply appreciated the large and representative delegation that came from the United States. It is to be hoped that one day this Congress will be held in this country and that we be given the opportunity to repay our Belgian hosts for the kindnesses extended to us.

Anthony Bassler, New York City.

DELEGATES ON THE PART OF THE UNITED STATES TO THE FIRST INTERNATIONAL CONGRESS OF GASTRO-ENTEROLOGY  
APPOINTED BY THE DEPARTMENT OF STATE,  
UNITED STATES GOVERNMENT  
Brussels, Belgium, August 8 to 10th, 1935

---

Lieutenant Colonel John H. Trinder, Chairman,  
Medical Corps, Retired, United States Army.

Dr. Henry L. Bockus, 250 South 18th Street, Philadelphia, Pennsylvania.

Dr. Russell S. Boles, Rittenhouse-Plaza, Philadelphia, Pennsylvania.

Dr. Max Einhorn, 20 East Sixty-third Street, New York, New York.

Dr. Sara Jordan, 605 Commonwealth Avenue, Boston, Massachusetts.

Dr. B. B. V. Lyon, 2031 Locust Street, Philadelphia, Pennsylvania.

Dr. William Gerry Morgan, 1801 Eye Street, Washington, D. C.

Dr. De Witt Stetten, 850 Park Avenue, New York, New York.

Dr. Franklin W. White, 322 Marlboro Street, Boston, Massachusetts.

REPORT ON THE ANNUAL SESSION OF THE  
AMERICAN PROCTOLOGIC SOCIETY,  
JUNE 10, 1935

The Atlantic City meeting was the largest in the history of the Society with a total of 218 members and guests present. 70% of the Fellows and 64% of the Associates attended the sessions.

*The following Associates were elevated to Fellowship:*

Dr. Jesse Hall Allen, Philadelphia.  
Dr. James Kerr Anderson, Minneapolis.  
Dr. Harry E. Bacon, Philadelphia.  
Dr. Karl Brucker, Lansing.  
Dr. Emor L. Cartwright, Fort Wayne.  
Dr. A. W. Martin Marino, Brooklyn.  
Dr. Frederick G. Smith, Philadelphia.

From a very large group of applicants, the follow-

ing were selected for Associate Membership in the Society:

Dr. Hulett H. Askew, Atlanta.  
Dr. Hugh Beaton, Fort Worth.  
Dr. F. B. Bowman, Hamilton, Ont.  
Dr. E. A. Daniels, Montreal.  
Dr. Geo. F. Eubanks, Atlanta.  
Dr. Benjamin Haskell, Philadelphia.  
Dr. E. J. Lynch, Detroit.  
Dr. S. D. Manheim, New York.  
Dr. W. J. Martin, Louisville.  
Dr. J. P. Nesselrod, Rochester, Minn.  
Dr. John C. Noss, Altoona.  
Dr. R. A. Scarborough, San Francisco.  
Dr. M. S. Woolf, San Francisco.

The 1936 meeting will be held in Kansas City in conjunction with the A. M. A. next May. Dr. Frederick B. Campbell will be Host to the organization at that time. Kansas City, in the heart of America, is accessible to all portions of the country and there is every prospect of a splendid attendance.

Curtice Rosser, Secretary, Dallas.

## ABSTRACTS

HINTON, J. WILLIAM, AND CHURCH, REYNOLD B.

*The Incidence of Gastrojejunal Ulcer Following Gastro-enterostomy.* S. G., and O., 60:65-73, Jan., 1935.

During the five year period beginning Jan. 1, 1928, the Gastro-Enterological Clinic of the Fourth Division of Bellevue Hospital admitted 583 cases of peptic ulcer, 143 of which had been previously operated upon. Of this latter group 79 had had gastroenterostomies and 13 of these patients (16.4%) presented marginal or gastrojejunal ulcers. The reports of these 13 cases are adequately and concisely presented by the authors. One patient had two gastroenterostomies performed and developed a marginal ulcer after each operation. Another patient who developed a marginal ulcer after a gastroenterostomy submitted to a gastric resection and yet 1½ years later showed another marginal ulcer. The authors' plea for a ten year follow-up is endorsed by the fact that in three of the cases symptoms did not develop until seven years or more after the operation. They attach little dependence upon a follow-up letter because of the periodicity of symptoms presented and prefer a frequent personal examination. Conservative medical treatment is recommended as long as it affords symptomatic relief. Continued severe pain generally means perforation into some adjacent viscus and is therefore the chief indication for operation. Six of the 13 patients reported required operation of some type. The medical treatment used included the Sippy routine, gastric mucin, Saunder's streptococcus vaccine, intravenously, and in one case aolin, subcutaneously.

J. Duffy Hancock, Louisville.

WILBUR, DWIGHT L., AND OCHSNER, HAROLD C.

*The Association of Polycythemia Vera and Peptic Ulcers.* Ann. Int. Med., Vol. VIII, p. 1667, June, 1935.

After a review of the literature on the association of polycythemia vera and peptic ulcers, beginning with the first report published in 1905 by Weber and Watson, to 1934, when Boyd reported a case, the authors summarize by stating that not all writers have been able to concur in the opinion that duodenal ulcer and polycythemia are frequently associated. Doubt as to the accuracy of the diag-

nosis of polycythemia vera in some of the cases covered by the literature is expressed, the belief being entertained that some of them were cases of concentration polycythemia or polycythemic hypovolemia. Reference is made to a suggestion that both of these diseases appear to be a result of disturbance in secretion of epinephrine, that polycythemia is relative or secondary to a loss of fluid and that duodenal ulcer associated with hyper-secretion results in an excessive production of an intrinsic hematopoietic factor and that the occurrence of ulcer is a result of a thrombosis of blood vessels in the mucosa of the stomach and duodenum. In all, the authors studied 143 cases of what they termed proved polycythemia vera, the basis for such proof being elevation of the erythrocyte count and the hemoglobin content above normal values, increase in viscosity and volume of the blood and a hematocrit reading indicating a higher percentage of erythrocytes than the normal value of 45 to 48 per cent. Patients represented in the group were closely observed over a considerable period, hence the opportunity for discovering gastro-intestinal symptoms was considered good. In another group of 143 cases 1114 gave no history suggestive of gastro-intestinal disease; 17 cases were subjected to roentgenologic examination of the stomach and duodenum and no pathological process was disclosed; in 12 cases there were roentgenologic or pathologic evidences of peptic ulcer. The ulcer was located in the duodenum in 10 of these cases and in the stomach in 2. Of the 10 duodenal ulcer cases one was diagnosed at post mortem, 9 were demonstrated by X-ray examination. In 7 cases the history of ulcer antedated the history of polycythemia vera by periods varying from one year to 21. Singularly, of the two cases with gastric ulcer, one gave no history suggestive of ulcer, the lesion being an accidental finding post mortem. In the other case symptoms had obtained for four years and polycythemia symptoms for about two. The study of the acidity contents of the stomach in patients of the group with polycythemia disclosed that of the 24 cases so studied only one showed a marked increase in hydrochloric acid. Four cases showed moderate increases, 16 had acid values within normal limits and 4 had low or

no free hydrochloric acid. In all cases of polycythemia without ulcer high acid values were not found. The authors comment on the problem of a relationship between changes in the gastric juice and an elevated red cell count. Attention is called to the variation in incidence of healed or active ulcers discovered at post mortem, the figures ranging between 10 and 20 per cent. They thought that the incidence of ulcer of the stomach or duodenum in cases studied for all classes ranged between 2 and 3 plus per cent. In the group of proved *polycythemia vera* studied by the authors, 8 per cent showed X-ray pathologic evidence of peptic ulcer, but inasmuch as all of their patients with *polycythemia vera* were not studied to determine the presence of ulcer, an accurate estimate of percentage of the association of the two diseases cannot be made. The authors suggested that *polycythemia vera* may belong to a group of diseases including tumors of the brain and spinal cord, diseases of the prostate, chronic nephritis, chronic cholecystitis and diseases of the thyroid gland in which gastric and duodenal ulcers are more frequently seen at necropsy than other conditions. On account of the relationship that exists between the secretion of certain constituents of gastric juice and the activity of bone marrow, interest is expressed in the speculation that disturbances of gastric function may be of importance in either the production or the continuation of *polycythemia vera*. They conclude with the statement that there seems to have been little to support the hypothesis that production of an excessive amount of hematopoietic factor may be responsible for increased formation of red cells and that repeated loss of gastric juice by removal has resulted in a decrease of the red cell count. Neither were they able to determine with definiteness the relationship of thrombosis of duodenal vessels to the development of duodenal ulcer in patients with *polycythemia vera*, though the tendency of polycythemic blood to form thrombi is well known.

Virgil E. Simpson, Louisville.

WADHAMS, R. P., AND CARABBA, V.

*Electrosurgical Aseptic Intestinal Anastomosis. S., G., and O., Vol. 60, No. 6, pp. 1082-1092, June, 1935.*

The authors present the experimental technique, pathological physiology and some suggestions as to the application of aseptic intestinal anastomosis by electro-surgical methods.

The intestinal loops to be anastomosed are approximated by a seroseros continuous suture of 20 day No. 00 chromic catgut. With the bipolar electrode attached to a 1000 millampere coagulation current the tissue is coagulated along a line parallel to the line of suture. The coagulation points must enter the intestinal wall about 1 centimeter away from the line of suture; they should begin about 1½ centimeters proximal to the ends of the suture line. The tissue between and around the coagulating points turns white and then pale grey in color indicating that the optimum point of coagulation has been reached. The coagulated areas are apposed by several Lembert sutures of plain catgut and the seroseros suture completed around the anastomosis. After seven days the coagulum has sloughed away, the anastomosis is functioning and healed. The line of anastomosis usually contracts about one-third of its length.

Specimens studied at 24, 48, 72 hours and 8 days after operation showed that the slough had separated after 48 hours; the edges of the anastomosis showed healthy granulation after 72 hours. In 8 days the mucosa is completely regenerated throughout the anastomosis.

The authors have used this method in making anastomoses between the duodenum and the colon, and between various other parts of the intestinal tract in the dog. In one case they successfully anastomosed the ureters to the colon in the dog.

They propose the operation for all types of side-to-side anastomoses as done in man, and particularly in the obstruction type of resection of the colon in which operation

this procedure done at the time of the first operation will obviate the necessity of applying the Mikulicz clamp later. Nine figures accompany the article.

N. M. Percy, Chicago.

REES, C. E.

*Anterior Gastro-enterostomy by the Short Loop Method. S., G., and O., Vol. 60, No. 6, pp. 1125-1128, June, 1935.*

The author presents a short loop method of anterior gastro-enterostomy which offers the advantages of the posterior gastro-enterostomy and avoids some of the disadvantages of the classical anterior operation.

The gastro colic ligament is cut near the greater curvature of the stomach and the transverse colon is elevated above the stomach. An avascular area in the transverse mesocolon is located and incised sufficiently to allow room for the anastomosis. The edges of the incision in the transverse mesocolon are sutured to the anterior wall of the stomach and the anastomosis made between that area in the stomach and the uppermost part of the jejunum. After the anastomosis is completed the colic side of the gastro-colic ligament, first detached from the stomach, is sutured to the anterior wall of the stomach. The abdomen is closed without drainage.

Three figures accompany the article.

N. M. Percy, Chicago.

GEORGE DE TARNOWSKY, M.D., AND P. JOSEPH SARMA, M.D., Chicago, Ill.

*The Surgical Treatment of Chronic Pancreatitis. Annals of Surgery, June, 1935.*

The authors state that a bare generation ago, chronic pancreatitis was considered a rarity—or its entity denied by internists. Opie taught that its symptoms were so indefinite as to make it impossible of preoperative diagnosis intra vitam. As clinicians began to grasp the all important fact of the close interrelation which exists between the liver and its biliary tract on the one hand, and the pancreas with its ducts on the other, dysfunctions of the latter organ began to assume greater importance.

In disturbances of a gland having such varied and all important functions as has the pancreas one would—a priori—be justified in assuming that clinical revelations would be many and almost pathognomonic. Unfortunately, the only two striking clinical manifestations are fat necrosis and pancreatic hemorrhage, both present in the severest of cases, both demonstrable only at the time of surgical intervention. The authors analyze 30 cases of chronic pancreatitis, illustrating the extreme difficulty of making a positive preoperative diagnosis.

Clinically, the authors divide pancreatic dysfunction into three main groups:

(A) Disturbances of external secretion interfering with the digestive apparatus in the subacute or chronic types, or producing autolysis in the fulminating cases of pancreatic apoplexy.

(B) Disturbances of internal secretion leading to glycosuria.

(C) Carcinoma of the head of the pancreas.

The authors feel that direct continuity to gastric or duodenal ulcers plays an occasional role as an etiological agent in chronic pancreatitis, and they believe that repeated, subsiding attacks of pancreatitis are, at least in the vast majority of cases due to the entrance of bile into the pancreatic duct or ducts and that as long as normal bile from the gall bladder is discharged thru the common duct into the duodenum, no pancreatitis will result. As other positive etiologic factors, they mention arteriosclerosis, cysts or tumors of the pancreas, alcoholism, tuberculosis, syphilis, hemochromatosis and hepatic cirrhosis.

In dealing with symptomatology and the difficulty in establishing a diagnosis of pancreatic pathology they quote J. W. Hinton, "The pancreas is the only intra-abdominal

organ that produces symptoms of a chronic surgical nature that physical examination, roentgenologic or laboratory studies will not aid in establishing a diagnosis except by negative findings."

The authors state that cholecystostomy with prolonged drainage is the operation of choice in chronic pancreatitis—thus agreeing with Gask, Mayo-Robson, Moynihan, Cambridge, Gosset, Petit-Dutallis, Hartman, Hey-Grove, Deaver, Finney, Horsey, Archibald, Cecil, Osler and others who make the same recommendation.

They also advocate choledochotomy to relieve the pancreatic dysfunction in cases where there are valid indications for cholecystectomy.

Charles T. Sturgeon, Los Angeles.

BLALOCK, A.

*Experimental Studies on the Effects of the Perforation of Peptic Ulcers.* S., G., and O., Vol. 61, No. 1, pp. 20-26, July, 1935.

The author performed experiments designed to determine the factors which are responsible, in the main, for the early severe signs and symptoms of perforation of ulcers. Bile, pancreatic juice, gastric juice, and duodenal secretions were obtained by cannulating the various structures. Those juices were then injected with a syringe and needle into the peritoneal cavities of other dogs, and the effects noted.

The following results were obtained: (1). Following the injection of large amounts of one or more of the upper intestinal juices, the animals became ill almost immediately. (2). The injection of sterile pancreatic juice in large amounts produced very little reaction. Infected pancreatic juice in smaller quantities caused death. (3). The injection of bile produced immediate and severe reactions, but only one died. The reaction to bile was much more severe than that to pancreatic juice. (4). A mixture of bile and pancreatic juice causes a reaction more severe than the same quantity of either juice alone. (5). Quantities of gastric or duodenal secretions equal to those of bile injected did not cause death in any of 9 experiments. (6). All of the animals, which died as a result of the introduction of one or more of the secretions, exhibited marked reddening of the intra peritoneal structures. When mixtures of pancreatic juice and bile were injected there was massive fat necrosis. Large amounts of free fluid were found in the peritoneal cavity at autopsy, but that quantity alone was not sufficient to account for the marked decline in blood volume at time of death. (7). The earliest major changes in the cardio-vascular system following the injection of bile and pancreatic juice were a drop in blood pressure and later, a marked drop in the cardiac output.

The author feels that the early circulatory failure may be classified as vasogenic, while the later stage is mainly hematogenic.

N. M. Percy, Chicago.

ROSSER, CURTICE.

"Cancer of the Anal Canal." *South. Med. Jour.*, 28:527-530, June, 1935.

General opinion locates the majority of rectal cancers in the ampulla but the author believes that most will be found to originate in the narrow rectosigmoid canal where the bolus enters the rectum or in the narrow anal canal where it leaves. In a study of 75 cases of rectal cancer, he found that 23.3% of the growths apparently had their origin in the anal canal. In the 25 cases of cancer of the anal canal where biopsy and follow up observation were attainable, 84% were found to have an associated benign pathological lesion—fistula, hemorrhoids, polyp, or cryptitis—which in the majority of the cases was believed to be primary with the malignancy developing at least partially as a result of long continued irritation.

The outstanding symptoms of cancer in various parts of the colon are described and differentiated, the character-

istic symptom of cancer of the anal canal being *localized* pain which is not true of growths elsewhere in the colonic tract. In spite of this and the accessibility of the lesion, the patients in this series came for treatment rather late. The end results were not satisfactory, due in part to the delay in diagnosis and in part to insufficient radical surgery. It is suggested that more careful attention be given to complaints of "rectal trouble" and that treatment should consist of wide resection rather than radiation alone or with local excision.

J. Duffy Hancock, Louisville.

ERB, M. B., AND FARMER, A.W.

*Ileocolitis.* S., G., and O., Vol. 61, No. 1, pp. 6-14, July, 1935.

The authors report and discuss four cases of a form of ileocolitis, heretofore not described, characterized by marked edema of the terminal ileum, ascending colon and Peyer's patches. Clinically, the condition is indistinguishable from acute appendicitis. At operation the appendix is found to be normal, while the ileum and colon with their mesenteries are engorged and solidly edematous. Post-operatively the patients run a course characterized by persistent fever (up to 100.4 degrees F. in cases terminating favorably), some distention of the abdomen, and malaise. In cases terminating unfavorably the temperature rises to 104 to 106 degrees F. and a clinical picture simulating intestinal obstruction develops.

This condition is recorded as a new entity and its differences from other similar affections of the intestinal tract pointed out. From some of the cases the authors recovered an organism called *Bacillus W.* which showed positive agglutination reactions with the area of most of the patients tested. While the etiology of this condition is obscure, the authors feel that it may be a phase of the condition called "chronic cicatrizing enteritis" or "regional ileitis."

N. M. Percy, Chicago.

J. A. BARGEN AND E. T. LEEDY.

*Carcinoma of the Rectum.* *J. A. M. A.*, 104:1210, April 6, 1935.

Two hundred patients with carcinoma of the rectum were interviewed by the authors. The purpose of the study was to find out the reason for the poor prognosis in rectal cancer.

Ninety-two patients had consulted a physician within a month from the onset of symptoms. The others waited from two to twenty-four months after the onset of their trouble and until their own treatment had failed, before consulting a physician.

The earliest symptoms in the whole group were bleeding, then pain, then constipation and lastly diarrhea. Most patients had combinations of these complaints.

Self medication was the rule among these patients. Diet, constipation remedies and "pile" cures were resorted to.

Rectal examination was not made by the first physician consulted in many of the cases. The patients in many instances objected to such an examination or the physician did not wish to hurt the patient. In many instances palliative treatment gave relief and the patient did not ask for further examination and care.

Therapy was further delayed because of the hopeless attitude with which operations for rectal carcinoma have been regarded.

Results from operation for rectal carcinoma will improve as patients consult physicians earlier, also with more widespread employment of the digital examination among physicians and as knowledge spreads as to the safety and satisfactory results from operative intervention.

Francis D. Murphy, Milwaukee.

# CANNED FOOD IN INFANT NUTRITION

## II. Strained Foods

● During the first few months of life, breast milk or modified cow's milk, properly supplemented, is the major article of food in the infant dietary. In later infancy and early childhood, however, it is desirable that other foods be included to supply the increasing demand for food essentials in which the milk diet is inherently deficient.

Modern practices in infant nutrition, while similar in broad aspect, may differ in detail. The first addition to the supplement milk diet is usually that of cereals or cereal broths. Later, strained vegetables and fruits, valued for their contributions of iron and cellulose materials, are included. Finally, other foods, such as egg yolk, broths and soups, are added to the dietary at the discretion of the physician.

Especially designed and well suited for use in this phase of infant nutrition are the canned strained foods. Manufacturers of such products are mindful of the fact that the highest possible standards as to quality and food values must be maintained—that endorsement or acceptance of these products by the profession can be obtained only after actual trial. Consequently, precautions are taken in the commercial procedures to retain in as high degree as possible the quality characteristics and nutritive values of the raw products used.

Only selected materials at the proper de-

gree of maturity enter into the manufacture of commercially strained foods. Within a few hours of harvesting, the raw products are subjected to preparatory operations such as cleansing, peeling or trimming. After preliminary heat treatments, the materials are strained through screens whose interstices are measured in the thousandths of an inch; filled into cans and the cans sealed, heat processed and cooled.

In the canning procedure a number of factors are favorable to the retention of certain fugitive food values. Among these may be included the use of selected, properly matured raw stock; the rapid handling of the harvested crop; the use of steam or a limited amount of water in preliminary cooking operations; the exclusion of air during pre-cooking and straining; the straining of the foods in the liquid in which they were cooked; and the heat processing in sealed containers from which most of the atmospheric oxygen has been removed.

Research has demonstrated that these factors operate effectively in the retention in high degree of food values in the canned strained products (1). Consequently, commercially strained foods or food combinations—readily available on every market—deserve a high place among foods adapted to infant and child feeding, not only from the standpoints of economy and convenience, but by virtue of their nutritive values as well.

## SECTION XII—"The Clinic"

### Unusual Causes for Symptoms of Biliary Tract Disease, With Case Reports

By

J. W. THOMPSON, M.D., F.A.C.S.  
ST. LOUIS, MISSOURI

STATISTICAL reports of end results in the treatment of diseased abdominal viscera frequently cause one to lose sight of the individual patient. The clinician, searching through columns of tabulated "percentages" is frequently disappointed and has a distinct sensation of inadequacy when he fails to find some assistance in the solution of a special case problem. An interchange of related case reports around a luncheon table often will provide the needed enlightenment which is notably lacking in the perusal of columns of figures. That master clinician, George Dock, once remarked to a group of students on a ward walk: "There are no diseases, only people who are sick." The student of statistics of end results compiled by the questionnaire method frequently has little comprehension of the actual status of individual trees in his forest of figures. The family physician or consultant "back home" is the more capable interpreter of end results after a period of observation sufficiently long, properly to evaluate therapeutic benefits. Therefore, the report of clinical observations on individual cases covering a long period of time would seem to be of some value.

There is no physician or surgeon who has not been plagued by the individual patient who did not get well and remain so following a surgical procedure. This is particularly true in the field of abdominal surgery, especially so in operative procedures on the biliary tract. "Operation can only be held responsible if the improvement persists for a period of years or if it becomes permanent"

(1). The amount of benefit generally corresponds to the degree of pathologic change in the involved organs. Synhorst (2) in a series of 300 cases presented data admirably substantiating this conclusion. Poor results were noted in 33.3%, four cases having minimal pathologic change. Even in cholesterosis of the gall bladder, the so-called "strawberry" might, in the mind of a patient who was unbenefited, be justifiably metamorphosed to "raspberry." In distinct contrast are the 93% good results in cases of marked pathologic change.

The causes of persistence of symptoms following cholecystectomy may be briefly enumerated as follows: stones in bile ducts, hepatitis, cholangitis, pancreatitis, trauma to the ducts with subsequent stricture, adhesions. The last mentioned item covers a multitude of excuses and "adhesions" have plagued both physician and patient from the beginning of history in abdominal surgery. It is only recently that the research of Ochsner and Garside (3), Trusler (4), and others had begun to throw some helpful light on the problem. Lacey (5) concluded that amniotic fluid concentrate does no harm but he was not convinced of definite benefit through its use. The experiments of Ochsner and Garside, based upon the work of Walton (6), who prepared a trypsin-papain combination, demonstrated in animals the value of the principle of injection of substances intraperitoneally in prevention of postoperative adhesions.

The following two cases are considered to be worthy of report because of the unusual nature of the conditions which were believed to have been the cause of the symptoms.

Sufficient time has elapsed since the operative procedure to justify the conclusion that to the operation in each case could be attributed the relief obtained by the patient.

*Case No. 1.* E. S. A spinster, aged 38. Came to this Clinic in February, 1929. Her complaint at that time was attacks of general abdominal pain more severe on the right side, and relieved by vomiting. The attacks were quite incapacitating and had occurred so frequently that she had been unable to follow her work as a milliner since 1920.

The patient's past history was of great interest. She had survived the usual childhood illnesses without complication. She had, however, in her adult life undergone numerous surgical adventures. In 1922, her hemorrhoids were removed and a uterine displacement corrected. She remained well for a year and another abdominal operation was done to remove a fibrous growth around her colon. Following this procedure she did not get along so well; required enemas of oil to relieve constipation. In 1926 she had been examined by a roentgenologist who diagnosed "colon trouble with gall stones." Again she submitted herself to surgical intervention and in November, 1926, the gall bladder was removed and abdominal adhesions "broken up." She recovered, but the attacks of abdominal pain accompanied by nausea and vomiting occurred at increasingly frequent intervals. She presented herself to us for relief.

Physical examination of the patient was of little help. She was already a battle-scarred veteran of several surgical campaigns. A careful study was made of her psyche in order to eliminate the possibility of

a "dyed in the wool" surgical neurosis, but after numerous interviews with the clinician and psychiatrist it was conceded that the patient was not the victim of neurosis or a malingerer.

Clinical laboratory studies were undertaken in the interim and may be briefly summarized as follows: Counting of blood cells. Wassermann, gastric analysis, examination of urine and stool, basal metabolic rate, and blood sugar estimation. All gave values within normal limits. Food allergy tests—not significant.

Roentgenologic examination of the stomach and intestines elicited the following information:

1. Evidence of adhesions about the duodenum.
2. Stomach emptied in five and three-quarter hours.
3. Strikingly atypical small intestinal loops.
4. Twenty-four hour ileal stasis.
5. Obstruction of the ileum, kink, highly characteristic of post-operative adhesions. Definite narrowing at point of obstruction with marked dilatation of the small intestine proximal to kink. There was definite tenderness over the cecum.

Cystoscopic examination and ureteral catheterization did not reveal any cause for slight urgency complained of by the patient.

Diagnosis: Partial Intestinal Obstruction and Constipation.

After a period of two months observation and study under careful dietetic and medical regimen without definite improvement, with some trepidation surgical intervention to relieve the obstruction was suggested to the patient. After careful thought she was reluctantly willing to submit, urged a bit by an attack of cramp-like pain accompanied by nausea and vomiting.

Operation—St. Lukes Hospital, April 18, 1929.

Pre-operative diagnosis: Partial intestinal obstruction.

Low-right rectus-muscle splitting incision. There were three distinct points of partial obstruction in the terminal ileum; the first being at the brim of the sacrum; the second to the right ovary; and the third deep in the pelvis, adherent to the pelvic colon. These areas were carefully dissected free and the raw areas covered with sterile olive oil (7, 8) in the hope of prevention of new adhesions

and points of obstruction. Exploration of the upper abdomen disclosed dense adhesions in the right upper quadrant binding all structures together.

*Subsequent course:* The patient's symptoms were relieved. The attacks of nausea and vomiting ceased. Post-operative roentgen examination of the gastro-intestinal tract revealed normal pattern in the small intestine which have been shown in illustrations of a previous paper (9).

Her nervous system suffered some shock due to the sudden cardiac death of her father shortly after her dismissal from the hospital. Since the same accident had befallen a favorite older sister, this event was interpreted as a possible cause of pain in the right upper quadrant which came in quite alarming attacks requiring mid-night visits and administration of hypodermic of morphine to give relief. There was vomiting of bile associated with the attacks, a slight elevation of temperature of 99.6° to 100° F.; a leucocyte count of 10,000; and on one occasion a faint icteric tint to the sclera. The attacks, so the patient stated, were almost identical with

## An Atlas on Biliary Drainage Microscopy

By

B. B. Vincent Lyon, M.D.

This album contains thirty-eight pages of explanatory text and one hundred and twenty photomicrographs of the various objects observed microscopically during a biliary drainage as part of the clinical study of selected patients.

The photomicrographs demonstrate exfoliated epithelial cells from the mouth, esophagus, stomach, duodenum and gall bladder; various types of mucus indicating catarrh; bacterial colonies indicating infection; crystals, suggesting gall stones; some of the upper intestinal and biliary tract parasites; and various food "rests" observed in gastric or duodenal stasis.

A considerable portion of the text is devoted to a description for their easy recognition, for their diagnostic interpretation, and for their clinical application. Such microscopy has often puzzled the well-informed, as well as the novitiate in gastro-intestinal work.

Each atlas is literally an original copy; attractively bound in black leather and is offered to a limited number of subscribers for educational purposes such as medical schools for student instruction; hospital or private laboratories for training of technicians in biliary drainage microscopy; or to such doctors as may be interested in gastroenterology.

Anyone interested in securing a copy at a price of \$25.00 plus postage charges may do so by mailing the following slip.

.....  
Dr. B. B. Vincent Lyon.  
2031 Locust Street,  
Philadelphia, Pa.

I wish to subscribe for ..... Atlas on Biliary Drainage Microscopy. Kindly mail by insured parcel post, to

Name ..... Address .....

Please note: Because each Atlas is made up by hand as an original copy, delivery cannot be made earlier than four months from receipt of order.

Check for \$25.40 must accompany order.

## TOXIC CONDITIONS

may be the organic trouble occasioning apparent symptoms in the gastrointestinal tract.

It is highly important to treat the effects of the gastrointestinal troubles adjunctly with the proper treatment of the Toxic Conditions. This is best accomplished through Bile Salts Therapy in the administration of

## TAUROCOL Bile Salts Tablets

## TILDEN HAS KEPT FAITH WITH PHYSICIANS

## MALTOPEPSINE (Tilden)

*For Prescription in Alleviating Digestive Distress and as a Vehicle for Administering other Therapeutic Ingredients*

Composition: Dioscorein, Lactic Acid, Diastase and Pepsin balanced with other ingredients in a manner exclusive with Tilden. **DECIDEDLY PALATABLE — RAPID RESULTS — ECONOMICAL**

### Gastric and Intestinal Upsets

For many years physicians have prescribed the specialties of The Tilden Company more than any others in the ethical pharmaceutical field, because Tilden has always kept them under the exclusive control of the medical profession.

Our Medical Information Department will be honored by physicians' requests. Inquire for the New Calberon tablet of Buffered Gluconate, adjunctive to Maltoprepine.

those she suffered before the removal of her gall bladder.

Thereupon, after consultation with the clinicians, again including a psychiatrist among them, surgical approach to the solution of the enigma was elected.

**Operation:** Operation on September 20, 1929, under ethylene anesthesia through an upper right rectus incision, disclosed a mass of dense adhesions with a complete distortion of all anatomical relationship. The round (falciform) ligament together with the duodenum was adherent to the lower costal margin. The duodenum was quite densely attached and twisted as a torque, pulling up the mid-portion of the common duct (Fig. 1). After careful dissection, freeing the adherent structures from one another, the common duct was explored. Clear bile found. No stones were discovered in the biliary ducts. A thin small Penrose drain was placed above and a second one below the gastro-hepatic ligament and her abdomen closed without further exploration. Immediate post-operative recovery—uncomplicated.

**Subsequent course:** The patient's symptoms were relieved and she remained well until September, 1930, when it became necessary to do a diagnostic D. & C. to rule out a possible malignant condition of the uterus as a cause of intermenstrual bleeding; microscopic examination of the uterine scraping was negative.

During the intervening five years the patient has been under frequent observation. She has had no more severe attacks, her complaints being those of minor ailments. The function of the colon has been only fair. She requires lubrication and an occasional saline cathartic to control constipation. She has entered into the menopause and symptoms of hot flashes are readily controlled and diminished in severity by the administration of ovarian hormones.

During the interim, the patient has been exceptionally cooperative—has carried on her work as private secretary to a minister, and in the opinion of the author, is not a sufferer from neurosis. There was an organic basis for her symptoms which have been relieved by a combined medical and surgical regimen covering a six year period of observation.

**Case No. 2.** Mrs. F. W., aged 42, housewife. Came to this Clinic

August 25, 1929. Her complaints were abdominal pain generalized but more severe across the upper abdomen. The pain was almost constant and had no direct relationship to meals or food. She had been slightly jaundiced one year prior to admission. Her appendix had been removed because of an acute attack. The surgeon had told her the operation was very difficult, due to her obesity, and required two hours to perform it.

**Family history:** She is the mother of a son who is a typical case of pituitary adiposity.

**Physical examination:** Entirely negative except for the observation that she was of the hypersthenic type with a suggestion of ovarian and pituitary obesity (weight 217, height 5'-6").

Clinical laboratory examination revealed normal condition of her blood (including Wassermann), complete blood counts, blood sugar. A cholecystogram produced no shadow of the gall bladder.

A diagnosis of cholecystic disease was made, possibly with stones obstructing the cystic duct. Operation was advised after medical management failed to relieve her symptoms during an attempt of ten months duration.

**Operation:** May 9, 1929. Cholecystectomy was performed under gas-ether anesthesia. The patient had been operated elsewhere previously when a transverse upper abdominal incision was made. A new longitudinal muscle splitting incision was made. Dense adhesions were encountered between the abdominal wall and the hepatic flexure, the colon and the falciform ligament. The gall bladder was kinked under torsion about 3 c.m. from the fundus with a definite point of constriction caused by pressure from the liver edge. The gall bladder in the proximal two-thirds was almost completely surrounded by lobulation of liver tissue (Fig. 2). This condition apparently produced definite pressure upon the gall bladder during the process of filling. The liver in the region of the gall bladder was moderately scarred from chronic hepatitis. The stomach and duodenum were normal in appearance and to palpation. The pelvic organs were normal. The abdomen was closed around a small Penrose drain placed in the liver bed formerly occupied by the gall bladder.

*Subsequent course:* The patient made an uneventful post-operative recovery and has remained entirely free of all symptoms for the past several years.

#### DISCUSSION

The first patient is an excellent illustration of the difficulties encountered by the clinician and surgeon in the management of those people who are not relieved of their symptoms by one surgical procedure. The patient in his misery frequently goes from one medico to another until his resources are exhausted or until he can no longer find a sympathetic ear. Psychiatrists are apt to sneer at the futile efforts of internists and surgeons to relieve such people, attributing their symptoms to some vague neurosis. Since the ascendance of the science of allergy, the surgeon must be even more cautious lest he be guilty of placing his indelible marks on the virgin abdomens of those who are possibly sensitive to everything from wheat to seal fur. Consequently it is of vital importance to conduct an extremely careful diagnostic search in those patients who have been subjected to abdominal surgical procedures and failed to find the promised relief. The services of clinician, surgeon, roentgenologist, psychiatrist, allergist, and spiritual advisor may need to be enlisted. On the other hand it requires great courage mixed with common sense to advise repeated operations when success is lacking after the initial attempt at relief. The gratitude of those patients who are finally relieved of their symptoms and restored to useful activities is balm to the ego sufficient to soothe the pangs of regret induced in the clinician whose advise occasionally proved to be wrong. There is no field of medicine or surgery requiring closer cooperation of various specialists with astute observation on the part of each than in the management of the patient who was not benefited by operation. Wisdom is required lest conditions are aggravated by ill-advised attempts to remedy the difficulties allegedly brought about by our surgical predecessors in their efforts to obtain a desirable end result. The permanent benefits derived by the cases presented in this report, after

a period of more than five years of observation, seem to justify reporting them in the hope that the diagnosis of "surgical neurosis" be not made without careful clinical studies and cooperative observations.

LEITHAUSER, DANIEL J., AND CANTOR, MEYER O.

*Lugol's Solution in Acute Secondary Parotitis. Annals of Surgery, Vol. 101, No. 5, May, 1935.*

The authors remind us that although acute secondary parotitis is a rare complication occurring in .03 per cent of a series of cases reported by Pique in 1907, in .04 per cent of cases reported by Beckman from the Mayo Clinic, and in .75 per cent of 135 cases of operations on the colon and rectum by Rankin and Palmer, never-the-less it is very important in that about a 50% mortality is recorded for it.

The authors give brief case histories of ten patients with acute secondary parotitis to whom they gave Lugol's Solution in large and repeated doses by mouth and by hypodermoclysis in saline with beneficial results. They gave from 15 to 20 minims every three hours over a period of from three to eighteen days.

They state that they were prompted to adopt this therapy knowing the beneficial effects of antiseptics which are eliminated through the kidneys in urinary tract infections and knowing that iodine is promptly and rapidly eliminated by the parotid gland.

Of the ten cases reported and treated with Lugol's Solution there were no deaths and only two went to abscess formation, one of which was drained thru incision and the other by repeated aspirations through a large calibre needle.

HENRY A. RAFSKY, New York.

*Injection Treatment of Peptic Ulcer (With Special Reference to the Use of Histidine Monohydrochloride). Med. Record, Vol. 142, No. 6, pp. 289-292, Sept. 18, 1935.*

Rafsky reviews in a critical way the experimental work on dogs by Weiss and Aron in which the deviation of the duodenal secretions into the lower end of the ileum regularly produced ulcer, two to four weeks after operation. Other findings resulting from the experimental operation were anemia, diarrhea and strong acidification of the intestinal contents. Weiss and Aron presented their theory of peptic ulcer, based on an amino-acid deficiency. The experimental ulcers were treated by daily injections of a mixture of histidine and tryptophane and proved cures regularly resulted. Eventually it was found that histidine itself was responsible for the favorable effect and consequently the tryptophane was eliminated.

Histidine is now available under the trade name of larostidin and consists of 5 c.c. ampules of a four per cent specially prepared iso-tonic solution of levorotary histidine monohydrochloride,

which is adjusted for intramuscular injection.

Rafsky used the larostidin treatment on 26 cases. He is very careful not to employ the word "cure," since his patients were under observation for only about 4 months and he considers a period of 5 years observation necessary before speaking of actual cure. The treatment is ambulatory, quick in action and requires relatively little dieting. Twenty-four of his cases were duo-

denal, one gastric and one marginal. Symptomatic relief occurred promptly in 73.3 per cent. The patients who did not respond were those with penetrating duodenal ulcer and niche deformity. Marked diminution of acidity almost to the point of anacidity occurred in 25 per cent of the cases. Pain was alleviated in comparatively short time. Improvement is accompanied by a definite gain in weight.

## SECTION I—*Clinical Medicine: Diseases of Digestion*

### The Experimental Study of Visceral Disease<sup>\*</sup>

By

DR. MARTIN E. REHFUSS

and

DR. GUY M. NELSON

PHILADELPHIA, PENNSYLVANIA

**T**WENTY-FOUR years ago one of us was impressed by the presence of visceral infection following the experimental injection of various pathogenic organisms into laboratory animals. In a relatively large series of animals, dead of bacterial infections, many forms of digestive pathology were noted. Some eight years ago, through the facilities of the Frankford Foundation for Medical Research, we were able to institute a study of the effects of ordinary pathogenic organisms encountered in visceral disease and their effect on laboratory animals.

The two groups of organisms which interest the gastro-enterologist are the colon group and the streptococcic group. The colon bacillus is of interest to every student of digestive pathology. It has been demonstrated that closely allied types of colon bacilli are normal inhabitants of the intestines of most lower animals. We all realize that this organism has its normal habitat in the large bowel but we are also impressed with the fact that the colon bacillus can be the subject of widespread pathology. Medical literature is full of references as to the ability of the colon bacillus to produce disease. Colon Bacillus Septicemia, discussed by Merry; *B. Coli* Sepsis by Keefer; *B. Coli* Pyemia by Enright and Baugher; Meningitis and Pyelitis are described by numerous authors while its significance in pernicious anemia is pointed out in communications by Whichels, Lucksch, Cohn. That it may induce renal lesions is discussed by Helmholz; gastric ulcer by Turck; cholecystitis by many authors and the same holds for appendicitis. The presence of the colon bacillus in the infant's stomach is mentioned by Pilosker and Rosenbaum; *B. Coli* in the small bowel by Bernheim and in the Digestive Tract by Tinozzi; while the importance of the colon bacillus in the urinary tract is attested by innumerable references on this subject in the literature.

Our attention has been called to this organism principally because it is found so frequently in the bile of duodenal intubation. We began our study with the aid of Crellin and Edson by studying four strains of the colon bacillus. These strains were isolated and prepared for us by Dr. Crawford, pathologist of the

Jefferson Hospital. *Strain A* came from a gall bladder removed at operation. *Strain B* came from the stool of a healthy individual. *Strain C* was obtained from colon bacilluria and *Strain D* from a case of colon peritonitis.

We immediately injected a series of animals with these four strains of organism and found *Strain A* to be far the most toxic. *Strain B* was less toxic but could kill the animal. *Strain C* was much less toxic so that it was practically impossible to kill a rabbit. *Strain D*, while undoubtedly toxic, was less so than *Strain A*. *Strain A* killed six animals in twenty-four hours and the *B. Coli* was found in every organ. *Strain B* killed only four in twenty-four hours and there was no septicemia, the organisms being found only in certain organs. *Strain D* killed five in twenty-four hours and the *B. Coli* was found in all the organs examined.

The most interesting thing about this series of observations was the difference in toxemia in animals of a given body weight. We then continued to use *Strain A* for our studies. At the end of three months, after the continual passage of *Strain A* through rabbits, this organism was able to kill the animal in a little over two hours. In other words, at the end of the summer, after *Strain A* had gone through more than 200 animals, 2 c.c. of this strain would uniformly kill animals weighing 800 Gm. in a little over several hours. One of the striking findings was the almost explosive effect of this strain on the stomach, producing hemorrhage and even perforation. If, on the other hand, the dose was sublethal the organisms were almost always found in the biliary tract on the one hand and the urinary tract on the other. If the larger dose was given, septicemia was the effect. When we injected a group of animals with this organism in much smaller doses the localization of the organism was almost invariably found in the biliary tract, liver and kidneys. The same thing was true when the organism was injected into the mesenteric system.

Another interesting experiment was to inject these organisms into the gall bladder. The organism was then invariably found in the duodenum but all cultures of the surrounding liver tissue were entirely negative for the presence of the organism. With more than 300

<sup>\*</sup>Read before the 38th Annual Session of the American Gastro-Enterological Association, Atlantic City, N. J., June 10-11, 1935. Approved by the Publications' Committee of the Association.

animals we were able to demonstrate the overwhelming tendency of all forms of this colon bacillus to strike the biliary tract, liver and kidneys. We were unable to produce chronic gastric ulcers, but with the highly virulent strain which killed rapidly, severe necrotic lesions were obtained in the stomach. We tried all forms of immunity but were unable to produce an immunity against this strain with dead organisms. On the other hand, we were able to produce by very small, graduated doses, an immunity which was sufficient to withstand the lethal dose of this organism in its most virulent form and cause a total disappearance of the organism in practically every organ in the body. In other words, Edson and Crellin, were able to obtain in their second series, by small, graduated doses of the living colon bacillus, immunity sufficient to withstand a dose which has been proven lethal for a rabbit of given body weight. Furthermore, it is apparent that this immunity is associated with some mechanism by which the colon bacillus is effectively combatted so that these immunized animals killed two days after the administration of a lethal dose fail to reveal the colon bacillus in every organ of the body which we ex-

Fig. 1

amined. Edson and Crellin were able to demonstrate agglutinative phenomena.

We then studied the colon bacillus from the standpoint of the complement fixation tests such as has been elaborated by Burbank, Kolmer and others. For this purpose we used seven different antigens. It is hardly necessary to go into the details of these studies except to say that the colon bacillus gave a positive reaction in 141 consecutive cases. Antigen 6 gave 88 positive, 37 negative. Antigen 8 gave 103 positive, 35 negative. Antigen 9 gave 119 positive, 19 negative. Antigen 11 gave 121 positive, 15 negative. Antigen 29 gave 120 positive, 10 negative. Antigen 32 gave 91 positive, 38 negative. Antigen 56 gave 66 positive, 19 negative. We studied these seven antigens with 52 cases of cholecystitis, the majority of which gave rather strongly positive reactions but in the control group of 19 cases, an almost equal number of positive reactions was obtained. The striking findings from the complement fixation tests, and we employed three methods in performing this test, was the fact that a certain individual reacted only to certain antigens. The large number of positive antigens argued against the value of this test but, on the other hand, the behavior of the blood serum of a given individual to respond only to certain antigens, strongly suggested that there were inherent differences in these colon groups.

Over the last five years we have had prepared 11 different colon antigens for skin testing and the same phenomenon was noted, namely the very large number of individuals who respond with a positive skin reac-

tion to colon antigens. This has been repeatedly stated in the literature. What is not apparent from this study however, is the frequency with which certain individuals show a marked skin reaction to certain strains in contrast with others. It is this peculiar behavior of the digestive invalid to respond differently to colon strains which suggests strongly the importance of investigating this problem more thoroughly.

Some of our experiences have been rather unique. One of us isolated a colon bacillus from biliary drainage and another, from the urinary tract, in the same patient. Separate vaccines were made from this patient of identical strength. The injections of the colon vaccine from the duodenum produced marked reactions in the cardio-vascular system with tachycardia and arrhythmia while the vaccine from the urinary tract produced a reaction in the urinary tract.

We used more than 300 animals for our colon studies but were unable to consistently produce with sublethal doses, a definite form of organic pathology. Certainly there was no preponderance of ulcer, cholecystitis, joint lesions, cardiac or renal disease. On the other hand the lethal dose produced some of the most pronounced acute digestive pathology that we have seen. We found that some of the colon strains showed slight changes in heat resistance and also alterations in growth on culture media to slight changes in the pH of the media. There is no question however as to the frequency of positive complement fixation tests and severe skin reactions in many digestive invalids who have nothing but colon stasis. The streptococcal problem is a much larger one because so many authorities have ascribed chronic, visceral infection to the activity of these groups.

We sent one of our technicians away for the summer of 1928 with the express determination of finding out how we could separate the pathogenic from the non-virulent streptococci. After passing the summer in two centers of advanced bacterial research, this lady informed us that the only way we could demonstrate or prove that streptococci were pathogenic was to inject them into laboratory animals. We then began a systematic investigation of streptococci from all available sources, injecting them into the rabbits, a strain of which we had at the Institute. To date we have used over 1300 rabbits, most of these being used for the injection of various strains obtained from every available focus in digestive invalids. Cultures of the nose, throat, teeth, sinuses, duodenum, bowel wall, feces and urine have been used.

To enumerate in detail these studies would require far more space than we have at our disposal. We began by taking the cultures of 41 strains of streptococci obtained from the throats of the patients in the Wards of the Jefferson Hospital. We were anxious to obtain a strain which would produce a typical ulcer of the stomach. This was our original purpose. We did produce various visceral lesions but we were unable to produce with any degree of uniformity, a gastro-intestinal lesion. We were able to produce gastric ulcer, cholecystitis in a relatively few cases, lesions of the intestinal tract, but the overwhelming majority of lesions were those confined to the joints, heart and kidneys. This work was largely done by Knox, Edson and Crellin under the direction of one of us. Of the first 41 strains obtained only five were definitely pathogenic for rabbits. One strain was extremely interest-

ing and this we called strain 24. This strain was recovered from the cervix of a woman with puerperal sepsis. It was again recovered from the uterus of the rabbit and it had an undoubted affinity for the joints, heart and kidneys. It was a hemolytic streptococcus. When we first studied this strain it produced arthritis in three weeks in laboratory animals. At the end of the summer, three months later, this strain produced an arthritis in about seven days. During that particular summer we used again some 300 animals and finally used this strain alone in an attempt to produce immunity. We attempted immunity in several ways: One—with the subcutaneous autoclaved vaccine. Two—with the subcutaneous living vaccine. Three—with the intradermal living vaccine. Four—with the intradermal, autoclaved vaccine. Five—with the Besredka skin

other words, we were able to obtain a group of antigens which were fairly successful in bringing about chronic cholecystitis and in the majority of instances we were able to recover the organisms from the gall bladder wall. It was apparent, both from the studies of the literature on the excised gall bladder at the operating table where every precaution was taken, that 45% of the gall bladders carefully studied revealed one of these groups. Furthermore, it is equally interesting to note that no one group is responsible for this lesion. We would point out particularly that these lesions were chronic lesions and not the subacute hemorrhagic lesions characteristic of acute cholecystitis. In a number of instances the lesions required six months to one year before they were produced. Intestinal lesions were by no means constant although instances of severe colitis and enteritis were noted. It is only fair to point out that in these studies, embracing 1300 animals, the commonest lesion encountered was arthritis. Cultures from gastric ulcer at operation, revealing the viridans streptococcus, failed to produce experimental ulcer in our hands. The suggestion that a positive streptococcal complement fixation test is evidence of the bacterial causation of peptic ulcer does not agree with our experience.

We prepared a large number of antigens from streptococci from various sources of proven infection. The number of positive reactions, both with the Burbank method and the modified Kolmer method in human beings was as great in the control non-ulcer cases as it was in those individuals proven to be suffering from peptic ulcer. We spent 1½ years investigating the possibilities of the streptococcus complement fixation tests and our own conclusions scarcely bear out the diagnostic value which we had so hopefully sought. The end reaction of the Burbank test is sharply defined and his technic, as well as the Kolmer technic, were followed exactly. We obtained many positive reactions to the ulcer group and to many other varieties of digestive pathology but we made it a rule to test carefully as many control individuals in whom we could reasonably rule out such lesions as cholecystitis and peptic ulcer. With minor exceptions there were as many positive reactions in the control group as there were in those showing advanced organic pathology. While the number of individuals, 141 in all, is too small to draw an adequate conclusion we believe that anyone who has had experience with this method of testing will realize the multitude of antigens that are possible and will be confronted by an array of evidence which is scarcely conclusive. We have given up this method of testing because of the great frequency of positive reactions in control cases with every form of antigen that we used. The skin tests, or the antigens used intradermally, we believe to be more suggestive and at the same time more valuable. The reaction to the colon group, as we have mentioned, is almost universal but there are distinct differences in the reaction of the individual to the various colon antigens. Positive reactions to the different members of the streptococcal group are far less frequent and to our mind far more suggestive. Cutaneous hyper-sensitivity to many of the streptococcal group is not at all uncommon and when pronounced we believe is of diagnostic import. On the other hand, we feel that the most valuable method of all is to culture consecutively all possible avenues of infection and this we have done clinically for many years. We consider any organism but the

Fig. 2

dressings. Six—with the filtrate. We succeeded in producing almost complete immunity only with the filtrate.

During the last three years gradually we segregated the cultures of streptococci which were capable of producing visceral infection. At no time during the eight years were we able to produce or to obtain a strain which consistently produced a peptic ulcer although we were able to obtain peptic ulcer with several different varieties of streptococci. The gall bladder, on the other hand, showed a far greater frequency in its response to these organisms. The most successful organism that we used to produce chronic cholecystitis was a non-hemolytic streptococcus from a stool of a patient with colitis but we were able to produce chronic cholecystitis not only with the non-hemolytic group from the bowel but with the viridans affecting the teeth and with several hemolytic throat strains. In

staphylococcus albus as of importance from nasal cultures. Predominating hemolyticus or viridans cultures from the throat in the presence of obvious infection may be of significance. Both the viridans and hemolyticus from infected teeth are, in our experience, important. In duodenal study we attach little significance to this first specimen but a predominant organism after stimulation and found in the B. bile may be of great importance. This refers to the colon, streptococcus and staphylococcus groups. In our experience the bacteriology of the nose and throat and mouth and the organisms found in the throat are frequently encountered in the first specimen. We insist however that only a predominant organism after stimulation and associated with cystologic evidence of possible infection is of importance.

We would finally report a series of experiments which were destined to demonstrate whether or not it was possible to produce immunity against some of the streptococcal strains. It has been our desire from the beginning of this investigation to obtain an organism which would produce a visceral lesion with a relative degree of certainty. Two years ago we were able to obtain a non-hemolytic streptococcus from the stool which produced the greatest frequency of gall bladder lesions as well as joint changes. We then took a series of rabbits and we inoculated them both with the filtrate and with a vaccine containing 100 million organisms per cubic centimeter. We then carried out an immunization period which was 38 days in duration during which we inoculated with 2.6 c.c. of the filtrate or vaccine giving 10 doses in all. This was then followed by a 21 day rest period after which we divided into three groups. One—a control group which had received no immunization. Another, a filtrate group which had received the filtrate and finally, a vaccine group which received the vaccine. We then

inoculated simultaneously all three groups with a total 0.132 c.c. of a 24 hour broth culture of the organism in three doses. The entire series were then killed three months later and carefully studied. While it is only possible to briefly summarize the results of these studies which are clearly shown in Chart 3 it is to be noted that while 75% of the controls developed joint lesions the incidence was reduced to 6% by preventative inoculation, a figure which can be explained on no mere coincidence inasmuch as the animals selected were as nearly alike in weight as we could select. Less striking are the results seen with cholecystitis but even in this group it is apparent that the preventative inoculation group showed a smaller incidence of chronic visceral disease. Owing to the large amount of time and attention necessary to investigations of this type and the expense incurred it has not been possible for us to advance to the next problem which is one of paramount interest, that is, to reverse the procedure, producing disease first by inoculating a large series of animals and then subsequently treating them with the filtrate or vaccine. Our studies to date have had to do with preventative inoculation. The problem of the future is to determine the reverse, namely how far can we bring about cure by these bacterial procedures.

Our studies over the last eight years have emphasized the fact that it is not possible by ordinary means such as are available in routine bacteriological procedures to predict either the virulence of a chronic organism or its ability to strike a certain organ. This may be apparent during the acute stage of infection. It is far more difficult to demonstrate with chronic visceral disease but we do know that many carriers of foci of infection harbor organisms that are capable in laboratory animals of producing widespread visceral damage similar to that routinely encountered in ordinary gastro-enterological work. We are convinced that

Fig. 3

the future will reveal methods for differentiating these virulent strains and probably combatting their pernicious influence on the digestive tract.

# DISCUSSION:

DR. A. C. IVY (Chicago, Ill.): Several years ago, about this time and before this Association, I reported the difficulties that I and other workers in my laboratory have had in attempting to produce chronic ulcers of the stomach in rabbits and dogs by injecting bacteria that had been isolated from human ulcers.

We were able to obtain hemorrhagic erosions, ecchymotic hemorrhages and acute manifestations of that kind, but we were never able to obtain typical chronic ulcers. At that same time I stated that I had no reason, however, to disbelieve the claims of Rosenow, Hufford, and Nichols. I simply was unable to get their results.

Since Dr. Rehfuß is using rabbits, it may be of interest for me to report that if one sections the vagi just below the diaphragm in rabbits, and if they survive the operation longer than twenty days, 60 per cent of them will develop typically chronic, indurated ulcers. This is associated with gastric stasis; and the rabbit, you know, eats a very rough diet, oats, hay, and so forth.

Now, most bacterial filtrates, and I think whenever we inject bacterial suspensions of any kind, cause disturbances of the motility of the stomach and intestine. One observes spasms which may cause ecchymotic, petechial hemorrhages and erosions; and if the nutritional condition or the state of digestion of the animal is markedly altered, we might expect some of those acute lesions to become chronic. In the rabbit, I should like to point out again, we obtain typically chronic, indurated ulcers, by interfering with the motor activity of the stomach, namely, in the direction of production of stasis in the presence of mechanical trauma due to rough food.

In that regard I am tempted to say that I think most of our managements of peptic ulcer at the present time are palliative in nature only, and that we only get at the direct etiology, or only begin to bear upon the etiological factors, first, when we teach the patient how to live and how to eat; of course, if there are foci of infection, they should be cleared up for general reasons.

DR. ERNEST H. GAITHER (Baltimore): The Authors are to be congratulated upon this timely and important work.

The question of chronic visceral infection in relation to gastroenterological problems has been of outstanding interest to the profession for many years, and all internists are familiar with the researches of various investigators in regard to the specificity of bacterial invasion. However, it must be remembered that the thorough work of Swift appears to prove the lack of such specificity.

The theory that pathologic changes in the digestive tract may possibly have been inaugurated by septic emboli rather than by a single type of bacterium, has often been advanced, and for years we have pondered the question, considering in each and every case the relationship of infection to disease in this domain; some of the proof brought forward by these Authors causes us to realize that infection does in many instances fail to attack the digestive tract, and has a much greater affinity toward joints; again, when the digestive tract is invaded, the hepatobiliary system is more likely to be involved than the stomach or intestine.

The Authors make very notable observations regarding a strain of colon bacillus from a removed gall bladder, which they designate as "strain A," and its excessive toxicity as compared with the other strains, its continued toxicity after months of continual passage through rabbits, and the sudden hemorrhage and even perforation of the stomach produced by a lethal dose. After a sublethal dose, the organisms were usually found in either the biliary

or the urinary tract. Septicemia was caused by a larger dose, while smaller doses caused localization in the biliary tract, liver, and kidneys. Injection of the mesenteric system had similar results, and when these organisms were injected into the gall bladder, they were invariably found localized in the duodenum, while all cultures of the surrounding liver tissues were entirely negative. Because of the labile character of the digestive tract in rabbits and other animals, conservatism is advisable when application of the evaluated results to the human digestive tract is under consideration.

Here we may recall a fine piece of work by Braithwaite, who by a series of investigations called attention to the flow of lymph from the ileocecal angle, and its possible bearing on the cause of duodenal and gastric ulcer, suggesting that infection could reach that area by way of the lymph channels. In speaking of the action of infected lymph in producing gastroduodenal ulceration, he propounds the question: "Why then should the effects of the poisoned lymph be permanent only on the lesser curvature and near the pylorus?" and he answers by the statement: "It is in this place that lymph follicles are twice as numerous as, and are bigger than, those in any other portion of the stomach."

Wilkie suggested that emboli from thrombosed vessels in an infected omentum pass to the stomach and duodenum and give rise to ulceration.

Letulle claims to have produced gastric ulcer by inoculation of the general peritoneal cavity by the staphylococcus pyogenes aureus, probably via the great omentum.

Bolton and Balfour call attention to the fact that relics of a bacterial infection are to be found in the crater of many gastric ulcers.

Jaksch stated many years ago, that acute ulcers are known to occur in many infective diseases, e.g., puerperal fever, peritonitis, pleurisy, tuberculosis.

After careful perusal of the present paper one is immediately convinced of the comprehensiveness of the study and the difficulty of applying dependable tests and correctly interpreting the results. One of the most interesting points was the Authors' ability to produce by very small, graduated doses, an immunity sufficient to withstand the lethal dose of the organism in its most virulent form, causing a total disappearance of the organism in practically every organ of the body. They make an enlightening statement in regard to the large number of individuals who respond with a positive skin reaction to colon antigens, and the frequency with which certain individuals show a marked skin reaction to certain strains in contrast with others, and they naturally stress the importance of investigating this peculiar tendency of the digestive invalid to respond differently to colon strains. In this connection they demonstrated that the colon vaccine from one organ would produce reactions in a different organ or groups of organs.

Their studies of the action of streptococci upon the digestive tract are interesting and call for further study; time will not permit us to discuss this phase of their investigations except to say that the vast majority of lesions produced were found in the joints, heart and kidneys; also that at no time during the eight years of investigation were they able to produce or obtain a strain which consistently produced a peptic ulcer. The gall bladder showed a far greater frequency in its response to these organisms, and in the majority of instances they were able to recover the organisms from the gall bladder wall. It is well to ponder this observation in regard to the views of those who claim that drainage of the gall bladder relieves or cures disease of a part or the whole of the biliary tract. They emphasize that these studies embracing 1300 animals proved arthritis to be the commonest lesions encountered.

To me, one of their most interesting and instructive notations was that cultures from gastric ulcer at operation, revealing the viridans streptococcus, failed to produce

experimental ulcer. Certainly these observations do not bear out the assertions of those who have proclaimed specificity of bacterial invasion, having particularly to do with the digestive tract. It is well to take cognizance of their definite assertion that the bacteriology of the bile is largely dominated by the bacteriology of the nose, throat, and mouth, and that organisms found in the throat are frequently encountered in the first specimen. They insist, however, that "only a predominant organism after stimulation and associated with cytologic evidence of possible infection is of importance."

They report a series of experiments destined to demonstrate whether or not it was possible to produce immunity against some of the streptococcal strains, and their successful results in those with joint and gall bladder lesions were quite striking; those in the latter group less so than in the former, however.

Because of the fact that these investigators have not completed their interesting and important research, and are not as yet ready to present definite conclusions, it is impossible to do more than point out the great value of their work, and to lend our encouragement, so that they and their confreres may continue this meritorious line of endeavor.

DR. MARTIN E. REHFUSS (in closing the discussion): Dr. Gaither helped me out because he read part of the paper. You will have to read the paper to get the details regarding this subject. I know there was so little time at my disposal I would have to hurry.

As to the question of immunity, so far as that was concerned we tried several methods of immunizing against colon bacillus. We failed absolutely.

(Slide) Means of using the living organism.

(Slide) These are a few slides to show attempted immunization in animals.

(Slide) But, unfortunately, in none of them did we succeed until we used living organism in the rabbits, which I wouldn't dare do with a human being, but with the living organism we were able to produce immunity. After this we gave a "lethal dose," which didn't kill the animal, and twenty-four hours afterward we sacrificed these animals and not a single colon bacillus was found in the organs.

(Slide) Here is an interesting series on joints. We got strains that produced joints right along. Here is one using six different methods of immunity: subcutaneous, auto-clave, subcutaneous living, intradermal living, intradermal autoclaved cultures, Besredka skin, and Berkfeld filtrate methods. Every one of the animals in this group except this one (indicating), the filtrate developed arthritis. That was a streptococcus obtained from the cervical smear.

(Slide) This is the interesting one in which we finally got an organism which produced arthritis in 80 per cent of the cases. We injected one hundred animals and obtained pathologic joints in the overwhelming majority, and did it in the following way: This is based on trend of weight graphs during the respective periods, immunization over thirty-eight days in duration, and consisted in inoculation of both the filtrate and the vaccine. This would hit the joints in about 80 per cent of the rabbits and it was a non-hemolytic type organism which came from the bowel. We then had the control group.

(Slide) Here is the result after three and a half months, or nearly four months, and the most striking thing is 75 per cent of the controls had joint disturbances. (We have photographs and motion pictures) while the vaccinated animals showed only 6 per cent, which I should say was fairly successful vaccination.

So far as the other organs were concerned, it wasn't so successful. With the non hemolytic streptococcus, which was the most successful one in striking the gall bladder, 25 per cent produced gall bladder disease, and in the vaccinated group only 15 per cent.

It took us a whole summer to produce this chart, but we are satisfied that this joint disturbance can come not only from the nose and the throat organisms but also from the intestinal tract. The organism most successful in producing arthritis, was a colon organism and a non hemolytic streptococcus. People don't pay much attention to the colon in arthritis, but to teeth and tonsils, but I think in arthritis intestinal disease should receive more attention on our part and that might clear up some of these cases.

This is the most interesting chart we have because it proves beyond reasonable doubt, to my mind, that with that strain we were able to reduce the incidence of arthritis, at least from 75 per cent to 6 per cent.

## ABSTRACTS

LEE, W. E., M.D., F.A.C.S., AND TAYLOR, J. S., M.D.  
*"Argentaffin Tumors of the Terminal Ileum." A Cause of Intestinal Obstruction. S. G. and O., Vol. 59, No. 2, Sept., 1934.*

In this article, the Authors report two very interesting cases of argentaffin tumors of the terminal ileum, which were causing intestinal obstruction and which well might be mistaken for carcinomata.

The Authors review the work of Masson, who discovered the silver reducing properties of the cytoplasmic granules in the tumor cells of these carcinoids. He has shown that these tumors begin with the migration of the Nicholas-Kulchitzky cells in the intestinal mucosa into the neuro-mata in the wall of the intestines. These cells then grow very slowly, but eventually break through the nerve filament and invade the surrounding tissue. Metastases are rare, but the primary growth often may obstruct the intestinal lumen and occasional metastases to the regional lymph nodes are found.

Two cases are reported in detail. In both, small tumors at the terminal ileum were found and following radical removal these patients have been well for twenty-two and twenty-three months respectively.

Argentaffin tumors resemble carcinomata in that they

invade tissues locally and extend into the regional lymph nodes. They may be differentiated from the usual carcinomata by their yellow color, firm consistency, the absence of necrosis, lack of mitosis in the tumor cells and the ability of the cytoplasmic granules to reduce silver salts. The cases are usually of long duration before the terminal stages of cachexia.

N. W. Swinton, Boston.

WILLIAM BOYD.

*The Relationship of Polycythemia to Duodenal Ulcer. Winnipeg, Canada, p. 589-594, Vol. 187, May, 1934.*

The association of duodenal and gastric ulcer with polycythemia has been previously reported by other Authors. The relationship, if any, between the two conditions has seemed difficult if not impossible to determine. Boyd presents this case of the association in a patient of polycythemia, leukocytosis, splenomegaly, duodenal ulcers, myocardial fibrosis, coronary artery occlusion and marked ascites. The question whether the increased red cell count should be regarded as a true polycythemia or as a secondary erythrocytosis is discussed with a final conclusion that in this case the polycythemia is primary and probably bears a causal relationship to the duodenal ulceration.

## SECTION II—*Experimental Physiology*

### The Cause of the Faulty Digestion in Dogs Without Stomachs

By

EDWARD S. EMERY, Jr., M.D.\*  
BOSTON, MASSACHUSETTS

#### INTRODUCTION

THE writer's interest in the effect of gastrectomy on digestion goes back to 1928. In this year one of his patients developed large bulky stools with a high content of fat following the removal of approximately two-thirds of the stomach for an extensive carcinoma. The possibility of metastases in the pancreas naturally occurred to him, but there was no other evidence to confirm this suspicion. X-ray studies were entirely negative. The stools did not have the gross appearance and did not contain the quantity of starch with which we associate disease of the pancreas. A study of the literature brought to his attention the article of Gabrila and Danicico (1), in which those Authors showed that an increased elimination of fat followed resection of the stomach. As this was new to him and there was so little in the literature about the effect on digestion of removing the stomach, he decided to study the problem on dogs, particularly to determine why the removal of the stomach caused a greater loss of fat *via* the stools.

#### LITERATURE

In 1878 Czerny and Kaiser (2) reported that they had successfully performed a total gastrectomy on a dog. However, an autopsy after five years of life revealed that a small remnant of the stomach had been left and had formed a pouch. Hence the credit for the first true total gastrectomy seems to go to Carvallo and Pachon (3). These workers reported the removal of a dog's stomach in 1894.

The first total gastrectomy was done on man in 1883 by the American surgeon Connor (4), but the patient died on the table. It was 14 years later, in 1897, that a successful total gastrectomy on man was reported by Carl Schlatter (5), an assistant of Krönlein at Zurich.

Few of these operations were performed in ensuing years because of the technical difficulties and the seemingly little use for the operation. However, the growing recognition that former methods of treating peptic ulcer leave much to be desired, stimulated the surgeons to remove greater amounts of the stomach. The greater success experienced with these operations has en-

couraged more radical surgery with the result that operations for total gastrectomy are reported not infrequently. Stahnke (6) counted 62 successful gastrectomies in 1933 and by 1934 Ducuing *et al* (7) were able to list 132. As the latter writers point out, this does not tell how many unreported gastrectomies have been performed.

Within recent years, therefore, the effect of gastrectomy on the bodily processes has become a practical question. Previously to this time it has been the physiologists who have been interested primarily in this subject, and it is interesting perhaps to observe that most writers in recent years have paid more attention to the effect of gastrectomy on the blood than on the digestion.

Physiologists have made numerous studies in the past on the effect of removing various portions of the intestinal tract. For the most part their observations have dealt with resections of the small intestine, probably because this seemed to have a more practical bearing on human problems. It does not seem worth while to review all this work. In general, the results have shown that removal of sufficient portions of the gastro-intestinal tract results in an obvious loss of fat as revealed in the stools. The loss of nitrogen has not been so great. Most observers have agreed that an increased loss of fat, which follows a greater intake, is accompanied by an increased loss of nitrogen. Less attention has been given to the effect, which partial removal of the intestines produces on the assimilation of carbohydrates. Those who have studied this phase of the problem conclude that there is relatively little if any effect on their digestion. One may question the results regarding carbohydrates with justification, because the methods of studying them are rather unsatisfactory.

Few studies have been made on the digestion of man after the stomach has been removed in whole or in part. Moreover, the findings have been conflicting, and there has been no unanimity of opinion concerning the cause of the abnormalities in digestion when they have been encountered.

Hofmann (8) found that the amount of nitrogen in the stools of Schlatter's patient was normal when the individual was on a bread and milk diet. Heilmann (9) found a lowered assimilation of fat in three patients. There was a normal digestion of nitrogen in one patient, whereas there was an increased output of nitrogen in the stools of the third case. Troell,

\*Associate in Medicine, Peter Bent Brigham Hospital, with the Technical Assistance of Miss Eleanor P. Hicken.  
Read at the 38th Annual Session of the American Gastro-Enterological Association, Atlantic City, N. J., June 10-11, 1935.  
Approved by the Publications' Committee of the Association.  
†The expenses for this study were defrayed by The Proctor Fund for the study of chronic disease.

Losell and Karlmark (10) report a normal digestion in their patient.

Soloviev (11) studied only the nitrogen and concludes, from one patient, that removal of the stomach does not increase the loss of nitrogen. Shima (12) found that total extirpation of the stomach resulted in a disturbance of the fat metabolism, but that the protein metabolism was disturbed in only one of the three patients.

Gabrila and Danicico (1), from their study of 13 patients upon whom gastro-enterostomies and various kinds of subtotal gastrectomy had been performed, report that the digestion of fats was impaired in all the patients, whereas the digestion of protein was impaired only in 8. These Authors believe that the failure of digestion is the result of a pancreatic insufficiency following resection of the stomach. They believe that hepatic insufficiency must play a rôle also because occasionally the digestion of proteins is normal and the digestion of fats is much impaired. They believe also that an increased motility may be responsible for the digestive deficit because in nearly all cases of resection of the stomach the passage of food is greatly accelerated—ingested powdered charcoal appearing in the stools after 12 hours.

Burger and Konjetzny (13) found a disturbance in the digestion of nitrogenous foods after a large proportion of fat had been given in the diet; they believe the loss of nitrogen is caused by a laxative action of the fats.

Those observers who report abnormal digestion give different explanations for their findings. Burger and Konjetzny suggest that the anomaly is due to a lack of secretion of the intestinal glands dependent upon an absence of hydrochloric acid. Ducuing believes that there is a deficient pancreatic secretion probably as a result of achlorhydria.

This would seem to explain the situation in the cases reported by Von Haberer (14) and Drevermann (15) in which a diarrhea was controlled by giving an acid-pepsin mixture.

Gabrila and Danicico consider that their findings were the result of a disturbance in motility and an insufficiency of the pancreatic and biliary secretions. It is interesting that the case of Troell *et al.*, in which no abnormality of digestion was found, had a normal motility. Heilmann, on the contrary, found that the rate of motility was 18 hours and that a hyperistalsis was present in the whole digestive tube. He found the colon filled in 2½ hours. Schwartz (16) reported a motility rate of 19 hours as opposed to 36 hours in the case reported by Dreverman.

A summary of the literature reveals that no constant changes occur after extirpation of the stomach. Digestion may be normal or markedly deficient. Furthermore, there is no relationship between the behavior of the nitrogen and fats. The literature seems to suggest, however, that there is a greater tendency toward a disturbance in the digestion of fat than that of nitrogen. The assimilation of nitrogen has been normal in several patients, although the digestion of fat was abnormal, whereas the reverse is less likely to occur.

#### METHODS OF STUDY

The method of investigation was devised to determine the proportion of food substances lost through the feces of dogs after a total gastrectomy had been done.

Weighed diets were given and the food analyzed for its content of nitrogen, fat and ash according to the method outlined by McCrudden (17). The amount of carbohydrate was determined by subtraction. Usually the diet was given for five days before the collection of stools was started, but, in a few instances, this period of time was decreased to three days. Carmine was used at the beginning and at the end of the test-period to delimit the stools. Unless otherwise indicated, the period of stool collection was three days.

After the stools had been collected, their gross appearance was noted and their weight obtained. They were then acidified with dilute hydrochloric acid and dried at a temperature of 105° C. After drying, they were again weighed, ground and placed in tightly stoppered bottles.

The nitrogenous content was determined in the usual way by the Kjeldahl method. The fats were determined by the method of Folin and Wentworth (18). These Authors believe their procedure gives somewhat higher values for fat than the methods previously in use. They state that soaps cannot be entirely freed from fatty acids and that the attempt to do so leads to such inaccurate results as to make the procedure of little value. Therefore, we determined only the total fats, fatty acids and neutral fats. Since no significant differences occurred in the fatty fractions, the results are reported only in terms of the total fat. The ash was determined in the usual way by incinerating in a quartz crucible.

The determination of the carbohydrates was found to be most unsatisfactory. We first used Bertrand's procedure and later a yeast method suggested to us by Dr. Trimble. But the results were quite inconstant, and the total quantity which was obtained by this method was much less than by the process of subtraction. This difference was too marked to be explained by a reasonable error in the method. Because the stools could not be collected immediately after defecation, the opportunity for bacterial destruction made it impossible to obtain accurate results. Therefore, the carbohydrates were eliminated from this study.

Control studies were made on 16 normal dogs, and two animals were studied whose stomachs were shown at autopsy to have been completely removed. The stomachs of these dogs had been removed two years before for Dr. William P. Murphy who had been observing their blood. He kindly gave them to us. They were in good health and showed no evidence of anemia at any time.

Dog 4 was sacrificed and autopsied at the end of 1½ years, having lived for 3½ years in good health. Dog 5 was sacrificed after we had studied him for 3 years, he having continued in fair health for 5 years. The use of animals who had been without stomachs for 2 years was of value in this study because any abnormal digestion was of a permanent nature and ruled out the possibility of a temporary change following operations.

After determining that the animals without stomachs showed faulty digestion, the following plan was used to investigate the cause. Absence of the stomach might influence digestion by any one of the following ways: (1) loss of the digestive function of the stomach, (2) decreased or absent production of the secretions of the duodenum, pancreas and gall bladder, (3) increased motility.

Ludwig and Ogata (19) and Schmidt and Strassburger (20) have shown that in the absence of pepsin and hydrochloric acid the only evidence for failure of digestion occurs in raw connective tissue. No studies have been made on the importance or otherwise of the emulsification of fats in the stomach. Therefore, we studied this point.

We studied also the effect of supplying hydrochloric acid and made one observation on the effect of feeding each one of the following substances: fresh pancreas and pancreaticin plus bile. Finally, we studied the motility of the

gastro-intestinal tract by indicators, by the X-ray and by small feedings.

### ILLUSTRATIVE PROTOCOLS METABOLISM DETERMINATION 3: DIGESTION OF NORMAL DOG

*Dog No. 3.*—Normal adult female. Weight 13 kilos.

November 19, 1930. Dog started on diet of 350 grams of boiled horse meat and 100 grams of bread per day.

November 24. Carmine given to mark beginning of test period.

November 27. Carmine given to mark end of test period. Stools collected including both carmines.

Food:

|                      |             |               |
|----------------------|-------------|---------------|
| Nitrogen:            | 50.88 grams |               |
| Fats:                | 27.6 grams  | Dry weight:   |
| Feces: Moist weight: | 135.0 grams | 49.0 grams    |
| Nitrogen:            | 3.56 grams  | 7.28 per cent |
| Fats:                | 1.34 grams  | 2.73 per cent |
| Nitrogen absorbed:   | 47.32 grams | 93.0 per cent |
| Fat absorbed:        | 26.26 grams | 95.0 per cent |

### METABOLISM DETERMINATION 39: DIGESTION OF LARGE AMOUNT OF FAT

*Dog No. 2.*—Normal virgin female. Weight 13.3 kilos.

September 7, 1931. Dog started on diet of 350 grams of boiled horse meat, 100 grams of bread and 200 grams of lard per day.

September 11, 1931. Carmine given to mark beginning of test diet.

September 16, 1931. Carmine given to mark end of test diet. Stools collected including both carmines.

Food:

|                      |              |                |
|----------------------|--------------|----------------|
| Nitrogen:            | 76.3 grams   |                |
| Fat:                 | 1241. grams  | Dry weight:    |
| Feces: Moist weight: | 193. grams   | 64 grams       |
| Nitrogen:            | 3.81 grams   | 5.96 per cent  |
| Fat:                 | 3.87 grams   | 6.04 per cent  |
| Nitrogen absorbed:   | 72.51 grams  | 95.00 per cent |
| Fat absorbed:        | 1237.6 grams | 99.00 per cent |

### METABOLISM DETERMINATION 3: DIGESTION IN ABSENCE OF STOMACH

*Dog No. 4.*—Adult male with stomach removed in 1928. Weight 12.9 kilos.

November 19, 1930. Dog started on diet of 350 grams of boiled horse meat and 100 grams of bread.

November 24. Carmine given to mark beginning of test period.

November 27. Carmine given to mark end of test period. Stools collected including both carmines.

Food:

|                      |             |                |
|----------------------|-------------|----------------|
| Nitrogen:            | 50.88 grams |                |
| Fat:                 | 27.6 grams  | Dry weight:    |
| Feces: Moist weight: | 691. grams  | 169 grams      |
| Nitrogen:            | 15.36 grams | 9.09 per cent  |
| Fat:                 | 21.59 grams | 12.78 per cent |
| Nitrogen absorbed:   | 35.52 grams | 70.00 per cent |
| Fat absorbed:        | 6.01 grams  | 22.00 per cent |

### METABOLISM DETERMINATION 4: DIGESTION IN ABSENCE OF STOMACH

*Dog No. 5.*—Male Shepherd. Total gastrectomy done in 1928. Weight 12.8 kilos.

November 19, 1930. Dog started on diet containing 350 grams of boiled horse meat and 100 grams of bread per day.

November 24. Carmine given to mark beginning of test period.

November 27. Carmine given to mark end of test period. Stools collected including both carmines.

Food:

|                      |             |                |
|----------------------|-------------|----------------|
| Nitrogen:            | 50.88 grams |                |
| Fat:                 | 27.6 grams  | Dry weight:    |
| Feces: Moist weight: | 585.0 grams | 166 grams      |
| Nitrogen:            | 14.54 grams | 8.76 per cent  |
| Fat:                 | 23.02 grams | 13.87 per cent |
| Nitrogen absorbed:   | 36.34 grams | 72 per cent    |
| Fat absorbed:        | 4.58 grams  | 17 per cent    |

### METABOLISM DETERMINATION 11: DIGESTION OF EMULSIFIED FAT

*Dog No. 4.*

December 12, 1930. Diet started of 350 grams of boiled horse meat, 100 grams of bread, and 250 grams of medium grade cream.

December 17. Carmine given to mark beginning of test period.

December 20. Carmine given to mark end of test period. Stools collected including both carmines.

Food:

|                      |              |                |
|----------------------|--------------|----------------|
| Nitrogen:            | 120.9 grams  |                |
| Fat:                 | 228. grams   | Dry weight:    |
| Feces: Moist weight: | 427 grams    | 259 grams      |
| Nitrogen:            | 18 grams     | 6.95 per cent  |
| Fat:                 | 147.4 grams  | 56.92 per cent |
| Nitrogen absorbed:   | 102.88 grams | 85. per cent   |
| Fat absorbed:        | 80.20 grams  | 35. per cent   |

### METABOLISM DETERMINATION 10: DIGESTION OF EMULSIFIED FAT

*Dog No. 5.*

December 12, 1930. Diet started of 350 grams of boiled horse meat, 100 grams of bread and 250 grams of medium grade cream per day.

December 17. Carmine given to mark beginning of test period.

December 20. Carmine given to mark end of test period. Stools collected including both carmines.

Food:

|                      |             |                |
|----------------------|-------------|----------------|
| Nitrogen:            | 120.9 grams |                |
| Fat:                 | 228. grams  | Dry weight:    |
| Feces: Moist weight: | 1015 grams  | 352 grams      |
| Nitrogen:            | 29.67 grams | 8.43 per cent  |
| Fat:                 | 113.6 grams | 32.28 per cent |
| Nitrogen absorbed:   | 91.2 grams  | 75. per cent   |
| Fat absorbed:        | 114.0 grams | 51. per cent   |

### METABOLISM DETERMINATION 16: EFFECT OF TENTH NORMAL HYDROCHLORIC ACID

*Dog. No. 5.*

February 12, 1931. Diet started consisting of 350 grams of boiled horse meat, 100 grams of bread, 50 grams of lard and 500 c.c. of tenth normal hydrochloric acid per day.

February 17. Carmine given to mark beginning of test period.

February 19. Carmine given to mark end of test period. All stools collected including both carmines.

Food:

|                      |              |                |
|----------------------|--------------|----------------|
| Nitrogen:            | 38.2 grams   |                |
| Fat:                 | 171. grams   | Dry weight:    |
| Feces: Moist weight: | 478 grams    | 154 grams      |
| Nitrogen:            | 8.42 grams   | 5.47 per cent  |
| Fat:                 | 52.33 grams  | 33.98 per cent |
| Nitrogen absorbed:   | 29.74 grams  | 78 per cent    |
| Fat absorbed:        | 118.37 grams | 69 per cent    |

### METABOLISM DETERMINATION 40: EFFECT OF FRESH PANCREAS

*Dog No. 5.*

September 21, 1931. Started diet consisting of 350 grams of boiled horse meat, 100 grams of bread and 450 grams of fresh pancreas per day.

September 22. Carmine given to mark beginning of test period.

September 24. Carmine given to mark end of test period. Stools collected including both carmines.

Food:

|                      |              |                |
|----------------------|--------------|----------------|
| Nitrogen:            | 60.42 grams  |                |
| Fat:                 | 140.74 grams | Dry weight:    |
| Feces: Moist weight: | 784 grams    | 173 grams      |
| Nitrogen:            | 3.56 grams   | 2.06 per cent  |
| Fat:                 | 71.29 grams  | 41.21 per cent |
| Nitrogen absorbed:   | 56.86 grams  | 94 per cent    |
| Fat absorbed:        | 69.45 grams  | 49 per cent    |

#### METABOLISM DETERMINATION 52: EFFECT OF PANCREATIN AND BILE

Dog No. 5.

December 20, 1931. Started diet consisting of 350 grams of boiled horse meat, 100 grams of bread and 50 grams of lard mixed with 1 gram of pancreatin and 8 grams of powdered bile which had been incubated at 37.5 C. for 6 hours.

December 23. Carmine given to mark beginning of test period.

December 25. Carmine given to mark end of test period. Stools collected including both carmines.

Food:

|                      |              |                |
|----------------------|--------------|----------------|
| Nitrogen:            | 38.16 grams  |                |
| Fat:                 | 170.7 grams  | Dry weight:    |
| Feces: Moist weight: | 267 grams    | 98 grams       |
| Nitrogen:            | 6.33 grams   | 6.46 per cent  |
| Fat:                 | 18.31 grams  | 18.69 per cent |
| Nitrogen absorbed:   | 31.83 grams  | 83.0 per cent  |
| Fat absorbed:        | 152.39 grams | 89.0 per cent  |

#### METABOLISM DETERMINATION 55: THE ABSORPTION OF FATTY ACIDS

Dog No. 5.

January 12, 1932. Started diet consisting of 350 grams of boiled horse meat, 100 grams of bread and 39 grams of fatty acids derived from lard and 2.02 grams of glycerine.

January 12. Carmine given to mark beginning of test period.

January 15. Carmine given to mark end of test period. Stools collected including both carmines.

Food:

|                      |              |                |
|----------------------|--------------|----------------|
| Nitrogen:            | 51.2 grams   |                |
| Fat:                 | 190.0 grams  | Dry weight:    |
| Feces: Moist weight: | 528 grams    | 179 grams      |
| Nitrogen:            | 8.44 grams   | 4.72 per cent  |
| Fat:                 | 49.35 grams  | 27.57 per cent |
| Nitrogen absorbed:   | 42.44 grams  | 84 per cent    |
| Fat absorbed:        | 141.25 grams | 74 per cent    |

#### METABOLISM DETERMINATION 58: EFFECT OF SLOW FEEDING

Dog No. 5.

March 23, 1932. Diet started consisting of 75 grams of boiled horse meat, 50 grams of bread, and 50 grams of lard. Dog was fed so that approximately 8 grams of fat entered the intestine every half hour. This was carried out for 2 days.

March 23. Carmine given to mark beginning of test period.

March 24. Carmine given to mark end of test period. All stools collected including both carmines.

Food:

|                      |             |                |
|----------------------|-------------|----------------|
| Nitrogen:            | 7.25 grams  |                |
| Fat:                 | 101.9 grams | Dry weight:    |
| Feces: Moist weight: | 126 grams   | 57.0 grams     |
| Nitrogen:            | 6.77 grams  | 11.89 per cent |
| Fat:                 | 2.38 grams  | 4.17 per cent  |
| Nitrogen absorbed:   | 6.48 grams  | 7.0 per cent   |
| Fat absorbed:        | 99.52 grams | 98.0 per cent  |

#### PROTOCOL ROENTGENOGRAPHIC OBSERVATIONS ON MOTILITY

Experiment 1.—Normal dog.

Feb. 2, 1931. Animal given 100 grams of meat, 50 grams of bread and 50 grams of barium.

1½ hours p.c. Barium scattered in small intestine.

4 hours p.c. Stomach seven-eighths empty. Barium had reached cecum.

6½ hours p.c. Barium to splenic flexure and in descending colon. Jejunum empty.

Experiment 2.—Normal dog.

Feb. 8, 1931. Animal given 100 grams of meat, 50 grams of bread and 50 grams of barium.

1½ hours p.c. Barium scattered thinly in small intestine.

3½ hours p.c. Stomach half empty. Barium in jejunum and ileum.

6½ hours p.c. Stomach empty. Colon filled to splenic flexure.

Experiment 3.—Normal dog.

Feb. 13, 1931. Animal given 100 grams of meat, 50 grams of bread and 50 grams of barium.

3½ hours p.c. Stomach half filled. Small intestine well filled.

4½ hours p.c. Stomach almost empty. Lower ileum well filled.

6 hours p.c. Stomach empty. Colon ¾ filled—only small amount left in ileum.

Experiment 4.—Dog 5. Pathological.

Feb. 2, 1931. Animal given 100 grams of meat, 50 grams of bread and 50 grams of barium.

4½ hours p.c. Upper intestine markedly dilated, lower somewhat.

6½ hours p.c. Some in duodenal pouch. Colon filled and dilated. Ileum empty.

Experiment 5.—Dog 5. Pathological.

Feb. 8, 1931. Animal given 100 grams of meat, 50 grams of bread and 50 grams of barium.

¼ hour p.c. Upper intestine well filled, dilated. Barium well along jejunum.

1½ hours p.c. Intestine well filled throughout.

3¾ hours p.c. Barium appears to be near cecum.

5¾ hours p.c. Colon still empty.

Experiment 6.—Dog 5. Pathological.

Feb. 13, 1931. Animal given 100 grams of meat, 50 grams of bread and 50 grams of barium.

3¾ hours p.c. Both jejunum and ileum filled.

4 hours p.c. No apparent change.

6 hours p.c. Barium in colon.

6½ hours p.c. Barium has reached rectum but plenty of material in small intestine.

#### PRESENTATION OF RESULTS

Twenty-nine studies were made on 6 normal dogs to obtain results which could serve as controls. Animals were chosen whose size (approximately thirteen kilograms) were similar to that of the dogs without stomachs.

The absorption of nitrogen and fat was high in every study but one. Variations occurred as follows: The per cent of nitrogen absorbed varied from 86.0 to 98.0 except on one occasion when it was 68.0. The absorption of fat varied from 87 to 99 per cent. The high figures were due to the way by which the stools had to be collected, which resulted in the loss of some fecal material. However, since the same method was used for the collection of the stools from the dogs without stomachs, any differences in absorption would be recognizable.

The normal animals were able to absorb large quantities as well as small quantities of fat. Seven to 257 grams of fat were fed per day, and the per cent of

fat which was absorbed was as high with the larger amount as with the smaller.

In contrast to these findings the 2 dogs without stomachs showed a definitely lower ratio between the amount of nitrogen and fat in the stools to the amount fed. Expressed in terms of absorption, the nitrogen varied from 64 to 88 per cent. The absorption of fat was smaller and varied from 17 per cent to 86 per cent. The average absorption of nitrogen and fat in 16 studies made on the two dogs without stomachs was 76 per cent and 59 per cent respectively. The average absorption of nitrogen and fat by the normal dogs was 92 per cent and 97 per cent respectively. Hence the dogs without stomachs absorbed on the average 16 per cent less nitrogen and 38 per cent less fat.

#### STUDIES OF THE STOOLS

A consideration of the stools may be of some interest. Those from the pathological dogs were softer and of a different color. They were never formed but could be described as "mushy" in consistency in nearly all instances. On only one or two occasions were they so soft as to be liquid. They never had the dark brown or black color characteristic of the normal stool of a dog. Instead, they were a light gray and showed some soft mucus intimately mixed with the stool.

Gross evidences of fat were apparent in some specimens, thus providing the qualities of greasiness and a sheen. Table 1 compares the main characteristics

TABLE I

*A Comparison of the Stools from the Normal and Pathological Dogs*

|                                         | Normal | Pathological | Difference |
|-----------------------------------------|--------|--------------|------------|
| 1. Weight per day in grams.             | 21.5   | 50.6         | 29.1       |
| 2. Per cent of water in stools.         | 56.5   | 67.2         | 10.7       |
| 3. Weight of fat per day in grams.      | 1.39   | 14.04        | 12.65      |
| 4. Weight of nitrogen per day in grams. | 0.86   | 3.65         | 2.79       |

of the stools from the normal and the pathological dogs.

There seems to be no question, therefore, that absence of the stomach may result in an abnormal elimination of fat and nitrogen and may be accompanied by the passage of stools which are looser and softer than normal.

#### STUDIES ON THE CAUSE OF MALABSORPTION

Since the first process in the digestion of fats is thought to be emulsification, it seemed advisable to determine whether there would be any difference in

the utilization of an emulsified fat, as cream, over that of lard. Dogs numbered 4 and 5 were tested with a diet in which the bulk of the fat was given in the form of 20 per cent cream. However, there was no better utilization of cream than of lard. (See metabolism determinations, No. 11 and No. 10).

The next idea that occurred to us was that the absence of hydrochloric acid might be the important element, particularly because of the gross appearances of the stools. These were not unlike the type of stool which is encountered with patients who have complete achlorhydria and are relieved by the administration of hydrochloric acid.

Therefore, Dog No. 5 was started on increasing amounts of tenth normal hydrochloric acid. By the end of ten days the animal was taking 500 c.c. of acid solution with his diet without any great evidence of distaste for it. Grossly, the stools appeared more normal. Both the color and consistency had improved. There was, in fact, a slight decrease in the water content of the stool (see Table 2). The amount of fecal material, as determined by weight, was less when the dogs were taking acid than when they were not.

There was also some evidence that digestion was slightly better when acid was given. In six observations made on Dog No. 5, from 67 to 88, with an average of 78 per cent of the nitrogen in the diet was utilized, or 2 per cent better than without acid. From 45 to 90, with an average of 73, per cent of the fat was absorbed which was 14.0 per cent more than when no acid was given.

Next we tried the effect of giving some of the digestive enzymes in the form of freshly chopped pancreas and pancreatin plus desiccated bile.

When 450 grams of fresh pancreas was fed with the diet, 94.0 per cent of the ingested nitrogen was absorbed and 49.0 per cent of the fat. (See metabolism determination 40).

The attempt to add bile to the diet met with failure. Fresh bile was procured from the slaughter house and was given to the animal in quantities of 500 c.c. mixed with the diet. Diarrhea followed promptly the ingestion of so much bile, and this was true of 200 c.c. of bile. Since the administration of lesser amounts would seem to be futile as a therapeutic procedure, we did not persist in the attempt.

Later, however, one observation was made on the effect of mixing 8 grams of powdered bile and 1 gram of pancreatin with the diet and incubating for 6 hours at 37.5 degrees centigrade. The animal was able to take this preparation without developing diarrhea. With this mixture the dog absorbed 83 per cent of the

Diet No. IV 350 grams meat, 100 grams bread, 250 grams cream.

nitrogen and 89 per cent of the fat. (Metabolism determination 52).

Further studies of this kind should be made. The absorption of nitrogen was better than the average with both fresh pancreas and pancreatin and bile. The absorption of fat was lower with the pancreas and somewhat higher than the average with pancreatin and bile. But the index of absorption fluctuated so widely

| Pathological 5 | 36 hours                        | 24 hours                                        | 18 hours                                         |

in the pathological animals it is impossible to conclude much from single determinations of this kind.

Next, we fed the fat in the form of fatty acids and glycerine to determine whether the lack of absorption depends upon a failure to break down the neutral fat. Accordingly, Dog No. 5 was given a diet each day of 350 grams of meat, 100 grams of bread, 39 grams of fatty acids (obtained from lard) and 2.02 grams of glycerine per day. (See metabolism determination No. 55). The animal ate the diet well and from it absorbed 84 per cent of the nitrogen and 74 per cent of the fat. Therefore, absorption was no better when fatty acids were fed than when neutral fat was given.

*Motility* is another function of the intestinal tract that one would expect to be deranged by a gastrectomy; such proved to be the case. Powdered carmine (the substance chosen to delimit various stools) was recovered from the pathological animals in from 18 to 36 hours, in contrast to 21 to 96 hours from the normal dogs. (See Table 3). Carmine was obtained from the pathological dogs about two days sooner, on the average, than it was from the normal ones.

*Roentgenographic studies* threw more light on the nature of the increase in motility. (See Protocol). They revealed very definite dilatation, (later confirmed at autopsy), of most of the jejunum. This filled rapidly with the test meal, which the dog ate, in about 15-20 minutes. Hence, the upper intestine contained in a few minutes the same meal which left the stomach of the normal animals in from 4-5 hours. From 3½ to 4 hours the picture was not much different in the normal and abnormal animal. The barium had reached approximately the same distance in the small intestine. The only difference was that there appeared to be more barium in the intestines of Dog No. 5. The barium entered the cecum about the same time in both animals, namely, around 5 to 6 hours. However, it left the colon of the dog without a stomach more rapidly than it did that of the normal animal. One may say that, in the abnormal animal, food enters the intestine immediately. Once there, its passage through the small intestine is only slightly, if at all, accelerated. However, it leaves the colon more rapidly than normally. This rapid emptying of the colon could ac-

count for the fact that carmine came through more quickly in the dog without a stomach.

In order to determine the effect which the rapid passage of food into the jejunum might have on digestion, we tried feeding the dog small amounts at frequent intervals. By this means we could hope to distribute the food to the jejunum at about the same rate that the stomach normally does. Since the disturbance in digestion of the fat had been more marked than it had with the nitrogen, and since the stomach empties the fat more slowly than other food products, it seemed best to gauge the rate of feeding by the amount of fat in the diet. As a precedent for this, we had the work of Zawilski (21), who, in 1876, studied the absorption of fat by dogs. As he used animals of approximately the same size as ours (his weighed about 13 kg each), it was possible to determine from his figures that the stomach of an animal of this size discharged from 5 to 10 grams of fat per hour, and that the animal absorbed on the average about 6 to 7 grams an hour.

Therefore, at half hourly intervals we fed amounts of food which would introduce to the jejunum about 8 grams of fat per hour. Table 4 shows the result of feeding the diet slowly. Fractional feeding resulted in an absorption of fat varying from 92 to 98 per cent, with an average of 95 per cent.

The absorption of nitrogen was low, varying from 4 to 31 per cent with an average of 14. These very low figures were obtained on diets low in nitrogen and will be discussed more fully later on. But the table shows that absorption was better with slow feeding than when all the food was given at once.

## DISCUSSION

The results of this study are not easy to evaluate at first glance, and it is unfortunate that we were unable to repeat many of the studies. But several factors over which we had no control forced us to discontinue the work, before we had an opportunity to obtain conclusive answers on all the doubtful points. However, our study shows certain things.

Removal of the stomach can result in decreased digestion. The differences in the figures obtained on the normal and the pathological dogs are significant. The absorption of nitrogen by the normal animals was

TABLE IV

*A Comparison of the Absorption of Nitrogen and of Fat After Feeding Diets Slowly and Rapidly*

| Diet          | Method of Feeding | Per cent Nitrogen Absorbed | Per cent Fat Absorbed |
|---------------|-------------------|----------------------------|-----------------------|
| 75 gms. meat  | Fractions         | 7.0                        | 98                    |
| 50 gms. bread | Fractions         | 4.0                        | 94                    |
| 50 gms. lard  | Together          | Negative Balance           | 88                    |
| 175 gms. meat | Fractions         | 31                         | 92                    |
| 50 gms. bread | Together          | 16                         | 79                    |
| 50 gms. lard  |                   |                            |                       |

less than 86 per cent in only one test, in which instance it reached a low point of 68 per cent. Since this was the only time that we obtained a figure on this dog different from the other normal animals, it seems justifiable to exclude it as being due to a technical error.

In contrast to these findings, the highest figure for the absorption of nitrogen on the pathological dogs

was 88 per cent. The animals without stomachs absorbed, on the average, 16 per cent less nitrogen than did the normals. The difference in the ability to handle fats was even more marked. The lowest absorption of fat by the *normal* animals was 87 per cent in contrast to the highest absorption by the *pathological*

TABLE V

*The Amount of Fat and Nitrogen Lost in the Stools Per Day in Relation to the Amount of Fat Fed Per Day*

| Fat in diet per day in grams | Grams of fat in stools per day |                  | Grams of N <sub>2</sub> in stools per day |                  |
|------------------------------|--------------------------------|------------------|-------------------------------------------|------------------|
|                              | Normal Dog                     | Pathological Dog | Normal Dog                                | Pathological Dog |
| 7.0                          | 0.52                           | 5.57             | 1.0                                       | 3.7              |
| 22.71                        | 0.65                           |                  | 0.52                                      |                  |
| 37.0                         |                                | 9.18             |                                           | 4.6              |
| 47                           |                                | 10.1             |                                           | 3.64             |
| 54                           | 0.37                           | 8.38             | 1.23                                      | 2.55             |
| 57                           | 0.91                           | 24.14            | 0.871                                     | 4.26             |
| 82                           | 1.00                           |                  | 0.85                                      |                  |
| 108                          | 0.62                           |                  | 0.93                                      |                  |
| 157                          | 2.31                           | 24.59            | 1.15                                      | 2.33             |
| 206                          | 0.61                           |                  | 0.63                                      |                  |
| 257                          | 3.49                           |                  | 0.84                                      |                  |

dogs of 86 per cent. The abnormal dogs absorbed on the average 38 per cent less fat. That there is a true disturbance in digestion is further supported by the fact that the dogs without stomachs had had no normal stools during the one to three years of observation.

A second important observation is that the absorption of food by the test animals varied over a greater range than it did in the normal. The figures show a variation for the normal animals of 12 per cent for both nitrogen and fat, as opposed to a variation for the pathological animals of 24 per cent for nitrogen and 69 per cent for fat. We may admit that some of this fluctuation may result from the occasional loss of fecal material. However, the difference between the pathological and control animals is sufficiently great as to be significant. Therefore, the failure of digestion would appear to depend upon something which fluctuates from time to time.

Moreover, the data show that this fluctuation is not the result *per se* of a variation in the amount of the foodstuffs which are exhibited. (See Table 5). Although the amount of fat in the stools of both the normal and the pathological animals increases with an increase of fat in the diet, this occurs with smaller amounts of fat in the case of the pathological animals. Table 6 clearly shows that the amount of fat in the diet does not influence the loss of nitrogen, as postulated by Burger and Konjetzny.

Now, if we turn to Chart 1, which enables us to visualize the results of the work more clearly, it is found that the assimilation of food was better after feeding certain "sham" digestive secretions.

Both the fat and nitrogen were absorbed slightly better when the animal was taking hydrochloric acid. In the one experiment in which fresh pancreas was given with the diet, there was a normal absorption of nitrogen, whereas the absorption of fat was markedly deficient. We have no explanation to offer for this apparent inconsistency. When pancreatin and dessicated bile were given together, the absorption of both fat and nitrogen definitely was higher. The fatty acids were absorbed to the same degree as was the neutral fat when hydrochloric acid was administered.

These results appear to conflict. The improvement in assimilation suggests that the failure of digestion may result from an inadequate supply of ferments. However, if this be true, one would expect the giving of pancreatic substance would improve the assimilation of fat as well as of nitrogen, and one might anticipate a better absorption of the fatty acids.

It is possible that some of the apparent inconsistencies are exaggerated by the amount of fluctuation which has been found to occur in the digestion of the dog without a stomach.

However, slow feeding gave a better assimilation of fat than did the administration of the sham digestive secretions and ferments, and, in fact, the absorption of fat was essentially normal. Since we introduced the fat to the intestines at approximately the same rate as it normally leaves the stomach (according to the figures of Zawilski), it becomes evident that the intestine must have supplied lipolytic ferments as fast as it is called upon to do under normal conditions.

Hence, it seems to be evident that, so far as the fat is concerned, the failure of digestion can be explained satisfactorily by the fact that, in the absence of the stomach, material enters too fast for the normal supply of lipolytic enzymes adequately to mix with the food. Also, we have shown that the upper part of the small intestine was dilated to a marked degree and therefore, it seems reasonable to suppose that this may be another reason for insufficient mixing of the food with the digestive secretions. In these conditions, the fat may be washed along without obtaining an adequate breakdown into its simplest components suitable for

Chart 1. The amount of nitrogen and fat eliminated in the stools expressed in per cent of the quantity ingested. Solid black shows per cent of fat. Strip shows per cent of nitrogen.

absorption, when and if it comes into contact with the walls of the intestine.

It now becomes clear that the rate at which the animal ate the other diets will account for some of the hitherto unexplained discrepancies. He ate the mixtures of acid and pancreatin and bile (which had a

sour odor) more slowly than usual. This fact can explain why absorption was better when these substances were given, whereas, it would not be possible to explain the normal absorption of fat with slow feeding, if one assumed an inability to secrete a normal supply of lipolytic substances.

Chart 1 shows an apparent objection to these statements until the facts are understood. The absorption of nitrogen appears to be poorer with slow feeding than is usual. This depends upon two conditions, namely, the small amount of nitrogen in the diets used in the fractional feeding and the increased amount of nitrogen in the stools as a result of a chronic irritation.

As seen in Table 6 the intake of nitrogen was very small, it being per day, 3.62 grams in one diet and

TABLE VI

*The Amount of Fat and Nitrogen Lost in the Stools Per Day in Relation to Slow and Rapid Feeding*

| Nitrogen in diet per day in grams | Grams of fat in stools per day |               | Grams of nitrogen in stools per day |               |
|-----------------------------------|--------------------------------|---------------|-------------------------------------|---------------|
|                                   | Slow Feeding                   | Rapid Feeding | Slow Feeding                        | Rapid Feeding |
| 3.62                              | 2.09                           | 6.21          | 3.44                                | 4.42          |
| 6.36                              | 4.11                           | 11.09         | 2.28                                | 5.35          |
| Fat in diet per day in grams      |                                |               |                                     |               |
| 51                                | 2.09                           | 6.21          | 3.44                                | 4.42          |
| 53                                | 4.11                           | 11.09         | 2.28                                | 5.35          |

6.36 in the other. At the same time, the dog excreted a greater amount of nitrogen in his stool than normal because of chronic irritation resulting from a long continued indigestion. Hence, the fixed loss of nitrogen is higher than normal in the pathological dogs. Low values of nitrogen in the diet give an unduly low ratio to the nitrogen excreted in the stools. But Table 4 shows that slow feeding favorably influences the assimilation of nitrogen. The disturbed motility, therefore, interferes with the absorption of the nitrogen in the same way that it disturbs the absorption of fat.

The observations which we have made on these dogs serve to explain the variable reports in the literature concerning *digestion subsequent to gastrectomy*. Evidence for failure in digestion will depend upon the rate at which the food is eaten, the amount of dilatation which has developed in the intestine and the type of food that is eaten at the time of the study. The degree of dilatation is important, for the greater it is, the more food the patient can ingest before feeling filled. Hence, he will eat more food in a given time and may exceed the physiological rate at which the intestine can supply the required digestive secretions. Marked dilatation also may interfere with the mechanical treatment of the food, in respect to mixing and bringing it into contact with the walls of the intestine.

The more or less generally reported fact that the digestion of fat is interfered with to a greater extent than is the digestion of nitrogen is easy to understand, when one remembers that the stomach discharges fat more slowly than it does nitrogenous substances. This is evidence that the intestine is able to digest protein more rapidly than fat; if a mixture of food is allowed to enter the intestine too rapidly, the absorption of fat will suffer to a greater degree.

The relative proportion of nitrogen to fat in the diet also will influence the apparent efficacy of digestion of the two substances. If the intestine is overloaded by a mixture of food, in which one element largely outweighs the other, it is possible to have a situation in which one substance is supplied in excess of the intestine's ability to digest the product; whereas the amount of other substance may be within the physiological limits of digestion. Normally, the stomach regulates this condition by discharging the various food components at different speeds.

Finally, this study emphasizes the importance of the stomach as a distributor of the food to the intestine. As a result of the work of Cannon (22) and others, it has been known for a long time that different foodstuffs leave the stomach at different rates of speed. Yet clinicians have given less attention to this function than to that of secretion and digestion, in spite of the proof by Ogata and Schmidt and of Strassburger that gastric secretion and digestion are unimportant factors in the final utilization of food. Further study of the distribution of food by the stomach to the duodenum might be of distinct value.

### SUMMARY AND CONCLUSIONS

This paper reports a study of the digestion of two dogs upon which a total gastrectomy had been performed two years previous to the initiation of this investigation. The study shows an inability of these animals to utilize the nitrogen and the fat of the diet as effectively as did normal animals. The digestion of carbohydrates was not determined because the available methods of study were not satisfactory. Although fluctuations in the absorption of nitrogen and of fat occurred in both the normal and the pathological animals, the extent of this fluctuation was much greater in the pathological dogs. The maximum absorption of nitrogen and fat in the pathological animals never was more than the minimum absorption by the normal dogs. In general, the dogs without stomachs did not utilize the fat so well as they did the nitrogen.

It was found that, if the diet is fed slowly so that the fat enters the duodenum at the approximate rate at which it leaves the normal stomach, the absorption of fat is normal. Also this slow feeding results in better absorption of nitrogen than when the diet is eaten rapidly. This would appear to show that the intestines are capable of utilizing fat as effectively and rapidly as they are called upon to do under normal conditions. It is suggested that the slight improvement in digestion which follows the administration of hydrochloric acid and of digestive enzymes results from a slower rate of food ingestion. It is further suggested that the amount of intestinal dilatation which occurs following removal of the stomach, determines the efficiency of digestion by influencing the rate at which a patient can eat. The study emphasizes the importance of the stomach as a regulator of the rate at which the different foodstuffs reach the intestine.

#### DISCUSSION:

FRANKLIN W. WHITE (Boston): This paper is well planned and carefully worked out, and ought to clarify our ideas of what happens to the functions of the digestive tract after a total gastrectomy. The paper is doubly welcome, since most recent studies after gastrectomy have been of the blood, not of the digestion.

I wish to make a mild objection to the method of measuring the absorption of food. There may be a source of error in weighing the food and in analyzing the stool for nitrogen and fat, and calling the difference the amount absorbed: *First*, the gastrointestinal tract is a secreting as well as an absorbing organ; that is, some nitrogen is added in addition to that given in the food; *Second*, the food nitrogen may be reduced in the stool not because it is absorbed, but because it is destroyed by enzymes or bacteria. In spite of these objections it is probably the best method we have at present.

We get a sidelight on this question of digestion by the study of other cases where there is lack of gastric secretion or changes in emptying time of the stomach. Take the first group of achylia or pernicious anemia. Here there is no HCl in the stomach, and the emptying time is more or less normal. Our stool studies with the Schmidt-Strassburger test diet and rough quantitative methods have shown that the proteid digestion is complete, and the nitrogen output in the stools is normal, and the patient's nutrition is good as a rule, even when under observation for six or seven years or more. On the other hand, if a motor change occurs, such as diarrhea, there at once appears a large nitrogen loss in the stool.

In subtotal gastrectomy for gastric ulcer or cancer we have both lack of HCl in the stomach and some motor changes. The X-ray shows a funnel-shaped stomach with no peristalsis, and *rugae* coarser than normal in the stomach and duodenum. At first the stomach empties rather rapidly in twenty to sixty minutes, depending on the kind of operation. Later it tends to empty periodically in one to one and one-half hours. The upper jejunum is dilated to two or three times normal size, and there is

small intestine hurry, so that the meal reaches the lower ileum in one-half to two hours. At first all these patients take small frequent feedings. Later most cases gradually take ordinary feedings. The stools are approximately normal unless there is diarrhea, which causes at once increased loss of nitrogen and fat. In the third group of total gastrectomy I have seen only two patients, both cancer, sick and anemic, and rather short-lived, and it is impossible to say that any changes observed were due to the gastrectomy alone.

All this data bears out Dr. Emery's idea that the cause of faulty digestion after gastrectomy is not lack of secretion and proteid digestion, but is largely due to changes in motor function, such as the rapid emptying of the stomach and the dilation and hurry in the upper small intestine, and secondarily to changes in absorption.

I agree with Dr. Emery's explanation that the variable data of other authors on digestion after total gastrectomy may be largely due to such variable factors as ordinary feeding in one case and small, frequent feeding in another: the degree of accommodation changes in the bowel, whether early or late, such as dilatation and increased motility; perhaps also to a third factor which Dr. Emery did not mention—the degree of the anemia. I am not speaking of pernicious anemia, but the hypochromic, microcytic type. The anemic group after gastrectomy is largely a group of surgical failures with pain, gas, vomiting, diarrhea, etc., which often lead to deficient diets.

Finally, it is evident that the stomach is not indispensable as a reservoir or a ferment-producer, and that the necessity for HCl to stimulate intestinal secretion has been greatly exaggerated. Dr. Emery is to be congratulated on an excellent and useful piece of work.

DR. LEON BLOCH (Chicago): Dr. Emery's report of an excellent piece of work coincides fairly well with the clinical phenomena in the wake of subtotal resection of the stomach for peptic ulcer. Especially interesting is that phase of the work dealing with the reduction in digestion of fats. This undoubtedly contributes to the failure of some patients to gain weight, post-operatively, and may, as has been stated, occur both after resection and gastroenterostomy.

While this discussion should be limited primarily to experimental work, I have had no such experience and will therefore refer to clinico-physiologic data which bear out the findings of the essayist. The symptoms which manifest themselves after resection are mainly of a three-fold character, the results of jejunal overdistention, too rapid propulsion of the intestinal contents and occasionally a sort of indigestion ascribable to lack of hydrochloric acid.

Normally the jejunum receives its contents in small quantities from the duodenum. After resection, large quantities of poorly comminuted food enter the jejunum in a short time and over distend it. The subjective symptoms which result from the ensuing irritation of the intestinal sympathetic nerves are fulness, faintness and perspiration coming on a short time after eating; such may recur over a period of months, eventually to disappear, or, in a few instances, recur for a year or more, especially in cases of resection of a high lying gastric ulcer on the lesser curvature.

Diarrhea is a frequent symptom after resection and may be accompanied by cramps, particularly so, if a high residue diet is partaken of too early. Dr. Emery has called attention to shortening of the time of the intestinal passage of food as one of the causes of faulty digestion. This is of particular interest because two of the points mentioned by the essayist are encountered clinically. One is that experience has shown that frequent feedings of small amounts of comminuted low residue food decrease peristaltic activity. This therapeutic measure is not unknown and has resulted in considerable improvement in the nutrition of the patient.

The second point is the last one in my discussion and refers to symptoms which for some reason or other are relieved by the administration of hydrochloric acid. It is a peculiar thing that the lowered or apparently absent acidity, which is one of the *desiderata* of resection should lead to symptoms of indigestion after the operation and which in some patients are relieved by hydrochloric acid. Dr. Emery has noted an increase in the absorption of the diet after the administration of hydrochloric acid and thereby confirmed clinical experience. It may be given after meals, before meals, or both. Not only is there relief of the distress but also there is an increase in weight as a result of the improved digestion.

DR. EDWARD S. EMERY, Jr. (closing the discussion): I should like to apologize for having presented

this work in a way that might appear as though it was not finished, and it really wasn't—in, that further work should have been done on the absorption of nitrogen, but, unfortunately, the laboratory was about to undergo repairs by carpenters and plumbers, and I had to stop before I could finish to my satisfaction the study of the nitrogen factor.

What Dr. Bloch says about hydrochloric acid is interesting in that von Haberer and one other European have reported definite diarrhea following total gastrectomy, which was controlled by the administration of hydrochloric acid. I do not know just why that should be so. I should like to know.

I wish to thank Dr. White and Dr. Bloch for discussing this paper.

## Experimental Studies in Gastric Physiology in Man: the Mechanism of Gastric Evacuation After Partial Gastrectomy as Demonstrated Roentgenologically\*

By

HARRY SHAY, M.D.

and

J. GERSHON-COHEN, M.D., M.Sc. (Med.)

PHILADELPHIA, PENNSYLVANIA

LITTLE over a half century has elapsed since Billroth (1) performed the first successful resection of the pylorus in man. Since then, many contributions concerned with the resulting altered gastric physiology have been made. Most investigators, however, have been occupied rather with the changes in gastric chemistry than with the altered motor function which has been considered, clinically, the result of another "dumping operation." We have been unable to find any studies in man which show whether or not any real alteration in the mechanism of gastric evacuation occurs after partial resection. Our data demonstrate that if the resected stomach be properly classified with regard to its gastric secretory change and compared with an intact stomach of corresponding secretory response, the alteration in the behavior of the gastric-emptying mechanism will be only quantitative. Our comments refer only to the Billroth I and Polya types of resection. The Billroth II type will be considered in our studies of the gastroenterostomized stomach, since this resection presents essentially the problem of a gastroenterostomy with the pyloric end of the stomach occluded.

### EXPERIMENTAL METHOD

This report is based on sixty-seven serial X-ray examinations performed on six cases of partial gastrectomy. The method of investigation was identical with that recorded for our previous studies (2). The patients studied had had partial gastric resections at periods varying from one-and-one-half to six years

previously and who, at the time of the investigation, after a complete diagnostic survey, appeared to be in good health. All patients exhibited a complete anacidity by fractional gastric analysis following the usual Ewald meal.

Intubations, both gastric and jejunal, were repeated to eliminate any psychic disturbance. Standard conditions for the studies were maintained. The evening was selected for the examinations because of its convenience. The patient was permitted to eat his usual luncheon at noon, but at 3 p. m., three slices of dry toast and a cup of tea without cream were taken. Nothing was taken thereafter until 8 p. m., when the studies were begun.

The X-ray test-meal consisted of 250 c.c. of tap water at 38° C. containing two ounces of barium sulphate. All test substances in this group of experiments were added to the water-and-barium meal, the total volume remaining constant. Gastric emptying-time, for each subject under the standard conditions, was determined with the water-and-barium meal. This was checked by a second study and rechecked at the completion of all the tests.

The emptying-time for the water-and-barium meal having been established, new studies were made in which various test substances were introduced: hydrochloric acid (0.09 to 0.49%), sodium bicarbonate (1% and 5%), glucose (5% to 40%), normal saline, 5% sodium chloride, varying amounts of olive oil, and meals of milk and of cream. The effects on gastric motor function were studied serially by fluoroscopic and roentgenographic examinations. Observations and records were made during the first five minutes after ingestion of the meal and at fifteen minute intervals until gastric emptying of the water-and-barium meal had occurred. With the other test substances, studies of the residues were continued up to the

\*Read at the 38th Annual Session of the American Gastro-Enterological Association, Atlantic City, N. J., June 10-11, 1935.  
Approved by the Publications' Committee of the Association.

emptying-time noted for the water-and-barium meal alone.

The group was then studied for the effects of the same agents upon the gastric-emptying of the standard water-and-barium meal when they were applied directly to the intestinal mucosa. The intestine was first intubated with a Rehfuß tube. The test agent was then slowly instilled into the intestines while the water-and-barium meal was taken. The intestinal instillation was regulated with a Murphy bulb. Before applying the various agents, however, gastric evacuation was determined after intestinal intubation alone, in order to note any mechanical effect of the tube. As recorded for intact gastro-duodenal segments, no change in gastric evacuation resulted from the mere presence of the tip of the tube in the jejunum and of the tube through the stoma. Serial roentgenographic data were recorded as before.

### EFFECTS OF ACIDS AND ALKALIES

A recent publication (2) reported data that show the effects of acids and alkalies on gastric-emptying in apparently normal individuals with the gastro-intestinal tract intact. Those agents were of concentrations similar to the ones used in the present experiments. Their effects were studied after ingestion by mouth and after direct instillation into the duodenum. From these studies, it was concluded that with an intact gastro-intestinal tract the pylorus is the local mechanism which determines gastric evacuation; that the local stimuli activating this mechanism arise from the intestinal mucosa and that the gastric hydrochloric acid is the normal intrinsic agent which, upon its arrival into the duodenum, acts as the mucosal stimulant.

It must be remembered that this summarized report was concerned with the *intact* gastro-intestinal tract; that it considered only the local mechanism involved, and did not mean to imply that gastric-emptying could not be modified by stimuli from remote areas, as, for example, inflammatory disease of the ileo-cecal region, pelvis, etc., or by some psychic factor. Further, it stressed the fact that gastric hydrochloric acid is not the sole agent that can stimulate the intestinal mucosa but that ingested foods through their physical or chemical properties are usually efficacious stimulants. Of especial interest from this standpoint is the recent contribution of Johnston and Ravdin (3). These investigators, from studies of the effects of various concentrations of glucose on gastric-emptying in the dog, found that when hypertonic solutions of glucose were placed in the stomach, gastric-emptying was delayed. Although the concentration of glucose in the stomach in many instances remained high, that in the jejunum and ileum was always at or below isotonicity. They believe that the small amounts of hypertonic glucose which pass into the duodenum offer the stimulus to pyloric activity and gastric retention. Thus, Johnston and Ravdin, by an entirely different experimental approach, reach a conclusion similar to that deduced from our roentgen studies in man. This explains probably why patients with achlorhydria may so frequently escape symptoms suggesting any marked disturbance of gastro-intestinal motility.

The importance of considering the acid secretory response of the individual under investigation, especially in studies with acids and alkalies also has been pointed out (2). It would be impossible to interpret the results obtained were this response unknown.

All the patients who had had a partial gastric resection showed a complete anacidity in response to the Ewald and to the water-and-barium meals. The motor phenomena observed in these subjects after the various stimuli ingested or applied directly to the jejunal mucosa, were identical with those obtained in the intact achlorhydric stomach, except quantitatively.

The gastric-emptying of the standard water-and-barium meal in our normal group was more rapid in the achlorhydrics than in those who had normal or hyper-acidity. This is, of course, the usual observation in uncomplicated cases of anacidity. The anacid, resected group emptied the same meal even more rapidly than did the intact achlorhydric stomach. Thus, the group of achlorhydrics with stomachs intact emptied the standard water-and-barium meal in periods ranging from fifteen minutes to one-and-one-half hours, but in the resected group, the gastric-emptying time for a similar meal in no case exceeded thirty minutes.

A similar relationship was found when the test substances caused delay in gastric evacuation. Less delay was observed in the resected achlorhydric stomach when the test substance either was ingested or applied directly to the intestinal mucosa. These observations confirm, in the human subject, what McCann (4) clearly demonstrated in the dog. He found that the stomach from which the sphincter had been removed was able to retain the test meal successfully. However, there were smaller quantities of material retained in similar time periods, thus indicating that the efficiency of the mechanism for the proper retention of the meal had been impaired. The results of the studies of Thompson (7) also are very significant at this point. He found, in dogs, after graduated multiple resection of the stomach with a Polya gastro-jejunosomy, that the acid values of the gastric contents, subsequent to the ingestion of his standard test meal, varied indirectly with the amount of the pylorus removed. Free hydrochloric acid failed to appear only after removal of the entire pyloric antrum of the stomach. In the roentgenologic observations on the emptying rate of the stomach following these operations the rate was found to be more rapid than pre-operatively, regardless of the grade of resection. Absence of the pyloric sphincter, therefore, rather than the increase in diameter of the pyloric outlet, would seem to be responsible for the result observed.

The fact that a stomach, after a resection of the distal end, is capable of retaining its contents in a manner resembling that of the intact stomach, seems to indicate that the pylorus is not the sole mechanism which regulates gastric evacuation. Yet such evidence does not necessarily deny to the pylorus a determining rôle in gastric evacuation in the intact stomach. It may well be that the other gastric muscle-fibers in the distal end of the resected stomach attempt to compensate for the loss of the pylorus. Such a view is supported by the facts that a resected stomach is less efficient in retaining its contents than is an intact stomach, and that the antrum, pylorus and duodenal "cap" behave, from a motor standpoint, as a physiologic unit. The latter has been indicated in the work of Cole (6), Wheelon and Thomas (5), as well as in the experimental studies of McCann (4), Thompson (7), ourselves (2) and others. For example, we found that, in the intact stomach, adequate stimuli applied to the intestinal mucosa always produced pyloric

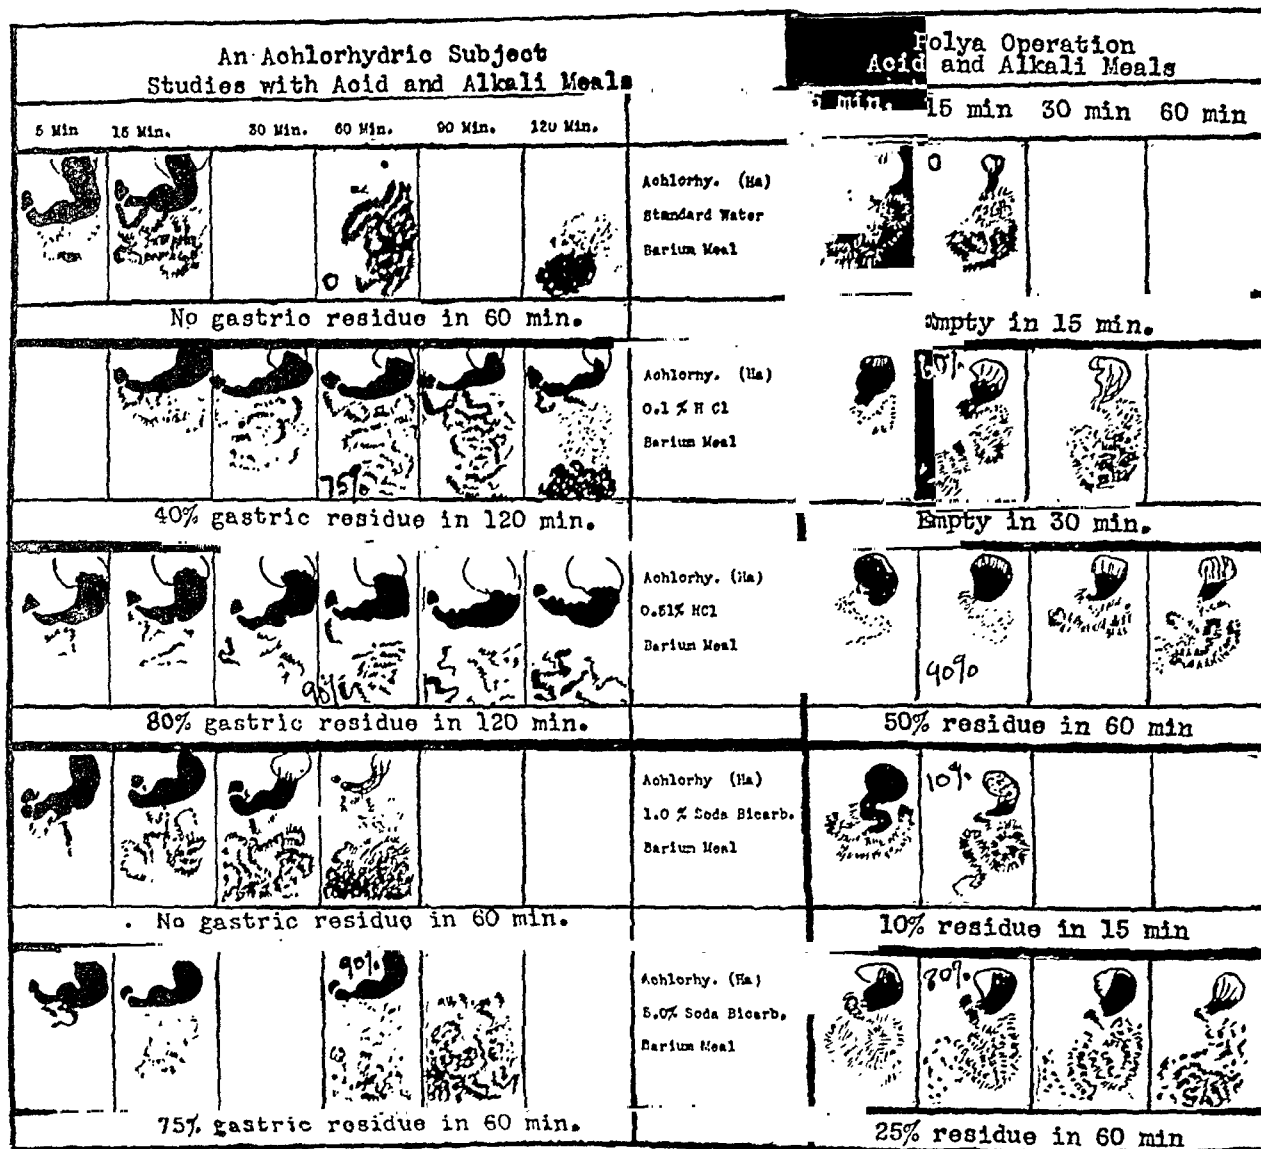

Fig. 1

closure, but antral spasm only when the stimulus was intense. We are disposed to believe from these facts that the remaining fibers act as a substitution mechanism to retain the gastric contents after pyloric resection. Too, they explain both the lesser efficiency of the mechanism and our observation that a stronger stimulus must be applied to the intestinal mucosa after pyloric resection to produce a retention of the gastric contents similar to that obtained in the intact stomach. The latter was especially apparent with the milder types of stimulant which produced relatively slight changes in gastric motility. With very strong stimulants, this difference was much less obvious or was lost entirely because they apparently (the stimulants) could call forth a maximum reaction in the mechanism of both the intact and the resected stomachs. Such reactions frequently were observed when 0.5% hydrochloric acid was applied directly to the intestinal mucosa.

Another question which must be kept in mind in this connection is whether the same stimulus, applied

to different portions of the intestinal mucosa, will equally activate the intestino-pyloric mechanism. Marbaix (8), in 1898, starting with the supposition that the intestine influences the action of the pylorus, attempted to determine the extent of intestinal mucosa from which this influence could be elicited. In his studies on dogs, Marbaix made one intestinal fistula at 10 to 15 cms. distant from the pylorus and others at varying points distal to the first along the course of the small intestine. He obtained clear evidence of the intestinal influence on the action of the pylorus when the mucosa of the upper half of the small intestine is stimulated. It may be, therefore, that the lower in the intestines the mucosa is stimulated, the stronger the stimulants necessary to produce similar gastric effects. In the resected stomach, not only has the pylorus been removed, but the segments of intestine which receive the gastric content are much lower than when the stomach is intact. In our studies on the normal intestinal tract by intubation with long tubes, we found that the delay of gastric evacuation varied

inversely to the distance from the pylorus at which the stimulant was applied.

### THE EMPTYING OF FATS AND HYPERTONIC SOLUTIONS

The observation that fat in the upper digestive tract decreases gastric motor activity was made by Ewald and Boas (9) in 1886. This has since been repeatedly confirmed. In 1901, Lintvarev (10), working in Pavlov's laboratory, published very interesting data of the effect of fats on gastric evacuation. Experimenting on dogs, who had both stomach and duodenal fistulae, and using olive oil, cod liver oil, butter, egg yolk, and cream, he found, in 150 experiments, that the pylorus closed as soon as oil passed into the duodenum. He concluded that fats introduced into the duodenum reflexly close the pylorus and do not permit any liquid to pass from the stomach for a considerable time. Recently, from roentgen studies on human subjects, we (11) came to the same conclusions, except as modified by the recent evidence that a humoral as well as a nervous reflex factor may activate the mechanism. Of particular interest here are the contributions of Quigley, Zettleman and Ivy (12); of Quigley and Phelps (13); of Ivy and Farrell (14); of Kosaka and Lim (15). The rapidity with which pyloric closure, the cessation of gastric evacuation and diminution and disappearance of gastric peristalsis, and often, antral spasm, follow the duodenal instillation of fats or any other equally active stimulant, forces one to suppose a nervous reflex mechanism. Yet the investigations of Quigley, Zettleman, and Ivy (12) clearly show that the nervous mechanism can not be the only one involved. These investigators, working with dogs and with entire stomach pouch preparations after complete denervation, found that total gastric inhibition followed the duodenal introduction of fatty substances. It is especially interesting to observe that the various fatty substances (12) and carbohydrates (13) were without effect upon gastric motility when applied to the gastric mucosa alone.

More recently, Quigley and Phelps (13), using auto-transplanted denervated pouches, were able to demonstrate similar phenomena following the arrival of carbohydrates in the upper intestines. In 1905, Carnot and Chassevant (17) (18), studying the effect of saline and glucose solutions on gastric-emptying in dogs with duodenal fistulae, came to very definite conclusions regarding the rôle of the osmotic pressure of solutions upon gastric evacuation. Isotonic solutions, they found, produced a series of pyloric openings which permitted the solutions to course very rapidly by successive jets from the stomach into the intestines without undergoing great modification. If, however, the solutions were appreciably far from isotonicity, the contact of the first portion of the liquid with the duodenum provoked reflex closure of the pylorus; this did not reopen until proper dilution of this portion had taken place. Carnot and Chassevant speak of this phenomenon as the "reflex delta-regulator" of the pylorus. Recently, Ravdin, Johnston, and Morrison (19), studying the concentrations of glucose in the stomach and intestines of the normal dog after intra-gastric administration, found that the introduction of hypertonic solutions was followed by an increase of volume and a decrease of concentration in the stomach, while the concentration of glucose in the intestines was approximately isotonic or lower at all times, re-

gardless of the concentration in the stomach. Later, Johnston and Ravdin (3), on the basis of these findings, suggested that the hypertonic solutions of glucose left the stomach slowly enough to permit their change to those fluid concentrations which would be acceptable to the intestines. This "control" was due to the reaction of the pylorus to stimuli from the duodenum caused by the small amounts of hypertonic glucose solution reaching it.

We have reported, for man, that the stimulation of the duodenal and upper intestinal mucosae by hypertonic and hypotonic solutions of electrolytes and non-electrolytes can produce pyloric closure, cessation of gastric peristalsis and evacuation (2). Although Quigley and Phelps (13) obtained gastric inhibition with approximately isotonic solutions of dextrose, it is worth noting that their results were "more striking, more conclusive and more constant when solutions of higher concentration (20% to 50%) were used." By our method of investigation we were unable to demonstrate any motor changes from the use of isotonic solutions. Quigley and Hallaran (16) also failed to cause any gastric motor depression with isotonic sodium chloride solutions.

In our studies, we found that the resected stomach responded to fats and to solutions of different osmotic pressures in a manner entirely comparable with the behavior of the intact stomach, but that these agents did not delay gastric-emptying to the same degree in a resected stomach as they did in the intact stomach.

### SUMMARY

Partial gastric resection apparently causes no basic changes in gastric evacuation. If the altered gastric chemistry which results from the resection is taken into consideration, then gastric evacuation is modified in the same way by the same agents that modify gastric-emptying of the intact stomach to a similar chemical response, except, of course, for quantitative differences. These differences appear to be due to the loss of the pyloric sphincter. The remaining gastric muscle-fibers appear to offer a substitution mechanism, but are not so efficient as was the pylorus. The response is similar to that of the intact stomach whether the test substances are ingested or are applied directly to the intestinal mucosa. The evidence also indicates that, even in a partially resected stomach, the mechanism of gastric evacuation is controlled from the intestinal side.

Since the stomach in this group was cut away from the duodenum, the intestinal effect upon gastric emptying cannot be dependent upon a reflex through the enteric plexuses. It does not however, rule out a long autonomic reflex. The data also indicate that resection of the stomach is in no real sense a "dumping operation" and that the roentgenologist in comparing gastric emptying times must take into consideration the nature of the meal used for the study.

#### DISCUSSION:

DR. M. J. WILSON (Toronto, Ont.): This paper is of great interest to me because the Authors have adopted a method which I abandoned some years ago. In my experiments on normal subjects the presence of the tube in the duodenum hastened gastric evacuation.

It is of interest to compare this communication with the Authors' previous paper on the normal stomach. In both cases strong acid in the duodenum delayed gastric emptying to a marked degree. This is in accord with many experiments on dogs.

The Authors do not state how extensive the resections were in their subjects. This is a point of considerable importance, because after extensive gastric resection there is usually very little peristalsis observable. Dr. Singleton has recently examined four duodenal ulcer patients who had had Billroth I operations, in each case with less than an inch of stomach removed. Thus the operations could be termed pylorotomies. Under the fluoroscope, gastric peristalsis was just as marked as before operation, and the stomach appeared to empty in exactly the same way as previously, and at the same rate. In two of the cases it was almost impossible to tell by fluoroscopic examination that any operation had been performed. Thus the removal of the pyloric sphincter had very little effect on the progress of the meal.

The Authors infer that, in the normal stomach, it is contraction of the sphincter which delays gastric emptying. I cannot agree with this. Thomas, Crider and Mogan made a very significant observation when they stated that irritation of the duodenum apparently delayed gastric evacuation not by contracting the pyloric sphincter but by decreasing gastric peristalsis. In my opinion the best of the available evidence tends to confirm this view.

I should like to ask the Authors if they made any observations on gastric peristalsis in these cases.

DR. JOHN P. QUIGLEY (Cleveland, O.): Consideration of the physiology of gastric evacuation emphasizes the existence of a mechanism well calculated to insure slow emptying of the stomach and prevent overloading of the intestine, especially with unsuitable material. The factor of safety is pronounced. Primarily, gastric emptying depends: first on a pressure within the stomach greater than is the intraduodenal pressure, produced essentially by gastric motor activity; second, on the "stop-

cock action" of the pyloric sphincter. Each of these mechanisms is controlled from the proximal intestine by reflexes and probably also by humoral factors, *e.g.*, by "enterogastrone."

Other factors modify gastric evacuation, usually to a minor extent and need not be emphasized in the present discussion.

The observations of Drs. Shay and Gershon-Cohen on gastric evacuation following pyloric resection are quite in accord with the above analysis. They have demonstrated that when the pyloric sphincter is removed, suitable substances in the intestine may still retard gastric evacuation.

The studies of Quigley, Zettleman and Ivy, and of Quigley and Phelps are pertinent to this subject. They observed motor inhibition of the pyloric-obstructed stomach when fats or sugars were introduced into the jejunum. Since this phenomenon could also be demonstrated following denervation of this stomach preparation, the humoral mechanism must be involved.

Applying these results to the investigation of Drs. Shay and Gershon-Cohen it appears evident: (1) that a humoral mechanism is involved in the retarded emptying of the pylorotomized stomach, (2) it operates by depressing gastric motility, (3) this inhibition is initiated by the presence of suitable substances in the upper intestine, and (4) hydrochloric acid is not essential for the initiation of this mechanism.

DR. HARRY SHAY (closing the discussion): Dr. Wilson, we have in the course of our gastric motor studies in the past five years utilized some fifty or sixty patients. In all cases have we studied the effect produced by the tube alone. In neither the intact gastro-duodenal segment with the tube through the pylorus, or in the resected stomach with the intestine intubated by way of the stoma, have we noted any material change in the gastric emptying time of the standard water and barium when compared with the results obtained in the absence of the tube.

(Slide): (See Fig. 1). These are representative pen and ink drawings made from the X-ray photographs and illustrate the effects of the various meals then ingested. The group on the left shows the results obtained in an achlorhydric subject with an intact gastro-intestinal tract. The right group picture similar studies in a case after partial gastrectomy. The upper line of drawings represents the results obtained in each with the standard water and barium meal. We note, for example, that the emptying time in this instance was sixty minutes for the intact tract. The same individual after the ingestion of a 0.1% hydrochloric acid solution showed a gastric residue of 40% at the end of two hours. This is of interest since a 0.1% hydrochloric acid solution certainly is physiological for the upper duodenum.

In the second row, we find the results obtained in the same patient following a meal of 0.51% hydrochloric acid. We see a much greater residue at twice the normal emptying time. The 1% sodium bicarbonate (essentially an isotonic solution) produces no effect in the achlorhydric. This meal in the individual with normal or hyperacid response, shortened the gastric emptying time as compared with that obtained with the standard water and barium meal. You will note, however, that the 5% sodium bicarbonate meal (a hypertonic solution) caused a 75% gastric residue at sixty minutes at which time the standard water barium and 1% bicarbonate meals had been emptied.

On the right we note that in this resected stomach the 0.1% hydrochloric acid doubled the emptying time of the standard water and barium meal while the 0.5% meal more than quadrupled the same period. The isotonic bicarbonate again caused no material change, while the hypertonic (5%) bicarbonate again slowed the emptying of the resected, achlorhydric stomach.

Our other slides, illustrate the effects of various other meals used. They leave no doubt that the emptying-time

of the resected stomach may be delayed in the same way as that of the normal stomach, not only by acid solutions but by hypertonic solutions of electrolytes or non-electrolytes, fats or any substance capable of adding the proper stimulus to the upper intestinal mucosa. May we thank Dr. Quigley and Dr. Wilson for their discussions; I regret that adequate time is not available to answer the rest of Dr. Wilson's questions.

Dr. Ivy (Chicago): I should like to ask whether there were any observations of the effect of the duodenal tube on gastric emptying: the rate of emptying? That was the first point made by Dr. Wilson.

Dr. Shay: We have now studied more than fifty patients and find that the duodenal tube through the intact pylorus or through the stoma produces no change in gastric emptying.

## ABSTRACTS

PEARSE, H. E., JR.

*Experimental Chronic Intestinal Obstruction From Blind Loops. S. G. and O., Vol. LIX, No. 5, pp. 726-734, Nov., 1934.*

In view of the present day practice of short-circuiting the fecal stream by entero anastomosis above a point of obstruction, the Author set about to study the fate of that inactive segment of bowel between the point of anastomosis and the point of obstruction. Experiments were made on dogs under conditions of surgical anaesthesia and asepsis. The abdomen was opened, and a point twelve inches below the duodeno-jejunal angle determined and marked with a silk stitch. From that point loops of intestine measuring from six inches to six feet were measured in different animals. The distal point was marked and brought beside the proximal one, and an entero-anastomosis made. The loop was obstructed by section and inversion of the ends; the ends were tied together to prevent intussusception. The loop was obstructed in the proximal limb just beyond the anastomosis, at the mid point of the loop or in its distal limb just before the anastomosis giving varying lengths of bowel on both sides of the obstruction. For the sake of comparison in a few animals the loop was created and anastomosed but not obstructed.

It was found that those animals having blind loops distal to the obstruction lived normally in every way and without any disturbance of digestion or nutrition. Peristalsis tends to keep that segment empty. Intussusception of this segment of bowel is apt to occur if it is not guarded against.

When the direction of peristalsis is toward the blind end, material is trapped in it and cannot get out. It was found that such a loop dilated tremendously forming a veritable cesspool. If these loops are less than one foot long, they may empty at intervals and cause no disturbance. Those slightly longer become filled with inspissated material, and if they are not perforated by a foreign body, give rise to mild symptoms of toxæmia. Blind loops over two feet in length become tremendously dilated and hypertrophied, and if perforation does not occur they give rise

to symptoms of chronic intoxication characterized by anorexia, lassitude, weakness, lethargy, emaciation, and finally death. No significant changes were found in the blood non-protein nitrogen, sugar, chlorides, carbon dioxide combining power, sugar or haemoglobin in these animals.

The animals in which the loop was created and anastomosed, but obstructed, showed no symptoms of an intestinal disturbance.

The Author feels that the demonstration of the deleterious effects of blind intestinal loops does not contra-indicate the use of such anastomoses in cases of acute intestinal obstruction when enterostomy is the only alternative procedure. He feels that the avoidance of the messy, often excoriated and painful enterostomy wound, and the necessary subsequent operation, makes entero anastomosis preferable. Such cases should be followed for a long time, and any gastro-intestinal derangements attributable to the blind loop indicate a re-operation.

Two cases are discussed. Four figures and one table accompany the article.

ELMAN, ROBERT, M.D., AND ECKERT, C. T., M.D.

*Gastric Acidity as Influenced by Pyloric Closure and Stenosis. Arch. Surg., Vol. 29, No. 6, pp. 1001-1014, Dec., 1934.*

This article is a continuation of experimental work being done at the Washington University School of Medicine on the relation of gastric acidity to the activity of the pyloric sphincter.

These experiments show quite conclusively that pyloric stenosis leads to spontaneous high gastric acidity and interferes with the normal neutralization of acid introduced into the stomach. Closure of the pylorus in the non-anesthetized dog delays or halts while opening re-establishes the normal rapid neutralization of gastric acidity. The Authors feel that these findings add further evidence supporting the idea that duodenal reflex controls in a large part the level of gastric acidity.

These observations show quite conclusively how high gastric acidity can be maintained and suggests that in

turn it may, of itself, initiate inflammatory changes which lead eventually to ulceration, hemorrhage and perforation.

The Authors feel that these experiments add very definite evidence of the relation of acidity to the pathogenesis of peptic ulcer.

LESSER, ALBERT, AND GOLDBERGER, H. A.  
*The Blood Sedimentation Test and Its Value in the Differential Diagnosis of Acute Appendicitis. S. G. and O., Vol. 60, No. 2, Feb. 1, 1935.*

The Authors using their own modification of the original Westergren technique studied the blood sedimentation test in a variety of clinical conditions. In their study a reaction of from 6 to 15 millimeters in the hour was considered normal, while the reaction of from 80 to 140 millimeters in the hour was considered severe.

In cases of acute full blown pneumonia, regardless of type, the average readings were between 80 and 100 millimeters. As convalescence advanced there was a gradual decrease in that reading; as a complication developed there was a sudden sharp increase in that reading.

In tuberculosis of the lungs the height of the sedimentation reaction was found to be an accurate indication of the extent and activity of the process.

In acute rheumatic fever a high sedimentation reading (from 90 to 100 millimeters) was found during the acute stage, while a lower reading was found as the patients general condition improved. The onset of any complication was marked by a sharp increase in the reaction.

In all cases of acute adnexal disease the reaction was increased, varying from 40 to as high as 150 millimeters. A reading of 20, or less, was found to be absolute assurance of the absence of any acute pelvic infection.

In all cases of acute appendicitis, excepting those with abscess or generalized peritonitis, the reaction was found to be normal, while all other conditions simulating acute appendicitis showed definitely abnormal reactions.

Two tables and a bibliography accompany the article.

N. M. Percy, Chicago.

## SECTION III—*Nutrition*

### Present Conceptions of Calcium Metabolism<sup>\*</sup>

By

DAVID LANDSBOROUGH THOMSON  
MONTREAL, CANADA

THE fundamental fact in the chemistry of calcium, which dominates its physiological behaviour, is that some of its commoner salts are highly insoluble. Large quantities of calcium salts, especially complex basic phosphates, are stored in the skeleton in solid form. Sodium and potassium, on the other hand, are present in the body almost wholly in soluble forms; these elements cannot be stored in the tissues unless large amounts of water are stored with them, since otherwise the concentration of the sodium and potassium ions in the tissue fluids would rise above the physiological limits. The metabolism of sodium and potassium is therefore very closely bound up with the metabolism of water: potassium is related to the fluid content of the living cells, and sodium to the external fluids in which the cells are bathed; and the behaviour of potassium and sodium under various circumstances may be taken as an indicator of the behaviour of the intracellular and extracellular water stores, respectively (1). Since calcium, however, can be stored in solid form without the question of concentration of calcium ions arising, its metabolism is not directly connected with the metabolism of water, and is regulated on different principles and by different means and mechanisms.

On the other hand, all recent studies support the view (2) that the stores of calcium in the bones are readily accessible. They may be added to or drawn upon, depending on the physiological circumstances; they do not form an unalterable rigid framework like the steel girders of a concrete building, but rather are to be compared with the stores of glycogen in the liver even if the usual range of fluctuation is not so great. Just as the controlled breakdown of liver glycogen maintains the approximately constant level of the blood sugar during fasting, so the skeletal calcium serves to maintain the serum calcium concentration within normal limits; and just as the formation and breakdown of liver glycogen is largely controlled by insulin and other hormones, so the formation and breakdown of the calcium stores in the bones is largely controlled by the hormone of the parathyroid glands.

The constancy with which the serum calcium is maintained in the neighborhood of 10 mg. per cent in

normal individuals is indeed striking, and becomes still more so when one repeatedly finds this same amount of serum calcium in all the commoner laboratory mammals with the exception of the rabbit. Very striking evidence of the efficiency and accuracy of the regulating processes was supplied by Hastings and Huggins (3). The experiments carried out by these Authors were of the following nature: They removed up to 50 per cent of the whole volume of the circulating blood of a dog and shook it with the highly insoluble salt lead phosphate; this process removed 90 per cent of the calcium present in the blood; the calcium-free blood was then reinjected into the animal. They were able to repeat this procedure again and again upon the same animal, at intervals of only 20 minutes, without greatly lowering the serum calcium content of the successive samples. This indicates that the dog is able to make good sudden loss of 45 per cent of its total serum calcium within 20 minutes, and to do so repeatedly; a very remarkable indication of the lability of the calcium stores in the skeleton.

Until very recent times, all discussions of the importance of the accurate regulation of the serum calcium level have been complicated by the fact that the calcium is present in more than one form. It is well known that if serum be forced through an ultra-filter only a fraction of the calcium passes the membrane. This, and similar experiments, lead to the distinction between diffusible and non-diffusible calcium. Many workers have also considered that even the diffusible fraction may be further subdivided into ionized and un-ionized calcium. Since it is generally considered that only the ionized form is of immediate physiological significance, and since there has not been until recently any convincing account of the equilibrium controlling the various calcium fractions or adequate means of measuring the ionized fraction, it has been difficult to relate determinations of total serum calcium to physiological problems. It has also been supposed that agents which affect calcium metabolism (the parathyroid hormone, for instance) may exert their effects by disturbing the equilibrium between these different forms of calcium. Recently, however, the matter has been convincingly clarified by the brilliant investigations of McLean and Hastings (4). These workers have found sufficiently accurate means of estimating the concentration of calcium ions in serum or other fluids by biological assay, using the

<sup>\*</sup>McGill University, Montreal.

Approved by the Publications' Committee of the Association.

isolated frog heart as a test object, and the results of this study indicate that in most cases we need take account of only two forms of calcium in the serum—free calcium ions and calcium bound to the serum proteins. The equilibrium connecting these two fractions is a reversible one governed by simple chemical laws (the law of mass action in particular), and from our knowledge of this equilibrium it is possible accurately to predict the concentration of ionized calcium if the total calcium concentration and the serum protein concentration are known.

With a normal serum calcium of 10 mg. per cent and 7 per cent total serum protein, approximately two-fifths of the calcium is in the free ionized state. If the serum be simply diluted with calcium-free saline, the ionized calcium is not so greatly reduced as the total calcium: that is to say, proteins liberate some of the bound calcium. If the total calcium concentration of the serum falls while the serum protein remains unaffected, the decrease in ionized calcium is relatively greater than the decrease in total calcium, though not very strikingly so. If the serum protein concentration falls while the total calcium remains constant, the fraction of the calcium which is ionized will naturally be increased. The ratio between free and bound calcium is only slightly affected by changes in the albumin-globulin ratio or in the hydrogen ion concentration, and is not directly controlled by the amount of parathyroid hormone or by any other of the agents known to intervene in calcium metabolism. These studies have eliminated from discussion numerous theories of calcium metabolism which invoked shifts in the equilibrium between the different forms of calcium and which, though difficult to disprove, were not helpful to an understanding of the fundamental problems involved.

We may turn now to discuss some of the physiological properties of the ionized calcium on which the therapeutic use of calcium salts largely depends. In the first place there is a certain sedative action, both peripheral and central, which has led to the use of calcium in such spastic states as those produced by spider bites. We have been accustomed to think rather of the sedative effect of magnesium salts administered intravenously, and to think of the sedative or even narcotic effect of calcium salts in a rather negative manner, since the neuromuscular irritability caused by decrease in the serum calcium is more striking and has been more studied than its converse. Moreover, calcium tends to inhibit magnesium narcosis. In recent years, however, irritability due to deficiency of magnesium has become familiar (5, 6), and on the other hand we are beginning to recognize the sedative effects of increased calcium ion concentration. My colleagues, Drs. Andreyev and Pugsley (7), have used the conditioned reflex method to study the effects of maintenance of the serum calcium at a high level by continued administration of parathyroid hormone or irradiated ergosterol, and have shown that dogs so treated display an enhancement of all inhibitory processes; they have thus given objective and quantitative expression to the not unfamiliar idea that animals subjected to such treatment are drowsy and apathetic. Others have shown (8) that calcium salts administered intravenously have a sedative action upon intestinal colic, especially the colic of acute lead poisoning. There can be no doubt of the efficacy of this mode of treatment although it has not been possible to sup-

port it in animal experimentation (9). The pains are so rapidly allayed that the effect cannot be due simply to removal of lead from the circulation, although as is well known the metabolism of lead is very similar to that of calcium and it is possible to cause lead to be deposited out of harm's way in the bones by creating circumstances leading to deposition of calcium. Whether the alleged therapeutic value of calcium in ulcerative colitis (10) and tuberculous enteritis should be considered under this heading or not is uncertain.

Calcium salts have also found therapeutic application in the treatment of allergic manifestations, especially bronchial asthma (11), although uniformly successful results are not always obtained. It is probable that this action of calcium is not to be linked with its sedative effect, but rather with a somewhat vague and elusive relation which appears to exist between calcium and the sympathetic nervous system; that is to say, the action of the calcium on the bronchial musculature may be regarded as analogous to the action of adrenalin or ephedrine. This relation between calcium and the sympathetic nervous system has recently been analyzed (12) but appears to be extremely complex and is not in all cases to be depended upon.

One important property of calcium salts, which falls under a different heading since it does not depend upon calcium ion concentration, is the acidifying action. If calcium chloride is given by mouth the calcium is less completely absorbed than the chloride, and partly remains in the intestine as calcium phosphate or carbonate. This tends to reduce the bicarbonate ion concentration of the blood and thereby to produce a relative alkali deficiency (13). In some circumstances the acidosis so obtained may have therapeutic value, since acidosis has in itself sedative effects—hence, for instance the use of the ketogenic diet in the treatment of epilepsy.

The control of calcium metabolism exerted by the parathyroid hormone has already been referred to and is of course very familiar. In the doses commonly employed the parathyroid hormone elevates the serum calcium by withdrawing calcium from the skeleton. The elevation is transient though longer than that obtainable by intravenous injection of calcium salts. Attention may be called at this time to the fact that the unit in which the dosage is most commonly expressed has now been discarded. The most widely used commercial preparations are biologically assayed on dogs, and the results have hitherto been expressed in the units originally defined by Collip (14). One hundred of these units is the amount required to elevate the serum calcium of normal dogs weighing 20 kilograms by 5 mg. per cent in 12 to 15 hours. It has now been decided that the unit proposed by Hanson has priority over the Collip unit. The Hanson unit was supposed to be determined on parathyroidectomized dogs and is a much smaller quantity than the Collip unit. Extracts which have hitherto been described as containing 20 Collip units per cubic centimeter are now described as containing 100 Hanson units in the same volume, although the extract itself is unchanged. It is to be feared that some confusion will result until the new dosage becomes familiar.

Several theories of the mode of action of the parathyroid hormone have been proposed. It has been suggested, for instance, that the parathyroid hormone lowers the renal threshold to phosphates, and that the

resultant fall in plasma phosphate concentration allows the plasma to hold larger quantities of calcium in solution. Against this theory may be cited the fact (15) that the characteristic histological changes produced in the bones by the administration of parathyroid extract are obtainable in nephrectomized animals. It has already been observed that the work of McLean and Hastings permits us to dismiss a number of theories of parathyroid hormone action. A survey of the available evidence (16) has led my colleagues and me to the conclusion that the action of the parathyroid hormone is best explained as a direct stimulus to the living cells of the bone. Moderate or large doses lead to the appearance of great numbers of osteoclasts, whose function it is to break down bone; but, if such doses are continued or if small doses are initially applied, elevation of the serum calcium is not observed and histological examination of the bones shows proliferation of osteoblasts which are concerned with the process of apposition (17).

Other agents which lead to release of calcium from the skeleton do not involve the osteoclastic reaction. This applies, for example, to the effect of all types of acidosis, to the effect of very large doses of irradiated ergosterol and to the effect of experimental or clinical hyperthyroidism. There is no explanation at present for the fact that, while both thyroid and parathyroid hormones lead to excretion of calcium removed from the skeleton, the former fails to produce hypercalcemia and the calcium is excreted chiefly in the faeces. Yet the thyroid hormone appears to be no less efficient than the parathyroid hormone in liberating calcium from the skeleton and there is evidence (18) that the effect is a specific one; it does not appear to be due merely to the general elevation of metabolism, since it is not observed in the elevated metabolism of subacute endocarditis. On the other hand, my colleague, Dr. Pugsley (19), has shown that the metabolic stimulant dinitrophenol, leads, like the thyroid hormone, to a marked increase in the faecal excretion of calcium in the rat.

#### DISCUSSION:

DR. A. C. IVY (Chicago, Ill.): Dr. Thomson in my opinion is to be commended for presenting a very concise abstract of our present knowledge of the physiologic aspects of calcium metabolism. It is a type of paper which does not lend itself to discussion.

About all that a discussant can do is to pick out certain points or facts that have been mentioned, and call upon his own experience for purposes of emphasis.

One point that I have in mind and which I think deserves emphasis is the importance of the reaction of the contents of the gastro-intestinal tract on the absorption of calcium. We all know that calcium is absorbed better when we have an acid reaction in the upper intestine; however, it was not until recently that I realized the importance of the secretion of hydrochloric acid in this regard.

Last year and about this time I removed the stomachs from four puppies about six weeks old. We kept them on a special diet that contained adequate quantities of calcium for growing puppies, more than 2 grams a day. About six months later two of these puppies became bowlegged.

X-ray pictures were taken which showed marked undercalcification of the bones of the body in all four puppies, and there was undercalcification to such an extent in two of them that bowleggedness had occurred.

Vitamin D was not concerned, because these puppies had been given daily tablespoonful doses of cod liver oil. That caused us to make X-ray photographs of our adult gastrectomized dogs, or dogs that had been gastrectomized when they were adults. We found that they had less calcium in their bones than dogs which had been kept in our colony about the same length of time, on the same diet.

This observation shows the importance of the secretion of hydrochloric acid for the absorption of calcium from the upper intestine and that the secretion of acid is more important, in infancy and childhood where large quantities of calcium are necessary, than in the adult where a large quantity of calcium is not necessary, because growth has occurred.

Dr. Thomson referred to the use of calcium in the relief of various types of visceral colics. Dr. Quigley and I, several years ago, and others in my laboratory on different occasions, have injected calcium intravenously to see its effect upon hunger contractions. Either it has no effect or only temporarily inhibits hunger contractions. I think Dr. Thomson is correct when he says that we do not know why calcium intravenously relieves biliary colic or colon colic. We can look upon it only as a "corrective." We have at present to view the therapeutic use of calcium in a number of conditions as a type of corrective. For example, the use of calcium in the bleeding tendency of jaundice—we don't know how the calcium works; yet we know there are some instances in which it works.

We have found that Vitamin D has a favorable influence on the hemorrhagic tendency in jaundice. It doesn't affect the calcium in the blood, but it does decrease the bleeding-time in the presence of jaundice. Since we do not know how it works, we can only say that it has a corrective action.

DR. LAY MARTIN (Baltimore, Md.): Dr. Ivy has well said that this paper does not lend itself to discussion. There is very little left to be said, particularly after Dr. Ivy has talked. There are a few related topics, however, that I should like to mention.

Dr. Thomson pays just tribute to the excellently conceived and completed investigations of McLean and Hastings. There is no doubt that their work is of tremendous importance, and, if their frog's heart method for the determination of ionized calcium is definitely applicable to human serum at its higher temperature, they have done a great deal to advance our ability to study this complex problem, "calcium metabolism."

It is simple to understand the algebraic approach to their formula for the determination of ionized calcium in relation to the law of "mass action." From the geometrical approach, however, it is not so easy. Suppose we take the two states of hypoparathyroidism and hyperparathyroidism: in the former we find a normal content of serum proteins, and according to their formula, a decreased amount of  $\text{Ca}^{++}$ ; in the latter condition, hyperparathyroidism, we find high ionized calcium, and a normal amount of serum protein. Is it not possible that there may be changes in the calcium affinity of the serum proteins in the two conditions?

Intimately connected with calcium metabolism is the condition known as tetany. In states of hypoparathyroidism (based on either disease processes or operative interference), and calcium low rickets, it has long been known that tetany will ensue when calcium decreases below a certain level. However, tetany is frequently seen in conditions in which serum calcium is found to be within normal limits, as examples of such states are protracted loss of gastric juice, and hyperpnea, either of which will produce an alkalosis.

In the former conditions, paliative relief may be at times obtained by calcium or ammonium chloride or HCl, in fact anything that will produce an acidosis. To permanently cure these types of tetany, measures must be made to raise the level of calcium serum in hypoparathyroidism by parathyroid hormone, and in calcium low rickets by readjustment of intestinal calcium absorptive ability, viz., Vitamin D or heliotherapy and increase in the acidity of intestinal contents.

The tetany that is found in instances of chloride or  $\text{CO}_2$  loss is best regulated by any chemical that will counteract the alkalosis. Calcium or ammonium chloride act in this manner.

In connection with the therapeutic usage of calcium chloride in cases of bronchial asthma, I would like to ask Dr. Thomson if he does not feel that its beneficial result is due more to its dehydrating effects than to the direct

action of the calcium ion. The similar effects obtained after injections of parathormone would seem to be indicative of this. Furthermore, may this not also apply to its helpful action in intestinal colic?

One more word on the mode of action of parathormone. The idea of increased osteoclastic action causing dimineralization does not seem to me acceptable especially as Dr. Thomson has already stated it is not seen in cases of dimineralization with associated acidosis, hyperthyroidism, and osteoporosis. It would seem that some marked disturbance of total serum ions as evidenced by their increase in the urine might be a more satisfactory basis.

DR. DAVID L. THOMSON (closing the discussion): There really remains very little for me to say except to thank Dr. Ivy and Dr. Lay Martin for their courtesy in discussing the paper which, as they both said, and as I firmly realize, does not lend itself to discussion in any way, and, as far as the questions raised by Dr. Martin are concerned, I think I can justifiably excuse myself from defenses of other people whose papers I have merely abstracted for your benefit.

In regard to the last point, that is one in which I have been interested myself. On account of lack of time I omitted a small section of the paper which dealt with that and I should like to make one comment upon it.

One popular view of the mode of action of parathormone has been that it affects the renal threshold for phosphates. There apparently is rapid increase in the rate of phosphate excretion immediately after the injection of the parathyroid hormone, and it has been suggested this leads to a fall of plasma phosphate which permits a corresponding rise in serum calcium.

I have been unable to subscribe to this view, for various reasons. First, that we have been able to show that a rise in serum calcium produced by parathormone is not necessarily preceded or accompanied by any decrease in total serum phosphate, or in the particular trivalent phosphate ion species which is presumably concerned in this equilibrium. Second, and perhaps more conclusive, is that we have been able to show that the characteristic histologic changes produced in the bone, the appearance of osteoclasts, is obtainable in the nephrectomized animal; and, therefore, whatever influence the parathyroid hormone has upon the immediate excretion of phosphate (and I don't doubt it has one, though I have not studied the question myself), I do not feel that is the cause of the subsequent and more conspicuous rise in the serum calcium.

## ABSTRACTS

GRAHAM, E. A., M.D., F.A.C.S., AND  
HARTMAN, A. F., M.D.

"Subtotal Resection of the Pancreas for Hypoglycemia." *S. G. and O.*, Vol. 59, No. 3, Sept., 1934.

In this article, the Authors report the case of a child, one year old, in which eighty to ninety per cent of apparently normal pancreatic tissue was removed for hypoglycemia with an excellent result at the end of nine months.

At the Barnes Hospital, a total of five successful cases of adenoma of the islet tissue of the pancreas for hypoglycemia have now been operated and several more have been reported by other surgeons. However, in the cases of hypoglycemia where normal pancreatic tissue has been found and less than two-thirds of the pancreas has

been removed, the results have not been entirely satisfactory. They call attention to the analogy which has been so often made between hyper-insulinism with hypoglycemia and hyperthyroidism and call attention to the fact that the end results in the surgery of the thyroid in patients with hyperthyroidism were not successful until radical subtotal removals of the thyroid gland were done.

The case reported will not be repeated in detail in this abstract. It was a child of one year who had had repeated convulsions and a marked retardation in mental development. Following the removal of eighty to ninety per cent of the pancreas, only a small remnant of pancreatic tissue being left to protect the common bile duct, the

blood sugar, although it first raised to an abnormally high level, later became practically normal in amount. All of the symptoms caused by the hypoglycemia promptly disappeared and had not recurred at the end of nine months. The mental and physical states of the patient showed marked improvement.

Microscopic study showed the removed tissue to be essentially normal. Although the Authors felt that the other known causes of hypoglycemia had apparently been satisfactorily excluded, they could not definitely state whether this case was due to hypo-insulinism or to some other factor.

This case is unique in that it is the youngest case reported and also larger portions of the pancreas were removed than have been previously done.

N. W. Swinton, Boston.

## SECTION IV—Roentgenology

### The Role of Vitamin B<sub>1</sub> in Tonus of the Large Intestine \*

By

M. I. SPARKS, M.D.

and

E. N. COLLINS, M.D.

CLEVELAND, OHIO

THE importance of the relationship between the tonicity of the colon and a diet deficient in vitamins and particularly one deficient in vitamin B<sub>1</sub> has received increasing clinical attention since the original experiments of McCarrison. The factors which are involved in the maintenance of tonicity of the colon are related not only to the function and disease of this organ *per se*, but also to those more generalized conditions in which improper action of the bowels seems to play a most important part.

Since the advent of roentgenology, it is well known that the incidence of atonicity of the colon is high. This has been ascribed to diverse causes, such as congenital abnormalities, constitutional states, the debility accompanying various "disease states," local mechanical factors or to pure neuroses. The present work was undertaken as a preliminary study in the investigation of one of these generalized conditions, and while the importance of factors mentioned above is realized, we wish to add evidence which appears to indicate that a deficiency in vitamin B<sub>1</sub> may be an accompanying factor, if not the important factor in the production of abnormal conditions of colon tonus.

In this work, roentgen studies including both fluoroscopic and film examinations, as well as volume-capacity determinations of the colon, were made on adult rats which were fed diets deficient in vitamin B<sub>1</sub>. The opaque medium used was a 10 per cent solution of sodium iodide and this was administered as an enema. In a period of seven months, more than 250 enemata were given to 80 rats.

Hargreaves, Fletcher, and Dickson (1) measured the volumes of colons of young rats before and after diets which were deficient in vitamin B<sub>1</sub> had been fed. They found that about two months after the deficiency diet was initiated, the colons definitely were increased in size and volume-capacity. They believed that vitamin B<sub>1</sub> was the most important factor in the production of this change, but that excess of carbohydrate and absence of vitamin B<sub>2</sub> accentuated the atonic changes. Harris and Bunker (2) have shown that vitamin D plays a part in maintaining normal motility

of the gastro-intestinal tract, but they do not mention specifically any effect on the tonus of the colon.

In our experiments, in addition to the larger group of adult rats which were fed a diet deficient in vitamin B<sub>1</sub>, a control group was examined. These two groups of animals were maintained on similar diets except for the deficiency in vitamin B<sub>1</sub> in the food of the experimental group. After atonicity of the colons had developed, Hargreaves, Fletcher, and Dickson (1), added vitamin B<sub>1</sub> to the diet of their animals and this resulted in a disappearance of the atonicity. In our experiments, it was desirable to use the rats for other purposes as soon as atonicity of the colon was demonstrated, so the effect of the relief of atonicity by the addition of vitamin B<sub>1</sub> in the diet has not been observed. However, we believe that the results of our study of the control group overcome this discrepancy, at least in part.

#### METHOD

*Diets.* Two different diets were used in feeding two separate groups of adult rats.

Diet 1.—This was the synthetic diet described by Chase and Sherman (3) and deficient only in vitamin B<sub>1</sub>.

Diet 2.—This was a complete synthetic diet in the same proportions as Diet 1. The yeast was not autoclaved and thus both vitamins B<sub>1</sub> and B<sub>2</sub> were retained.

*Enemata.* When we first worked out the method, one or more preliminary cleansing enemata were given, but this procedure soon was discarded because it was found that the results were more satisfactory and more consistent when no preparation was administered.

The rats were fastened in the supine position, a large cannula was inserted into the rectum and secured there by a tight ligature which surrounded the tail and the skin just cephalad to the anus. In our experience, if the enema is to be retained, correct application of this ligature is essential. If any seepage occurred during the experiment, the result was discarded.

The opaque fluid (10 per cent sodium iodide) was introduced from a 50 c.c. burette, in which the level of the fluid at the beginning of every enema was the same. This assured a fairly constant hydrostatic pressure for each enema. The top of the fluid level was approximately 45 cm. from the top of the table.

The fluid was allowed to run in slowly until it reached the ileo-cecal region, when the flow was stopped and the reading taken. The entire flow into the colon was followed

\*From the Cleveland Clinic.  
Submitted October 10, 1935.

under the fluoroscope and, as soon as the colon was filled, an attempt was made to secure a roentgenogram. This, however, was rather difficult to obtain because in the rat, there is little or no valve action at the ileocecal junction. This resulted in a very quick regurgitation of the fluid

less, there is considerable individual variation. We had expected to find considerable divergence and it has been surprising to find that the values on the same rat which had been fed Diet 2 have checked very

into the small bowel, and thus good roentgenograms of the colon were obtained in only a small percentage of the cases.

In a few cases, the enemata were repeated at short intervals to check the accuracy and constancy of the results. Usually, however, one opaque enema was given before the diet was started and a second one after the animal had been on the diet for approximately two months. Hargreaves, Fletcher, and Dickson (1) found the maximum effect to have occurred at this time and our results agree with their observations.

## RESULTS

By the use of the technique described above, the normal volume of the colon in an adult rat which

closely when the enemata have been repeated within a few days or even a few weeks.

The method, nevertheless, is a rough one and does not permit fine measurements. But even with this difficulty, we believe the results are sufficiently striking to show the effect of diet on colonic tonus. This definite change is shown in Figure 1 which exhibits the appearance of the colon before the deficiency diet was begun, and in Figure 2 which demonstrates the appearance two months later.

We secured the following results, which may also be noted in the Tables: In the group which received a diet deficient in vitamin B<sub>1</sub>, the volume of the colon was increased in 70 per cent of the animals, while in

77 per cent unchanged or decreased in volume. Average change, -19 per cent.

23 per cent increased in volume. Average increase 42 per cent.

weighs from 200 to 300 gms. is between 3.0 c.c. and 4.5 c.c. There seems to be no definite relationship between the weight of the animal and the size of the colon, even though the larger adult rats tend to have larger colons than the smaller adult rats. Neverthe-

30 per cent there was no change or there was a decrease in size. The striking feature was the amount of change which was found in each individual rat, if any increase in the size of the colon was noted. In most of these rats, the size of the colon was doubled.

Fig. 1. Roentgen appearance of colon before deficiency diet was begun.

Of those rats in which an increase in colon volume was shown, the average increase was 104 per cent. On the other hand, in the remaining rats in which no change or a decrease in volume was shown, the average decrease was only 20 per cent.

In the group which received the complete synthetic diet (Diet 2), the volume-capacity of the colon remained unchanged or decreased in 77 per cent, while in the remaining 23 per cent it was increased. Furthermore, the amount of change in each individual rat was much less than was found in those fed the diet deficient in vitamin B<sub>1</sub> (Diet 1). The average decrease in size was only 19 per cent, while in those in which the colon became larger, there was an average increase of 42 per cent.

Thus, the colons of rats maintained on a diet deficient in vitamin B<sub>1</sub> increase in size for a period of from two to three months. If the deficiency diet is continued longer than this, there is some evidence to suggest that a decrease in size takes place, although the original size has not been regained during the period of our observation. However, our results in this regard are not conclusive.

#### SUMMARY

1. By use of the technique described, it was found that the normal volume of the colon of adult rats is from 3.0 c.c. to 4.5 c.c.

2. The volume of the colons of rats maintained on a diet deficient in vitamin B<sub>1</sub> for two months increased strikingly in 70 per cent of the animals.

3. No such change occurred in a control group maintained on a complete synthetic diet.

Fig. 2. Roentgen appearance of colon two months after deficiency diet was begun.

#### INTRODUCTION

THE observations and conclusions outlined below supplement those presented by the same Authors in an earlier publication (1). In it the Authors' initial experience with autogenous polyvalent stool vaccine therapy was reported. During the subsequent four years it has been possible, without sacrificing therapeutic effectiveness, to simplify this method of therapy, and render it more practical, by using stock colon bacillus vaccine. Furthermore, a more extensive experience with this type of vaccine-therapy has contributed more exact knowledge, as to the indications and contra-indications for its use and regarding its limitations.

In the previously reported experience with autogenous, polyvalent stool-vaccines, 100 per cent of the 68 cases, with chronic irritable colon and associated symptoms, exhibited skin sensitivity to *B. coli* vaccine, viz., either to *B. coli communis* or *communior*. Positive skin reactions to *B. coli communis* occurred in 95% of the cases, and to *B. coli communior* in 96%. The skin reactions to both strains were marked, the average diameter being 4.5 cm. Positive skin reactions to other stool bacteria were less constantly present and less marked. Similar skin tests were carried out upon a group of normal individuals. In this control group, positive skin reactions to *B. coli communis* occurred in 65% of the cases, to *B. coli communior* in 69%, and to other stool organisms in a smaller percentage of cases. In the control group slightly more than 90% of the cases yielded a positive skin reaction to either one strain or the other of the colon bacillus. The average degree of skin sensitivity to *B. coli* vaccine in the normal control group was somewhat less than in the "irritable" colon group.

This original group of 68 *obstinate* cases of irritable colon, whose symptoms persisted after the usual

comprehensive therapy, were treated then with polyvalent autogenous stool vaccines. Each vaccine included those organisms to which the patient was skin sensitive. Definite and gratifying improvement was noted, in the majority of instances, in the following symptoms, viz., colon pain, associated pylorospasm distress, constipation, and associated headache and vertigo. It was apparent, therefore, that this type of vaccine therapy constituted a valuable supplementary therapeutic measure.

#### SIMPLIFICATION OF VACCINE METHOD

The preparation of autogenous, polyvalent stool vaccines, of various dilutions for each patient, involved considerable expense and loss of time. For several reasons, it was suspected that similar favorable vaccine effects might be produced by administering *B. coli* vaccine alone. This hypothesis was tested by treating a group of cases with colon bacillus vaccine. A stock vaccine was employed, including the two strains of *B. coli*. The therapeutic results obtained have been essentially similar to those previously resulting from autogenous polyvalent stool vaccines. The treatment of a larger and more varied group of cases, however, has added much additional knowledge relating to this subject.

#### SKIN TESTS

During the interval of four years since autogenous stool vaccines were discontinued, the preliminary skin tests have been continued, but with individual stock vaccines of the three commonest stool organisms to which these cases are skin sensitive, viz.: the colon bacillus, staphylococcus aureus and streptococcus fecalis. These skin tests could be omitted, but there have been three advantages in continuing them. In the first place, the degree of local skin sensitivity, and, in some cases, systemic reaction, have been evaluated. This information has been of help in determining the subsequent optimum dosage. In the second place, the

<sup>\*</sup>Read at the 38th Annual Session of the American Gastro-Enterological Association, Atlantic City, N. J., June 10-11, 1935.

†From the Gastro-Intestinal Division of the Medical Department, Henry Ford Hospital.

initial intradermal injection apparently has had a desirable desensitizing effect. Finally, in the occasional cases in which there is a marked reaction to streptococcus fecalis or staphylococcus aureus vaccine, this information is obtained; and either or both of these stock vaccines can be added, if desired, to the *B. coli* vaccine for subsequent therapy. However, in the much larger group of cases, showing only slight to moderate skin reaction to the other organisms, *B. coli* vaccine alone has been used routinely.

In a large group of 3,000 cases, with "unstable" colon and the related conditions referred to below, skin tests have been conducted with the three stock vaccines listed above. A one billion concentration of each vaccine has been used for the skin tests. In those patients whose tolerance to the vaccine has been questionable, the skin tests have been omitted entirely, to avoid any undesirable, temporary reactions, due to the initial use of a concentrated vaccine. The results are summarized in Table 1. In addition to the tabulated

TABLE I

*Skin Sensitivity to Stock Stool Vaccines in 3,000 Cases of Related Functional Conditions\* (One Billion Organisms per c.c. of Vaccine)*

| Vaccine Used                 | Cases with + Skin Reaction | Average Di meter of Skin Reaction |
|------------------------------|----------------------------|-----------------------------------|
| <i>B. Coli</i>               | 99%                        | 4.0 x 3.9 cm.                     |

\*Unstable colon, toxic vertigo, chronic headache, and functional diarrhea.

local skin reactions, there was some systemic reaction in 25% of the cases, e.g., transient malaise, fatigue or other evidence. Recently more dilute concentrations of vaccine have been used in conducting the skin tests.

#### MECHANISM INVOLVED IN *B. COLI* VACCINE THERAPY

Where vaccine therapy is used with good therapeutic effect, and the vaccine utilized has produced a positive skin reaction prior to treatment, the speculative question might be raised as to whether the results are produced by an actual allergic mechanism or a non-specific protein reaction. The purpose of this survey is to present certain observations and facts, and not to enter this field of speculation. The observation that the groups of patients treated were skin sensitive to the colon bacillus does not imply necessarily that the therapeutic results obtained with *B. coli* vaccine were produced by an allergic mechanism. Until more is known about the fundamental nature of allergy and the differentiation between the allergic mechanism and non-specific protein reactions, any discussion bearing upon this point would be controversial.

#### METHOD OF VACCINE PREPARATION

Colon bacillus vaccine has been prepared according to the following method. The *B. Coli communis* and *communior* strains are mixed in equal proportion. A viable, rather than heat killed culture is detoxified, by subjecting it for fifteen hours to a one per cent concentration of purified and tested sodium ricinoleate, according to the recommendation of Larson (2) and of Dorst and Morris (3). The organisms then are washed several times with normal saline, to eliminate the sodium ricinoleate and its irritating effect. Finally, trikresol (0.4%) is added to

sterilize and preserve the vaccine. Vaccines containing the following total number of organisms per c.c. are prepared, viz: One, five, fifty, and five hundred thousand, five, fifty, and two hundred and fifty million, and one billion organisms per c.c. For the preliminary skin tests, separate preparations of a one billion concentration or less, of vaccine, (not detoxified), of each of the three stool organisms referred to above, have been used.

#### VACCINE DOSAGE, INTERVAL BETWEEN INJECTIONS AND METHOD OF ADMINISTRATION

If there has been no systemic reaction to the preliminary skin tests, the first subsequent vaccine injection consists either of 2 minims of a 50 million, or one minim of a 250 million concentration. In the occasional cases exhibiting a marked, temporary, systemic reaction to the skin tests, the first subsequent injection consists of two minims of one of the more dilute preparations, e.g., the five or fifty thousand dilutions. If a systemic reaction occurred, but was only slight to moderate in degree, the first dose following the skin tests is intermediate between those mentioned above.

Each subsequent increase of dose will vary with the patient's response to the last previous injection. Valuable information regarding the tolerance for vaccine of each individual patient has been obtained, by maintaining a special form with a detailed record of any temporary reaction to each vaccine injection and of any improvement of symptoms following it. The dose is increased gradually, during the first three or four injections particularly. It is desirable that each dose should be a little under, rather than over, the patient's full tolerance at the time. On the other hand, it has become apparent that the best results are obtained if the dosage is not too far below the patient's full tolerance. The matter of determining the optimum dose each time is of cardinal importance; the following, further, empirical observations are of great help in making this decision.

If, for 12 to 24 hours following the last injection, the patient has had no systemic reaction, or else only transient fatigue, the dose has not been increased too rapidly. On the other hand, if the reaction to any injection consists of marked malaise, lasting 3 or 4 days, this dose was too large. In this case the next dose should be reduced, and a further interval of several days should be allowed before giving it. If there has been any appreciable reaction to any injection, further vaccine should never be given until the patient has completely recovered and has had one or two good days. In several very unusual cases of "unstable" colon, such an infinitesimal dose as one minim of a dilution containing only 1,000 organisms per c.c. repeatedly and consistently produced transient colon pain. Furthermore, it should be noted that if a large dose of *B. coli* vaccine is administered to a particularly hypersensitive individual, transient fever may result, with subsequent aggravation of unstable colon and related symptoms, persisting occasionally for one or two weeks. *B. coli* vaccine should be discontinued in those occasional cases, for whom it is impossible, even by marked reduction of dosage, to avoid disagreeable and prolonged reactions.

As noted above, it is essential in this particular type of vaccine-therapy to individualize the dose to each patient's tolerance, rather than trying to follow a set schedule. However, it is important to know the in-

crease of dose tolerated by the average patient. The following rate of increasing the dose is well tolerated by most individuals; *viz.*: 2 minims of a fifty million concentration for the first dose;  $1\frac{1}{2}$  minims of a two hundred and fifty million preparation for the second dose, and one minim of a one billion concentration for the third injection. Providing the above increase has been tolerated, the average case should receive, for the subsequent five to seven doses, an increase at each injection of 1 to  $1\frac{1}{2}$  minims of the one billion concentration. In such an average case, the ultimate or final dose would vary from 6 to 12 minims of the one billion concentration. Many cases need a more gradual increase of dose. In other types of vaccine, to which the patient has little or no skin sensitivity, a dose of the above final amount, *viz.*, 6 to 12 minims, is sometimes given as an initial dose. Most undesirable and prolonged reactions would occur frequently if such initial doses of *B. coli* vaccine were administered.

Cases of chronic functional diarrhea usually tolerate at least average doses of *B. coli* vaccine; whereas cases of toxic vertigo and chronic headaches should receive, at the onset of treatment, doses below the average, to avoid temporary aggravation of symptoms. In cases of "unstable" colon the well tolerated initial dose varies considerably.

In most instances the therapeutic results of *B. coli* vaccine are more striking and persist longer in those cases that either have or develop an average tolerance for the vaccine, than in those tolerating only minute doses. However, there are exceptions to this rule.

The common interval between vaccine injections has been four days. If very small doses are being given and are well tolerated, the interval should be reduced to two or three days. If large doses are being given, or if the last vaccine injection caused any appreciable reaction, the interval should be lengthened to five, six, or seven days or longer. In those cases receiving vaccine every four days, who note marked improvement for a couple of days and then a tendency to return of symptoms a day or two before the next injection, the interval between injections should be shortened.

Ordinarily all the vaccine injections, after the skin tests, have been given *intramuscularly*. However, more recently, the several initial injections, involving only a small volume of 1 to 2 minims, have been given *intracutaneously*, and all subsequent larger volumes *intramuscularly*. The purpose of this modification is to increase the effectiveness of the vaccine and to avoid reactions.

Before instituting vaccine therapy in any case the individual should be informed that a slight temporary reaction may occur after any one of the several initial injections, while the dose tolerated is being determined. *B. coli* vaccine should not be administered unless one is conversant with the above facts regarding dosage.

#### TYPE OF CLINICAL MATERIAL UTILIZED

Any attempt to evaluate the effects of a new therapeutic agent upon the symptoms of an underlying functional condition is difficult, and fraught with possible pitfalls in interpretation. The danger of underestimating psychological influence is recognized fully. In order to put *B. coli* vaccine to a severe test, and to eliminate any favorable results not related to this

type of therapy, 125 long-standing, *chronic* cases of headache, functional diarrhea, "toxic vertigo," and "unstable" colon have been selected for vaccine therapy. Obstinate cases of this type do not represent enthusiastic individuals susceptible to mental suggestion. Definite and prompt improvement or disappearance of symptoms, in such groups of cases, following the introduction of a single therapeutic agent, usually is significant. Only these 125 cases, divided into the above subgroups, are analyzed in the tables presented.

In the groups of chronic headache and unstable colon cases, the conditions under which *B. coli* vaccine was administered were rigidly controlled by the fact that these cases had *previously received* comprehensive therapy in this Clinic, and had resisted it with definite *persistence of symptoms*. The fact that vaccine therapy was introduced subsequently as the only new therapeutic measure allows critical deductions to be drawn from the identification of vaccine results.

In the groups of long-standing, chronic diarrhea and chronic "toxic vertigo" cases, the direct effects of vaccine therapy have been controlled in a different manner, *viz.*, by starting the *B. coli* vaccine *in advance* of any other therapeutic measures and noting the effect of the vaccine alone.

During the past four years a *total* of over 1000 cases has been treated with colon bacillus vaccine. Since the indications for, and value of, *B. coli* vaccine therapy have become apparent from a critical study of the above subgroups of cases, vaccine has been started frequently at the onset of therapy, along with other measures, in those cases who probably would need vaccine sooner or later, or, at least, benefit from it. In the larger subgroup of over 800 cases, it no longer appeared advisable, in the best interest of the patients, to continue separating rigidly vaccine therapy from other indicated treatment, merely to provide an unnecessarily large group of cases from which to draw convincing deductions. In this latter group, an effort was made, rather, to expedite as much as possible the maximum improvement of symptoms. In many cases within this large group, it was interesting to note the repeated spurts of improvement occurring after each subsequent vaccine injection when no additions were being made to the remaining treatment.

#### RESULTS OF *B. COLI* VACCINE THERAPY

(a) *Chronic functional diarrhea group.* As to the specific indications for colon bacillus vaccine therapy, the group of chronic functional diarrhea cases should be mentioned first. The therapeutic results are quite striking and constant in this group; and in the marked cases, *B. coli* vaccine constitutes a very valuable therapeutic agent.

The first case treated with *B. coli* vaccine was an isolated case, a middle-aged woman who was admitted to the hospital in an emaciated and dehydrated state *nine* years ago. Clinical examination, repeated warm stool and proctoscopic examinations, stool cultures, and barium enema failed to show any evidence of an organic basis for the frequent and profuse diarrhea. This symptom had been present for a number of years, but had been much more marked for several months. During a four week period almost every known therapeutic measure to relieve the diarrhea was utilized, finally including opiates. The patient's condition, however, steadily grew worse, and became critical. It was decided to try the effect of an autogenous stool vaccine, the colon bacillus being the only organism recovered in this instance. To the surprise of

everyone, the diarrhea promptly stopped; and, in a short period, the patient was restored to excellent health. At the time, it was felt that this was probably an unique case with an unusual etiology.

During the past four years, however, a group of thirty cases with chronic functional diarrhea has been treated with colon bacillus vaccine. Although none of the subsequent cases has been so acutely ill as the one referred to above, similar striking therapeutic results have been obtained in the majority of cases.

This group of thirty cases has included 13 males and 17 females. The average duration of the diarrhea was 3½ years, one patient having had the symptom for 20 years. There was an average number of 5.3 stools per day, per patient. The proctoscopic findings were essentially normal in 86% of the cases; there was only slight injection of the rectal mucosa in the remainder. With the exception of increased mucus in 60%, the stool findings were otherwise normal throughout. Barium enema examinations revealed evidence of hypertonus of the colon in 83% of the group. A positive skin reaction to *B. coli* vaccine was obtained in 100% of the cases. Skin sensitivity to the other common stool bacteria was much less frequent and less marked. (See Table II).

TABLE II  
*Skin Sensitivity to Stool Stool Vaccines in 30 Cases of Chronic Functional Diarrhea*

| Vaccine Used                 | Cases with + Skin Reaction | Moderate to Marked + Skin Reaction |
|------------------------------|----------------------------|------------------------------------|
| <i>B. Coli</i>               | 100%                       | 89%                                |
| <i>Staphylococcus Aureus</i> | 48%                        | 29%                                |
| <i>Streptococcus Fecalis</i> | 44%                        | 18%                                |

Colon bacillus vaccine therapy was started in advance of any other therapeutic measures in 29 of the 30 cases. In the other single case, the order was reversed, and comprehensive treatment was instituted first, with no improvement. Vaccine skin tests were then carried out in this case, and the diarrhea stopped promptly after this single dose of *B. coli* vaccine.

The degree of improvement of the diarrhea following vaccine therapy in this group of 30 cases is summarized in Table III. The time of onset of demon-

TABLE III  
*Chronic Functional Diarrhea Group (Results of *B. coli* Vaccine Therapy Upon 30 Cases)\**

| Degree of Relief | Number of Cases | Percentage of Total Cases |
|------------------|-----------------|---------------------------|
| ++++ (Complete)  | 18              | 60%                       |
| +++              | 6               | 20%                       |
| ++               | 3               | 10%                       |
| +                | 1               | 3½%                       |
| Total Improved   | 28              | 93½%                      |
| Unimproved       | 2               | 6½%                       |

\*Average duration of diarrhea prior to treatment was 3½ years. Average No. of stools was 5.3 per day.

strable improvement is noted in Table IV. In view of this experience it is obvious that colon bacillus vaccine possesses a unique value in the treatment of this condition.

In 2 of the total group of 30 cases, there was marked improvement of the diarrhea, occurring promptly after the first dose of *B. coli* vaccine contained in the

skin tests; and in two other cases, the diarrhea stopped completely and promptly after the skin tests had been carried out. In other words, 13 1/3% of the group, (4 cases), responded in this striking manner

TABLE IV  
*Chronic Functional Diarrhea Group (Time of Onset of Improvement—30 Cases)*

| Onset of Definite Improvement           | No. of Cases | Percentage of Cases |
|-----------------------------------------|--------------|---------------------|
| After 1st injection (Skin tests)        | 4            | 13½%                |
| After 2nd injection                     | 8            | 26⅔%                |
| After 4th injection                     | 4            | 13½%                |
| After 5th, or some Subsequent injection | 12           | 40%                 |
| No Improvement                          | 2            | 6½%                 |

to the first injection of colon bacillus vaccine. Only two cases failed to show improvement. These were two individuals with unusually marked and uncontrolled nervous tension factors. One of them had an agitated mental depression. The diarrhea in the other case disappeared only when the patient was subsequently placed in bed and given sedatives. It recurred when the patient became ambulatory. These two cases illustrate the important rôle played by nervous tension in aggravating the diarrhea in certain instances.

Gastric achlorhydria was found in a small percentage of these diarrhea cases. Inasmuch as an effort was being made to test the effectiveness of the vaccine, dilute hydrochloric acid was not given to any of the cases with achlorhydria, excepting, unintentionally, to one case. The diarrhea cases were all treated with *B. coli* vaccine, regardless of whether achlorhydria was present or not. Those cases with achlorhydria responded to the vaccine in a manner similar to the other cases. There is no intention, however, to belittle or deny the well known therapeutic value of administering hydrochloric acid to cases of functional diarrhea presenting achlorhydria.

(b) "Toxic vertigo" group. Sixteen cases of chronic "toxic vertigo" were selected for evaluation of colon bacillus vaccine therapy. There were 9 males and 7 females. The average age was 46 years. The average total duration of the vertigo was 21 months. In 75% of these cases the vertigo was either marked or extreme. Constipation and colon distress were both present in 75% of the group. Any possible organic basis for vertigo was carefully ruled out. In this group *B. coli* vaccine therapy was instituted in advance of any other treatment. The therapeutic results are tabulated in Tables V and VI. The two cases

| No Relief        | 2               | 12½%                      |

\*Average duration of vertigo prior to therapy was 21 mos.

obtaining no relief were very nervous individuals. Furthermore, nervous tension was present in certain of the cases obtaining partial, but not complete, relief.

(c) *Chronic headache group.* Twelve cases presenting chronic headache as the main complaint, who had obtained no relief from a comprehensive course of therapy, subsequently received *B. coli* vaccine therapy. The average total duration of headache in these cases was 11.7 years. The average age was 41 years. The location of the headache was variable. In 83% of the

| (1) After 9th vaccine injection | — Most frequently |

cases the headache was severe. There was associated constipation in 92%, and colon distress in 66% of this group. Some of these patients had noted aggravation of headaches when constipated; but frequently the headaches were present during periods of apparently normal bowel function. Only 2 of these cases had classical migraine features. Any possible organic basis for headaches was ruled out in each instance.

The unsuccessful program of general treatment preceding vaccine therapy in this group was directed particularly toward the correction of constipation and the reduction of nervous tension. *B. coli* vaccine therapy was introduced subsequently as the only new therapeutic measure.

Nine of the twelve cases (75%) obtained prompt, complete, and most gratifying relief from vaccine therapy. (See Table VII). One woman in this group,

TABLE VII

*Chronic Headache Group \* † (Results of B. coli Vaccine Therapy—12 Cases)*

| Degree of Relief | Number of Cases | Percentage of Total Cases |
|------------------|-----------------|---------------------------|
| ++++ (Complete)  | 9               | 75%                       |
| No Relief        | 3               | 25%                       |

\*Average duration of headache prior to vaccine treatment was 11.7 years.

†An additional group of 27 cases of chronic headache also received *B. coli* vaccine.

who had had almost constant headache for 20 years, reported 13 months later that she had enjoyed complete freedom of headache for this entire period following vaccine treatment. Three cases obtained no apparent relief. In two of these three cases there was obvious uncontrolled nervous tension.

In a group of 27 additional cases of chronic headaches, similar relief followed vaccine therapy in a high percentage of the cases. However, these cases cannot be included in the above group, since vaccine therapy in this group was not sharply separated from other treatment. However, convincing spurts of improvement occurred after successive vaccine injections, when no additions were being made to the remaining therapy.

(d) *Combined "toxic vertigo" and chronic headache group.* A group of 8 cases was studied, who had suffered for an average of 4 years from a combination of headache and "toxic vertigo." This group received

colon bacillus vaccine in advance of any other therapeutic measures. Definite deductions can, therefore, be drawn. In seven of these eight cases, either marked or complete relief was obtained following vaccine therapy. (See Table VIII).

TABLE VIII

*Combined "Toxic Vertigo" and Chronic Headache Group\* (Results of B. coli Vaccine Therapy—8 Cases)*

| Degree of Relief From Both Symptoms | Number of Cases | Percentage of Total Cases |
|-------------------------------------|-----------------|---------------------------|
| Either Marked or Complete Relief    | 7               | 87½%                      |
| No Relief                           | 1               | 12½%                      |

\*Average duration of symptoms prior to treatment was 4 years.

(e) *Obstinate spastic constipation group.* In the occasional cases of obstinate spastic constipation, in which normal bowel function was not obtained from the usually successful physiological therapy, colon bacillus vaccine has been administered subsequently. In most of these cases, excellent results have been obtained in breaking into the vicious circle and relieving the constipation. A number of patients have testified spontaneously, after a few vaccine injections, that the calibre of the stools had changed suddenly from small calibre to a normal diameter. In some cases, a "repeat" barium enema has been obtained after vaccine therapy, and has shown a disappearance of the marked narrowing of the distal colon, noted in the earlier film. These two sources of evidence both indicate that colon bacillus vaccine tends to reduce colonic spasm.

It is not surprising that the same type of vaccine therapy tends to relieve both chronic functional diarrheas and chronic spastic constipation; for in both instances, there is hypertonus or spasm of the intestinal musculature. In this connection, it is a well known fact that diarrhea and spastic constipation not infrequently alternate in the same individual.

(f) *Chronic "unstable colon" (non-ulcerative colitis) group.* In view of the gratifying results tabulated above in the treatment of simple alternations of colon function, such as chronic diarrheas and obstinate spastic constipation, it is not surprising that therapeutic aid has been obtained also in cases presenting a combination of altered bowel function and colon distress or pain.

In the majority of cases of unstable colon, the distress or pain, and associated symptoms, will clear up satisfactorily with a well planned comprehensive program of therapy. On the other hand, in a subgroup of cases with unusually marked symptoms, general treatment fails, in certain instances, to produce satisfactory results.

In order to subject colon bacillus vaccine therapy to a severe test in the treatment of the unstable colon, 59 obstinate cases, whose symptoms had not disappeared following comprehensive therapy, subsequently were given a course of *B. coli* vaccine. These 59 obstinate cases were selected from a very large group of cases, the majority of which had responded satisfactorily to comprehensive therapy.

The comprehensive program had consisted of physiological regulation of the bowels, a bland but well balanced diet with adequate vitamine content, elimination or reduction of neurogenic factors, so far as

possible, correction of faulty habits, antispasmodics, and, in some instances, changing the stool flora with lactodextrin and acidophilous milk. Recently sodium ricinoleate has been added, as noted below, to this comprehensive regime.

The presence or absence of improvement in the 59 obstinate cases, and the degree of partial improvement, following the comprehensive treatment, (without vaccine), are summarized in Table IX. When vaccine

| From +++ to ++++                           | 1               | 2%                        |
| Total Cases Improved                       | 41              | 70%                       |
| Symptoms Unchanged                         | 13              | 22%                       |
| Symptoms Aggravated Temporarily by Vaccine | 5               | 8%                        |

significant that 31 of the 41 cases showing improvement after vaccine therapy, showed a moderate to marked degree of improvement over that previously resulting from comprehensive treatment in the same group of cases.

#### SODIUM RICINOLEATE IN IRRITABLE COLON THERAPY

In the small group of "unstable" colon patients who presented extreme hypersensitiveness to *B. coli* vaccine, withholding vaccine and giving sodium ricinoleate by the mouth is, in our experience, the most effective therapeutic measure found thus far. Furthermore, the earlier observations of Morris and Dorst (3) have been confirmed, namely, that sodium ricinoleate is of real value in the routine, early treatment of "unstable" colon cases. These Authors maintained that better results can be obtained, if this preparation is added to the therapeutic program to supplement the effect of the stool vaccine. During the past year at

least one five grain capsule of sodium ricinoleate routinely has been given in these cases just before breakfast each morning, and in a number of instances, a second capsule before dinner, as an important initial addition to the program of comprehensive treatment. Sodium ricinoleate therapy has been continued usually for several months. It is especially helpful in relieving colon pain or distress. In fact, since sodium ricinoleate has been added to the routine comprehensive program, *B. coli* vaccine has been needed somewhat less frequently for the relief of colon pain. Recently sodium ricinoleate therapy also has been added routinely to the vaccine treatment of the functional diarrhea, toxic vertigo and chronic headache groups, to further increase the effectiveness.

It has been shown definitely that sodium ricinoleate has a detoxifying effect upon the bacterial protein or toxins (2) and vaccines (3). Doubtless, an essentially similar effect is produced upon the mass of bacterial protein in the intestinal tract. However, the exact mechanism by which sodium ricinoleate produces its desirable therapeutic effect is not definitely known.

(g) *Pylorospasm group.* The localized epigastric distress, which frequently accompanies "unstable" colon distress, tends to respond to *B. coli* vaccine in a manner similar to that of colon distress. Furthermore, certain instances of functional epigastric distress, unassociated with colon distress, and persisting after comprehensive treatment, have then received *B. coli* vaccine therapy, with resulting disappearance of this distress.

#### GENERAL EFFECTS OF COLON BACILLUS VACCINE THERAPY

Aside from the effects noted above, *B. coli* vaccine therapy has been noted to have certain important and gratifying side effects. These occur much too frequently, when vaccine therapy is employed, to be explained a mere coincidence. Many of these patients report a striking improvement in their general feeling of well being, such as they have not noted in many years. This subjective relief often is reflected in their general appearance, increased appetite and, in some cases, in increase in weight.

#### INDICATIONS FOR COLON BACILLUS VACCINE THERAPY

(1) All cases of chronic functional diarrhea should receive *B. coli* vaccine, unless one encounters a rare case presenting some contra-indication.

(2) All cases with either chronic "toxic vertigo," or the type of chronic headache which tends to be associated with colon distress or constipation, should receive *B. coli* vaccine, unless contra-indicated.

(3) In the unusual cases of obstinate spastic constipation, not yielding satisfactorily to other measures, *B. coli* vaccine is helpful in breaking into the vicious circle.

(4) In the obstinate cases of "unstable" colon, (non-ulcerative colitis), not responding satisfactorily to the commonly employed comprehensive treatment, definite help will be obtained from *B. coli* vaccine in the majority of cases, provided the vaccine is tolerated.

(5) Providing no contra-indication exists, most cases of unstable colon presenting marked colon pain or distress, will show more prompt and pronounced improvement if a course of vaccine therapy is in-

stituted at the onset of treatment, along with the comprehensive program. However, one can wait, if desired, to select only the obstinate cases for vaccine.

It is not necessary to administer *B. coli* vaccine in any routine manner to cases of "unstable" colon, since the majority of these cases clear up satisfactorily with comprehensive therapy alone.

#### LIMITATIONS OF COLON BACILLUS VACCINE THERAPY

1. The most important limitation rests in the observation that the desirable therapeutic effects obtained are not permanent. If one gives a single course of vaccine therapy, with no follow-up injections, after four to twelve months numerous patients note the good effect of the vaccine "wearing off." However, in those patients whose original symptoms were distressing and persisted after other therapeutic measures, and whose subsequent relief with vaccine was marked, frequently advice has been given to *avoid* subsequent loss of the vaccine effect, by obtaining a single vaccine injection about once a month. Patients obtaining such relief, and later having a recurrence of symptoms, frequently have *requested* further periodic vaccine injections. In such instances the dose can and should be maintained at a level sufficiently high to retain the benefit gained. As a rule, this subsequent optimum monthly dose is between 50 and 100% of the last maximum tolerated dose of the *course* of injections.

On the other hand, in many cases the vaccine seems to break a vicious circle, which is not re-established. In this latter group, if the patient adheres to the comprehensive treatment, the subsequent course continues satisfactory over an indefinite period without further vaccine.

2. The fact that *B. coli* vaccine is contra-indicated definitely in certain cases constitutes the second limitation. (See below).

3. In the unstable colon group the relief of pain or distress following vaccine does not occur in quite as high a percentage of cases as the relief of symptoms in the other groups of cases referred to above. In the unstable colon group, it is not always possible to prognosticate, in the individual case, the *exact degree* of improvement to be expected from vaccine. Vaccine produces brilliant results in some cases; whereas, in other cases, there is moderate or else no apparent improvement. This fact would suggest some variation. In different patients, in the *relative* importance of the particular etiological factor, which is favorably affected by *B. coli* vaccine.

#### CONTRA-INDICATIONS FOR COLON BACILLUS VACCINE THERAPY

1. In those cases of unstable colon presenting an associated chronic infectious arthritis, *B. coli* vaccine, in ordinary dosage, is definitely contra-indicated. Even though there be no active arthritis at the time, if there is a definite history of infectious arthritis, it is advisable, as a rule, to omit vaccine. In this particular group of cases, a single injection of *B. coli* vaccine very occasionally has induced a temporary flare-up of a quiescent arthritis.

In cases with no evidence of an arthritic tendency, on rare occasions, following a *B. coli* vaccine injection, slight *transient* joint pain, lasting a day or two, has been encountered. In such cases vaccine therapy has been discontinued at this point.

2. In the *occasional* cases of unstable colon, not tolerating even *minute* doses of *B. coli* vaccine, and having a disagreeable general reaction, with temporary aggravation of distress or pain, this type of therapy should be *discontinued* promptly. (If doses of *average* size are not tolerated at the onset, the dose should be decreased to a very small amount, and subsequent doses should be increased *gradually*, to avoid further reaction).

3. In the rare cases presenting a history of a marked tendency to urticaria, any *average* dose of colon bacillus vaccine should be considered with *caution*. A flareup of this condition may result from *B. coli* vaccine. (On the other hand, *minute* doses of this vaccine have been of marked therapeutic value in certain cases of urticaria).

4. If a head cold exists, or any other acute infection, no *B. coli* vaccine should be given until the acute infection has subsided.

#### SUMMARY

(1) The observations and conclusions outlined amplify and supplement those presented by the same Authors in an earlier publication. In this previous survey, the Authors' experience with autogenous polyvalent stool vaccine therapy was reviewed. These vaccines contained those organisms to which the patient was skin-sensitive.

(2) For several reasons it was suspected that similar favorable vaccine results might be obtained by administering *B. coli* vaccine alone. (This organism had been included in almost 100% of the polyvalent vaccines previously used). By instituting the use of stock *B. coli* vaccine, about four years ago, this method of vaccine therapy was simplified and rendered more practical. No resulting demonstrable loss of therapeutic effectiveness has been noted.

(3) Of three thousand cases, presenting one or more of the related chronic functional disorders referred to in this survey, 99% have yielded a positive skin reaction to *B. coli* vaccine. As a rule, the skin reaction has been marked. There is no desire, however, to enter the field of speculation, as to whether or not the desirable therapeutic results obtained have been produced through the operation of an *allergic mechanism*. The purpose of this survey simply is to present certain observations and facts relating to the therapeutic results obtained from *B. coli* vaccine.

(4) The colon bacillus vaccine has included both strains of the organism. The viable culture has been detoxified by exposure to sodium ricinoleate; and the organisms have been killed then with 0.4% trikresol.

(5) In administering *B. coli* vaccine, it is essential to individualize the dose for each patient, if satisfactory results are to be obtained. Overdosage tends to cause temporary aggravation of symptoms. Detailed information is outlined above, as to the method of determining or approximating the optimum dose for successive injections in each case. *B. coli* vaccine should not be used unless one is conversant with these facts regarding dosage.

(6) A *total* of more than 1,000 selected cases have been treated with *B. coli* vaccine during the past four years. These cases have included chronic functional diarrheas, cases with chronic "toxic vertigo," instances of long standing headaches of the type usually associated with chronic constipation or colon distress, and

selected cases of marked or obstinate "unstable" colon. (Chronic non-ulcerative colitis).

In 125 of these chronic and obstinate cases the conditions under which vaccine therapy was administered were rigidly controlled, so that critical deductions may be drawn as to the validity of vaccine results. In certain subgroups, vaccine treatment has been instituted *in advance* of other treatment. In the other subgroups, vaccine therapy has been *postponed*, and subsequently instituted in those obstinate cases whose symptoms have *persisted* after receiving comprehensive therapy. In either instance one can *identify* the results directly traceable to *B. coli* vaccine therapy.

In the larger group of over 800 cases treated subsequently with vaccine, vaccine therapy has been instituted at the onset, along with other therapeutic measures, for reasons specified. Although these cases cannot be included, for obvious reasons, in the groups of cases critically analyzed, it was interesting to note in this large group the repeated spurts of improvement occurring after successive vaccine injections, when no additions to the remaining treatment were being made.

(7) Thirty cases of chronic functional diarrhea, with an average duration of  $3\frac{1}{2}$  years, received *B. coli* vaccine in advance of any other therapy. There was improvement of the diarrhea in a total of 93  $1\frac{1}{3}\%$  of this group. There was complete disappearance of the diarrhea in 60%, and a marked degree of improvement in another 20% of the group. In 40% of the cases demonstrable improvement was noted after either the *first* or *second* vaccine injection.

(8) In the chronic "toxic vertigo" group, a total of 87½% of the cases obtained relief from *B. coli* vaccine.

(9) In a group of cases with chronic headache, with average duration of 11.7 years, and of the type usually associated with chronic constipation or colon distress, 75% obtained *complete* relief from *B. coli* vaccine.

(10) In a group of cases presenting a *combination* of toxic vertigo and chronic headache, of 4 years duration, either marked or complete relief occurred in 87½% of the cases.

(11) In the occasional cases of *obstinate* spastic constipation, when *B. coli* vaccine is added to the comprehensive therapy previously instituted, there is convincing evidence that the vaccine tends to relax the partially obstructing spasm of the distal colon.

(12) In fifty-nine selected cases of "unstable" colon, (non-ulcerative colitis), with obstinate distress or pain, which persisted in spite of the usual comprehensive therapy, *B. coli* vaccine was instituted subsequently. In 70% of this group there was either improvement or disappearance of the colon distress.

(13) The specific indications for *B. coli* vaccine treatment are summarized and emphasized.

(14) The limitations of *B. coli* vaccine therapy, and the contra-indications to its use, are outlined and discussed.

(15) *B. coli* vaccine constitutes a valuable therapeutic acid, if *judiciously* used in properly selected cases. In cases with chronic functional diarrhea, chronic "toxic vertigo," and chronic headaches of the type designated, the therapeutic results of *B. coli* vaccine are striking. In selected, obstinate or marked cases of unstable colon, *B. coli* vaccine is usually of

definite value. (The *majority* of cases of unstable colon can be treated satisfactorily without vaccine, through the aid of the specified comprehensive program of treatment).

## DISCUSSIONS:

DR. LEON SCHIFF (Cincinnati): During the past seven years or more, due chiefly to the work of Drs. Morris and Dorst, which is being continued by Dr. Dorst, a great many patients with unstable colon and its various manifestations have received injections of *autogenous* stool vaccine, containing organisms selected after preliminary skin testing. While the results have not been tabulated, they have been frequently striking; but no more so than those reported by Dr. Mateer and his associates from the use of *stock* vaccines. This confirms the Authors' own observations and tends to show that the benefits may be due to non-specific rather than specific allergic factors.

The experience in Cincinnati has been similar to that of Dr. Mateer and his associates, namely, that those individuals who are unable to receive the average dose of vaccine because of hypersensitivity, derive less benefit than those who can receive the average or larger doses. Recently, Dr. Dorst has been using urea and nascent nitrous acid in place of sodium ricinoleate as a detoxifying agent, and feels that by this means greater detoxification may be accomplished, thus enabling the patient to tolerate larger doses. The fact that urea acts as a detoxifying agent may be of interest in connection with some of the remarks our President made this morning regarding the detoxifying function of the liver.

The prompt disappearance of diarrhea associated with achlorhydria, following the use of vaccine is extremely interesting.

Dr. Mateer and his associates consider the existence of arthritis as a contraindication to the use of colon bacillus vaccine. Drs. Freiberg and Dorst are using autogenous stool vaccines in a large series of arthritic cases, mostly of the infectious form. They have found it necessary to use smaller doses because of the risk of inducing a flare-up of symptoms. Accordingly, suboptimal doses are given over a longer period of time, extending frequently over many months.

The Authors mention the oral use of sodium ricinoleate ("Soricin"), in five grain doses, to relieve the pain of unstable colon. We are using ten grain doses three times a day. It is necessary to give the Soricin in an enteric-coated medium, as it is said to be inactivated by the hydrochloric acid of gastric juice. Berger has reported a decrease in sensitivity to stool organisms, following the prolonged use of Soricin, as determined by repeated intradermal tests.

Dr. Mateer and his associates have presented a pains-taking study, carried out over a period of years, with very encouraging results. Having twice visited their Clinic, and being aware of the care with which their observations are made, I feel that they are to be complimented and that their work should receive serious consideration and wider clinical application.

DR. SARA M. JORDAN (Boston): I feel very inadequate in the rôle of discussant of this very carefully prepared paper of Dr. Mateer's, because I am not familiar with this form of therapy in this condition. I can't either confirm or disagree with Dr. Mateer's findings here, but when the term "unstable colon" is mentioned, I do like to say a few words about it.

By the way, we are indebted to Dr. Kantor for that term "unstable colon." We called it the irritable colon, but he suggested because it isn't always hyper-irritable, it should not be called irritable but unstable. I think, to Dr. Mateer and to all of us who have used the term, it means a disturbance in the tonus and in the irritability of the colon, and probably of the whole digestive tract, but in the colon it is more easily visualized than in the small intestine and in the stomach.

It is an important condition, of course, because I think perhaps all of you have had the experience of finding that in the cases who come to you with gastro-intestinal disturbances, about 35 per cent have no organic disease, and they are not just neurotics; that is, we all find, that by directing attention and focussing our therapy on the digestive tract, and perhaps particularly on the colon, we are able to relieve not only the digestive symptoms, but also the associated neurogenic symptoms in a large number of cases.

Dr. Mateer has already said that the ordinary cases of irritable colon do not need anything more than what he calls the "comprehensive" treatment, and we also find that to be true. I will show you a slide which will show that there is a large group of cases, about 61 per cent in our group, who have no other symptoms except the digestive complaints. In about 39 per cent there are associated neurogenic symptoms. The relief of the abdominal symptoms and of the neurogenic symptoms is very often synchronous and well coordinated.

The use of colon bacillus therapy, it seems to me, has been shown by Dr. Mateer to be apparently very valuable in this group of cases which apparently is not amenable to the so-called comprehensive treatment.

DR. JOHN G. MATEER (closing the discussion): As to the use of colon bacillus vaccine in arthritis, until the last two years, we also have given this type of vaccine to

cases of "unstable" colon with an associated arthritis. There have been certain instances in which both the arthritis and colon condition were relieved in a striking manner following small doses of the vaccine. However, it was very difficult, from the standpoint of the arthritis, to estimate consistently the ideal dose, and to select a sufficiently small dose to avoid a certain number of disagreeable flareup of a quiescent arthritis. In view of this experience, we now regard the presence of an associated arthritis as an important contra-indication to the use of *B. coli* vaccine. This viewpoint seems valid, inasmuch as recent advances in the treatment of arthritis along other lines, *c.g.*, in relation to diet, have rendered the treatment of chronic infectious arthritis reasonably satisfactory, without resorting to the risk of vaccine therapy.

In other words, we agree with the experience of Dr. Dorst, referred to by Dr. Schiff, that certain cases of associated arthritis may obtain striking improvement following minute doses of *B. coli* vaccine treatment. However, the risk of encountering overdosage before the course of injections is completed is appreciable; and, in such cases, the flareup of arthritic symptoms may persist for some time.

We also agree with Dr. Schiff in his remarks relative to the dosage of "Soricin," or sodium ricinoleate, as recommended by Dr. Dorst. There are some cases in which the small and probably ultra-conservative dose of one 5 grain capsule a day is insufficient to afford satisfactory relief of the unstable colon distress. In such cases we have increased the dose to two or three capsules a day, administering one capsule just before each meal.

In conclusion, we should like to state that colon bacillus vaccine therapy is not a panacea; but, if judiciously employed, it is an important additional therapeutic agent for a group of cases in which supplementary aid is needed.

## ABSTRACTS

CLUTE, HOWARD M., M.D., F.A.C.S., AND  
SWINTON, NEIL W., M.D.

*Exploration of the Common Duct in Gall Stone Surgery. S. G. and O., Vol. 59, No. 6, pp. 906-912, Dec., 1934.*

This article is a discussion of the indications for exploration and drainage of the common bile duct, a detailed description of the operative technique as used at the Lahey Clinic at the present time, and a report of the end results obtained between the years 1910 and 1934.

The common duct should be drained for the following indications: (1) The presence of jaundice, either in the history or at the time of examination. The point is emphasized that between thirty to forty per cent of patients having common duct stones have had no jaundice at any time. (2) The presence of a small thick-walled, contracted gall bladder. (3) The presence of thickening or stone along the gall bladder or in the head of the pancreas as evidenced by palpation of the duct, or dilatation of the common duct. (4) The presence of small stones in the gall bladder or in the cystic duct which

might easily pass into the common duct.

Spinal anesthesia is the anesthesia of choice in good risk patients where the operation is expected to last one hour or less. For the poor risk patients and where undue technical difficulties are anticipated, intratracheal ethylene anesthesia with regional field block is preferable.

The operative technique will not be reviewed in detail in this abstract. Adequate exposure of the common duct is first obtained, the cystic artery is ligated, following which a longitudinal incision is made in the common duct one to two centimeters above the ampulla and the duct is carefully explored through this incision. Following exploration and the removal of stones if present, a small T-tube is placed in the duct and closure made about this T-tube.

Following operation, after the first week, the tube is gradually clamped off and when the stools are colored and all bile is passing through the common duct into the intestine, the T-tube is removed.

At the present time, at the Lahey Clinic, common ducts are being explored in between thirty-five and forty per cent of the cases of gall stones. Common duct stones are being found in between eighteen to twenty-one per cent of those cases having the common duct explored.

The Authors report that from 1910 to 1934, at the Lahey Clinic, cholecystectomy has been done 1543 times. In this series, the common duct was drained 434 times. The mortality in all gall stone operations was 3.8 per cent. In the gall stone group where the common duct was drained, the mortality was 4.83 per cent, and in those cases in which the common duct was not opened, the mortality was 3.61 per cent. In those cases in which the common duct was explored but no common duct stones were found, the mortality was .25 per cent.

Stricture of the common duct has never resulted following exploration by this technique. It has not been felt that exploration of the common duct has increased operative mortality in this group of cases.

N. W. Swinton, Boston.

## SECTION VI—*Abdominal Surgery*

### Aseptic Electrosurgical Enterostomy<sup>\*</sup>

#### A New Method

(Preliminary Report)

By

LESTER R. WHITAKER, M.D.

BOSTON, MASSACHUSETTS

IT is generally agreed that whenever the bowel is unable to propel its content, enterostomy may be a life-saving procedure. This is particularly true in cases of obstruction of the small intestine where the patient is a poor risk, or in paralytic stasis from varied causes. Blockage of the colon by tumor, or otherwise, usually demands an enterostomy of some sort to obtain evacuation and return of normal tone preliminary to resection, as well as for prevention of post-operative distention with strain on the suture line.

Heretofore, an enterostomy has been a race between the surgeon and the bacteria to see whether the tube would go in before the content of the bowel came out. Usually the bacteria won, with more or less contamination of the operative site. Obviously an easily executed aseptic method of enterostomy is advantageous. An attempt at such a method will be described.

#### METHOD

The experimental apparatus consisted of a small rectal tube, cut off to a length of ten inches and the tip bevelled. Also a wire-loop electrode of the proper size with a handle of sufficient length to be put through the tube.

The trials were made upon the stomach of the dog: A stitch is taken in the wall of the stomach and tied; then the end of the tube is placed just proximal to it, and buried in the wall of the stomach by a continuous mattress or Lembert stitch for a distance of about one to one and one-half inches. The suture is held tightly around the tube to prevent leakage when the opening is made. The wire-loop tip of the electrode is bent a little to come into contact with the side of the tube. It is then inserted, and when by palpation it is felt to be in contact with the wall of the stomach at the end of the tube, the current is turned on from the

electrosurgical unit. The "cutting current" with low voltage and heavy dehydration is used. The object is to cut through the wall of the viscus, and at the same time to produce coagulation enough to stop bleeding from any vessels which might be encountered. For that reason the cutting must not be done too rapidly. More of a semi-cautery effect is desirable. The electrode is turned around to be sure to make a circular opening. Of course the anterior wall has to be held up in order to keep the electrode from damaging the opposite wall. With care, and avoiding too much pressure on the electrode, this is easily prevented. The free end of the tube is held out laterally over the edge of the wound to avoid contamination from escaping fluid. Then the electrode is withdrawn a little to bring it back just inside the tube. The handle acts as an obturator and gives the necessary stiffness for the tube to be pushed into the opening. This is done while the end of the suture is held taut to prevent leakage. Then the suture is tied in the tissues and the ends tied around the tube to hold it.

If the gut is distended it is preferable to insert a row of mattress sutures over the tube, and pull them up together—thus to distribute the tension and avoid tearing out of the sutures. If the tension is too great to allow suturing the wall of the gut over the tube the method described cannot be used.

The apparatus described is that used experimentally. The tube is perhaps a little too large for enterostomy in the small intestine of man. A smaller one could be used and an electrode with a thinner shaft made to fit into it. A tube even larger could be employed for a temporary colostomy or gastrostomy.

In gastrostomy, a comparatively avascular area for making the opening should be chosen. But, since the tube has to be inserted through an opening of smaller diameter in the stomach, there would be a tendency to occlude cut ends of vessels by pressure. For use on the small intestine and colon, however, there are no obvious dangers, and it appears that this aseptic method will be distinctly advantageous.

## SECTION VII—*Surgery of the Lower Colon and Rectum*

### The Haemorrhoidal Lesion:

Its Radical Cure by Submucous Injections with or without the Ligature Operation.

By

E. A. DANIELS, M.Sc., M.D.  
MONTREAL, CANADA

A CONSIDERATION of the haemorrhoidal lesion, will readily demonstrate that operation will be adequate in effecting a cure in a large percentage of patients. However, recurrences will consistently present themselves in a group of cases, where the mucous membrane lesion is not recognized together with the haemorrhoidal varix. It is the recognition of this mucosal abnormality in relation to internal haemorrhoids, which forms the subject of the present study.

#### THE HAEMORRHOIDAL LESION

One is concerned with the gross haemorrhoidal lesion in this presentation; and in considering the gross pathology of internal haemorrhoids, one will recognize the soundness of the treatment presently to be described.

The *histological appearance* of internal haemorrhoids is sufficiently well known. The typical haemorrhoid consists of a mass of dilated venules, (arterioles are present but are few in number and are practically unchanged) distributed through a stroma of connective tissue which shows chronic inflammatory changes. The venous walls show thinning, the result of replacement of their muscular and elastic coats by fibrous tissue. The haemorrhoidal varix is covered by a diseased, thinned, granular, more or less redundant mucous membrane. Grossly, internal haemorrhoids must be regarded as dilatations of the internal (superior) haemorrhoidal plexus of veins which run quite superficially in the submucosa and which drain into the portal circulation. Because of their superficial distribution, very feeble support is offered to these veins and a dilated state in these vessels is easily arrived at. The mucosa of the lower rectum is very loosely attached by fibrous and elastic tissue to the submucosa. The superficial course of the tributaries of the superior haemorrhoidal vein in the lower rectum, very feebly supported by a loose, redundant, mucous membrane, renders these veins especially vulnerable to pathological changes. Gravity, and the fact that the portal vein and its larger tributaries are without valves, are other factors which favour a dilated venous state in the haemorrhoidal plexus. This dilatation is the initiation of the haemorrhoidal lesion with its various sequelae. This leads one to a gross consideration of the further evolution of the haemor-

rhoidal lesion and will furnish an explanation for the *rationale* of submucous injections of a sclerosing fluid with or without a subsequent ligature operation.

The haemorrhoidal lesion in its early stages may be observed as a dilatation of the radicles of the superior haemorrhoidal vein running in the columns of Morgagni of the lower rectum. The three larger tributaries of the superior haemorrhoidal vein are, a left lateral vessel, a right anterior and a right posterior one. These varices are covered by an unhealthy, redundant mucous membrane which has a hyperaemic, granular appearance. This type of case presents occasional rectal bleeding. This is the result of fecal trauma, which might occur from time to time when a hard fecal mass passes over the granular mucous membrane and produces a pin-point rupture of the mucosa and its underlying superficial vulnerable varix. The redundant mucosa soon overrides the tiny pin point rupture of the venous wall and arrests the bleeding. It is for this reason that the source of haemorrhoidal bleeding, can rarely be demonstrated during proctoscopic examination (1). When the haemorrhoidal lesion becomes well established, the mucous membrane redundancy becomes marked, and in some cases rises high up into the ampulla of the rectum, almost filling the lower rectum in concertina-like fashion. One is now dealing with an actual mucous membrane prolapse. This prolapse is usually not extruded because of the competency of the anal outlet. (The external sphincter, the internal sphincter, which is the lower thickened circular fibres of the bowel wall and the *levator ani*). In this type of case, upon proctoscopic examination of the lower rectum and anal canal, one will find the three primary internal haemorrhoids, a left lateral varix, a right anterior and a right posterior one, all three varices being covered by a granular hyperaemic mucous membrane. These haemorrhoids may or may not be extruded with bowel movements and may or may not require reduction, depending primarily upon the degree of muscle tone of the anal outlet. These three varices will be found running up the bowel from the pectinate line (*i.e.*, the base of the columns of Morgagni, at the ano-rectum), and at their lower borders may have become epithelialized because of continual extrusion. These haemorrhoids are covered by columnar epithelium since one is dealing with internal haemorrhoids of the lower

Fig. 1

rectum. Continual extrusion of these internal haemorrhoids through the anal canal results in stretching and impairment of the tone of the sphincter muscles and the haemorrhoids may remain continuously outside or require frequent reduction especially after bowel movements.

If one now inserts the proctoscope a little higher into the rectum above the low rectal varices, one will encounter a degree of mucosal redundancy, which in certain cases is quite marked, and may rise high up into the ampulla of the rectum crowding this area, especially in the anterior and lateral quadrants. This superfluous mucous membrane has an unhealthy, granular, edematous appearance. It is continually being dragged upon by the varices which it overlies and above which it rises into the rectum. Prolapse and strangulation may now supervene at any time. This accident really occurs, when not only the haemorrhoids, but the mucous membrane redundancy, already described, descends outside and reduction is not immediately effected. Certain cases present only the haemorrhoidal lesion (varices) with very slight mucous membrane redundancy, but in a group of cases this mucous membrane lesion is marked and well established. On the other hand, the varices may be quite small with the mucous membrane lesion as the outstanding feature. It is this latter type of case that may not present any signs or symptoms until the sudden extrusion of the redundancy occurs and which may be erroneously described as haemorrhoids. This occurs when for some reason sphincter tone is reduced in effectiveness *e.g.*, after certain fistulae operations, after parturition, in the aged, in the acute febrile states and in wasting diseases. Straining for any reason favours extrusion of the mucous membrane redundancy. In children, mucosal prolapse occurs following faulty bowel habits with straining, when after a time a redundant condition of the mucosa becomes established with its consequent extrusion. In children, the comparative straightness of the rectum and sig-

Fig. 1. (a) Demonstrates the height of the mucosal redundancy associated with internal haemorrhoids. The redundancy prolapsing into the lumen of the proctoscope is being injected with the sclerosing solution. The Author's proctoscope (rectoscope) measures  $3\frac{3}{4}$  inches in length and is especially constructed to reach above the prolapse in the ampulla recti.

(b) Demonstrates the level of the haemorrhoidal lesion in the lower rectum. The redundant mucous membrane covers the haemorrhoidal varices and rises into the ampulla recti. the varices have been flattened by the passage of the instrument over them.

moid with the flatness of the sacrum further favour the descent of the mucosal redundancy. Here, one is dealing with a pure mucous membrane prolapse, without rectal varices or at the most, very small ones.

One may now summarize by concluding that internal haemorrhoids are associated with a degree of mucosal redundancy, which in certain cases may be quite marked and assume the proportions of a mucous membrane prolapse. It is the recognition of the association of the mucous membrane lesion with internal haemorrhoids, which forms the basis of this paper.

#### SUBMUCOUS INJECTIONS WITHOUT OPERATION

Several submucous injections of five per cent phenol in sweet almond oil, administered at weekly intervals high up into the mucous membrane redundancy, should be tried in such cases where the mucosal lesion already described is found accompanying the haemorrhoidal varices. Submucous induration results in the obliteration of the mucous membrane redundancy, which, in itself, often is responsible for much of the protrusion complained of by the patient. The redundant mucous membrane is pulled up, so to speak, by this reaction, and the varices become surrounded by the submucous indurative process, which soon results in their obliteration. The lower rectum should be theoretically divided into four quadrants and injected at weekly intervals. The dose is from three to ten c.c. depending upon the degree of mucosal superfluity present. Cases which present free rectal bleeding should certainly be treated by this method, before subjecting the patient to surgical interference. Marked anaemia often results in such cases, even when the bleeding has not been excessive in amount (1) (4). One or two submucous injections usually will completely arrest the blood loss. The administration of a high iron diet subsequently should be ordered, together with iron ammonium citrate or one of the Bland and copper preparations (1).

The redundant mucosa overlying the haemorrhoidal varices has an unhealthy edematous granular appearance and this condition is often observed for a distance of one or two inches above the haemorrhoidal area extending into the ampulla of the rectum. This condition could really be described as a proctitis accompanying the haemorrhoidal lesion. After several submucous injections, the redundancy becomes obliterated and the mucous membrane after a month or six weeks, takes on a much healthier appearance and, in fact, seems quite normal. In many cases, the haemorrhoids are practically cured or considerably reduced in size. Bleeding from the haemorrhoidal area is nearly always arrested by this technique.

## SUBMUCOUS INJECTIONS FOLLOWED BY THE LIGATURE OPERATION

In a high percentage of patients suffering from internal haemorrhoids, the treatment by submucous injections will suffice to effect complete control of signs and symptoms. The prolapse will no longer be extruded, bleeding will be arrested and the patient will feel quite comfortable. Clinically this picture may be regarded as a cure. After a few months it may become necessary to reinject one of the quadrants. This is usually sufficient; and patients have been followed who after several years have had no recurrence and who have shown no untoward effects resulting from the treatment.

Sometimes it is difficult to determine beforehand which cases must be rejected for this ambulant type of treatment. The degree or size of the prolapse is no criterion. A loose patulous sphincter, epithelialization of the base of the prolapse (from long-continued extrusion), bad rectoceles in which the perineal body is deficient, are definite contraindications to the injection treatment. In cases where fissure, fistulae, large hypertrophied papillae or other accompanying ano-rectal lesions are present, one does not attempt treatment by the injection method. Age is unimportant and old people respond remarkably well.

There are certain patients who have a large degree of prolapse, and in whom the only type of operation which could be employed would be the Whitehead procedure. The bad after-effects of this type of operation have been frequently observed and recorded. A preliminary course of injections will often convert such a case into quite a simple one. After three or four large injections, the whole prolapse will be pulled up and fixed in the ampulla, where the submucous indurative process practically obliterates the redundancy with any underlying varices. All that may now have to be done, is simple undercutting and ligature of one or two remaining varices, (covered by mucous membrane), low down which still continue to be protruded, and which will not be controlled by submucous injections. The case which would therefore have required a formidable amputation or Whitehead type of operation either is completely relieved, requiring no further interference, or converted into one requiring a simple ligature procedure.

In those patients who show a marked anaemia as the result of the bleeding varices, a course of preliminary injections completely arrests the blood loss. Should operation be subsequently decided upon, one can do so at one's leisure and meantime employ appropriate diet and drugs for the anaemia. The risk of operating upon an anaemic patient, whose forces of resistance are depleted, is thus avoided.

The *ligature operation* referred to in this paper consists as follows:

Low spinal anaesthesia is induced with 50 mgms. of novacaine or 0.4 to 0.5 c.c. of a ten per cent solution of stovaine and sodium chloride in distilled water. (The

latter is employed at St. Mark's Hospital, London). The stovaine solution because of its high specific gravity of 1080 (cerebro-spinal fluid has a specific gravity of approximately 1007) gives a restricted zone of perineal and low rectal anaesthesia, eminently suited for operations upon the rectum.

The three primary haemorrhoids, usually a left lateral, a right anterior and a right posterior, each is individually grasped with Spencer-Wells forceps and pulled down outside the external sphincter, which is now completely relaxed. The muco-cutaneous border is now undercut with a pair of Mayo scissors, and the haemorrhoid whilst it is gently pulled down is undercut for a short distance. This distance is usually up to the level of the anal canal with the pile under traction in the prolapsed position. The base of the haemorrhoid is now transfixed with No. 1 chromic gut, on a curved needle, passed through the center of the haemorrhoidal mass and the ligature thus firmly tied. The redundant part of the haemorrhoid is snipped off and the remainder will later slough out with the ligature. Each haemorrhoid is thus individually dealt with. A light vaseline packing is inserted in place at the completion of the operation.

This type of operation employed at St. Mark's Hospital for Rectal Diseases in London, is simple, satisfactory and gives excellent results. Submucous injections of phenol in oil are extensively used at that hospital in a high percentage of cases of internal haemorrhoids, and by Gabriel in practically all cases of rectal prolapse (3). A great number of surgeons employ the ligature operation today for internal haemorrhoids.

## SUMMARY AND CONCLUSIONS

The mucous membrane lesion in internal haemorrhoids is recognized and described. The relationship

Fig. 2. (a) Demonstrates view through end of proctoscope inserted full length. The mucosal redundancy can be seen prolapsing into the lumen of the instrument. (b) Demonstrates the haemorrhoids prolapsing into the lumen of the proctoscope in the lower rectum. The instrument has been withdrawn to (b) Fig. 1, below the area of prolapse. Note the difference in level between (a) and (b).

between mucous membrane prolapse of the rectum and internal haemorrhoids is studied.

The value of submucous injections of five per cent phenol in almond oil into the redundant mucous membrane in cases of internal haemorrhoids has been pointed out.

In cases of mucous membrane prolapse of the rectum such formidable and unsatisfactory operations as the Whitehead, and amputation of the prolapse have become unnecessary with this plan of treatment. Operative interference is often altogether avoided by employing the treatment outlined. This treatment is ambulant in nature and the patient does not have to be hospitalized or his activities curtailed. (In complete rectal prolapse in adults, Gabriel employs submucous injections of five per cent phenol in almond oil, together with para-rectal injections of a solution of quinine sulphate and dilute sulphuric acid in distilled water; the patient is hospitalized). His results in complete prolapse have been very satisfactory with this method, which he prefers to any type of operation (3). The treatment by submucous injections,

with modifications, (smaller dosage) is satisfactory in the type of prolapse often seen in children, which lesion does not respond to simpler measures.

This procedure is very useful in those patients with internal haemorrhoids who show secondary anaemia. The risk of operating upon an anaemic patient is thus avoided.

The ligature operation is described as a simple and satisfactory procedure in dealing with those cases of internal haemorrhoids that do not respond to the injection technique or where such is contraindicated.

## SECTION VIII—*Editorial*

NOTE: The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Gastroenterological Association is in no way responsible for editorial expressions.

### ON THE PROPOSED "INSTITUTE FOR GASTRO-ENTEROLOGICAL RESEARCH"

AFTER reading the presidential address of Dr. B. B. Vincent Lyon delivered before the American Gastro-Enterological Association last June, published in the October, 1935, issue of this Journal, we feel that the suggestion contained therein, as to the need for establishing a Research Foundation devoted exclusively to the study of the manifold unsolved problems connected with various gastrointestinal and metabolic diseases, is a most worthy one. We feel that it should have whole-hearted support, not alone of the members of the American Gastro-Enterological Association but from all members of our profession who recognize the timeliness of Dr. Lyon's suggestions. It is hardly necessary to call attention to the great need for such a concerted attack upon the day-by-day problems that confront the clinician or specialist interested in the field of gastroenterological medicine and surgery.

Dr. Howard F. Shattuck of New York, on assuming the 1935-1936 Presidency of the American Gastro-Enterological Association, appointed Dr. Lyon, Chairman of the Research Fund Committee and the latter, in turn, appointed the following doctors to serve with him:

 Pilcher, Jas. T., Brooklyn.  
 Rehfuess, Martin E., Philadelphia.  
 Shattuck, Howard F., New York (Chairman  
 Ex-officio).  
 Smithies, Frank, Chicago.  
 Verbrycke, J. Russell, Washington.

It is probable that distinguished clinicians and gastroenterologists not themselves members of the American Gastro-Enterological Association will be requested to serve on the General as well as on the Executive Committee.

The Fund to be raised should be five million dollars—certainly not less than three and a half million dollars—if the income alone is to be made use of, taking 3% as the maximum safest income-producing figure. If all or a portion of the principal can be spent during the life time of the Research, a lesser sum would be required.

We fully endorse Dr. Lyon's suggestion that any individual doctor who submits an idea for research which finally proves successful, should then receive as large a degree of credit as does the Research Staff which actually has done the technical work.

Already the Committee has been approached by several well-known promotion firms, who have requested that their services be made use of in the raising of this Foundation Fund. The charges for services of these firms vary between 6 to 12% of the amount of the fund raised. These promoters have elaborate plans, such as team captains, luncheons and dinners customary to such a campaign.

The Committee feels that such outside "professional" help should not be engaged until we, ourselves—the American Gastro-Enterological Association, its Committee and its medical friends—have exhausted the list of possible donors and have failed to reach the objective.

The Committee, therefore, hopes that each member of the American Gastro-Enterological Association or any clinician or specialist in diseases of digestion and nutrition or any individual interested in the successful

promotion of this worthwhile cause will communicate to the Committee the names of any philanthropically inclined person or persons who might desire or be induced to donate the entire Foundation or contribute a portion of it. When names of possible donors are forwarded, it would aid the Committee if proposers would offer their suggestions as to how such prospects best can be approached.

If the goal is to be reached, certainly, it is necessary that each of us who feels that such a Research Foundation as advanced by Dr. Lyon eventually would yield large dividends to the public, should get behind this movement and help consummate the plan. Recent acts of the Government in respect large fortunes make the time propitious for the possessors of wealth to avoid extraordinary demands in the form of taxes. How much more satisfactory it would be to individuals controlling large funds if they contributed generously of their means to a Foundation which not alone would perpetuate their families' names but at the same time, would be of far more service to humanity than if the ever-reaching tax collector forced their funds into a bottomless bin whose contents fed innumerable dubious, often politically-controlled, projects!

Reader, put *your* shoulder to the wheel and do not leave this worthy—and admittedly difficult—task wholly to the efforts of Dr. Lyon and a few of the "ever-faithful." Surely, some of the 130 members of the American Gastro-Enterological Association have contacts with men of large fortunes, of such nature, that when the character of the proposed Research Foundation is explained, they will respond generously—and promptly.

There is a big job ahead. Let's do it!

Frank Smithies.

#### PROCTOLOGY, A SPECIALTY, AND ITS INFLUENCE UPON THIS JOURNAL'S PUBLICATION POLICY

**D**URING the past two decades no diagnostic and surgical specialty has more thoroughly earned its right to serious consideration than has Proctology. Progress, too, has been made against most discouraging handicaps.

Within the memory of most of us, time was when certain lazy or a bit "off color" members of our craft, recognizing the anatomic limitations to patients directly inspecting their own anal sphincters and some twenty inches of cephalad bowel, thus determining how little or how much—especially how *little!*—ailed them, quite shrewdly appraised therein the possibilities for lucrative "business." Learnedly these practitioners dubbed themselves "proctologists." Living strictly up to the Greek roots, from which this word directly is derived, these pioneering lads "talked about the anus" long and oft. However, in "professional" activities, they *transposed* the zoölogic meaning of their specialty's name, so that (as in *fish*—of which they had many in their practices!) "*proctos*" became "the fin (theirs!) in *front* of the *vent*," rather than "the vent in front of the fin!"

That the "specialty" proved profitable, soon was demonstrated. Not alone was there a rapid increase of the proctologic clan but, before long, every city of importance harbored its nests of proctologic quacks who displayed—in newspapers or by electric signs—

their blatant advertisements. Indeed, to the layman, particularly the ordinary working man, the word "specialist" grew to signify one who either chased the festive "biscuit-boys" or who sadistically titulated the ever-vibrant sphincter ani.

Without full appreciation of the degree of popular and professional prejudice which obstructed them, it is not possible to credit the modern proctologist sufficiently for the broad strides forward which actually he has made. To be sure, yet we have abroad in the land numerous generous-paunched, pink-cheeked, old womanish, breezy, loquacious "Docs" (often boasting also several sub-titles, "earned" from cultist, self-styled "colleges") who possess such eagle eyes that they locate—and treat *endlessly*—lesions which only they and God can see, by means of tubes, syringes, tiny needles, bits of thread, the "radio-knife," smelly ointments, "lights," the "modalities," etc., etc. Usually, they "hold" their victims by claiming to be keeping them just a few hops ahead of cancer: missing a single treatment means having the "awful spectre" spring forward! These pathetic specimens of practitioner, ignorant or knowingly dishonest, make mountains out of mole-hills, botch the management of actual lesions or, all too often, wholly fail to recognize, not to mention, treat, true malignancy, serious infection, fistulae, parasitic invasion, organic nervous disease or frank psycho-neuroses. They are a menace to patient and profession alike: they have made most difficult the advance of the skilled specialist.

It has followed then, that in the "rehabilitation" of proctology—indeed in the proving it to be an *essential specialty*—the most important progress made by today's proctologists has been that concerned with the accurate *diagnosis* of affections which could be established in no way other than by intelligent, direct inspection of the parts involved. One need but linger a day in the Proctologic Clinic of a reputable institution, staffed by trained and skillful men, to realize that their's is a specialty. He will learn that to them diagnosis is something far beyond what is conceived by the internist or surgeon and, certainly, incomparably more than what the occasional, peeper-through-a-proctoscope ever imagined. The modern proctologist begins his diagnostic study where the general surgeon, the internist or even the gastroenterologist, believes it has been completed.

Our ranking proctologists have become experts in a most essential and specialized field of pathology. This should be recognized and appropriate credit given. When one stops and thinks, he becomes aware that proctologists have given us special, diagnostic information quite comparable in value with that advanced by the urologist, the cardiologist, the rhinolaryngologist, the thoracic surgeon. We should recognize that it is to proctologists that we owe the recognition of early amebic infection, the classical superficial pathology of chronic ulcerative colitis, the descriptions of low-lying tuberculous and luetic lesions, the discovery of early malignant disease, the location and the significance of polypoid growths, the "cord rectum," the various neuroses affecting—often in association with obscure pain—the sigmoid and rectum, the accurate appraisal of strictures and of fistulous tracts and, within the past few years, the pathology of lymphogranulomata. Proctology now means more than "piles" and "fissures," yet, undoubt-

edly, if one be himself a host to such pathology, the proctologist more accurately recognizes the location, nature and extent of these annoyances than can men who have not given special consideration to their origin, course and pathologic variations.

In *differential diagnosis*, the competent proctologist is capable of furnishing valuable information by returning reports of a *negative* character. In instances of bleeding from the bowel, in this book it should not be necessary to emphasize the worth, to the internist or the surgeon, diagnostically, of the proctologist's assuring him that the source of the bleeding lies *not* in the lower colon segments. Clinically, all too often, failure definitely to exclude the sigmoid, rectum and anus as *loci* of bleeding lesions, leads to haphazard, and unsuccessful, therapy. Further, from no specialized diagnostician other than the trained proctologist can information be obtained regarding the progression or cure of local, lower bowel disease. At no hands other than his, can one secure representative smears, scrapings or specimens of tissue for biopsy. Often, indeed, the proctologist, experienced in recognizing gross pathology within his field, can render a correct diagnosis long before smears and tissue-bits have been subjected to laboratory examination.

Those not familiar with the work in modern proctologic clinics make themselves ridiculous when they scoff at the specialty. Unfortunately, many of even our so-called prominent surgeons or internists never have visited a properly-staffed clinic for proctologic diagnosis. In fact, in many cities which style themselves "great medical centers," proctologic clinics actually do not exist. Rarely do medical students see a gut through the proctoscope; when they do, it is more than likely that those who are "instructing" them know little of what is seen. Indeed, many of our large hospitals do not even possess proper examining-tables and, certainly, few of them or their dispensaries can boast of down-to-date instruments or of men capable of using them. From such cities and institutions come the loudest outcries against the specialty, proctology. Sad, it is for patients who appear for diagnosis, that many critics hold positions in which it is taken for granted that their holding them, guarantees familiarity with all helpful, modern diagnostic procedures and that they will see to it that nothing is neglected which will elucidate the problems created by disease. While the patients put their trust in such don't-know-that-they-don't-know type of "chief," available scientific knowledge goes a-begging and disease which, if recognized early is curable, passes on to the hopeless stages.

*Surgically*, unquestioned advances have been made. One has but to see a patient in the old-fashioned, lithotomy position, under general anaesthesia or with pain incompletely deadened by insufficient "local" anaesthetics, having his "piles" removed (?) by the ancient, "clamp-and-cautery" method, by "blind" incisions or by the destructive Whitehead operation, to realize the beneficent surgery the proctologist has made possible by his leisurely, always visible, thorough dissection of each hemorrhoidal mass under spinal anaesthesia—and at no risk and with no distressing after-course to the patient. Ask the subject who is experiencing surgery for relief of hemorrhoids which have recurred, *subsequent* to operation by "the clamp-and-cautery" or the old ligature methods, whether modern proctologic surgery warrants recognition as a

specialty! Should a member of our own profession acquire hemorrhoids, if he is at all informed, his choice of operator is the modern proctologic surgeon, if he can reach him.

Dozens of surgical or non-surgical methods of treatment have made management of anal and lower colon affections surer and less distressing as a result of specialization. That these therapeutic advances *generally* are not known or understood, largely is due to there being relatively so few modern proctologic clinics and because, where such clinics do exist, physicians fail to visit them and acquire first-hand knowledge. Is it to be wondered that while an eminent surgeon may perform partial gastrectomy brilliantly, he fails lamentably in the presence of rectal stricture or fistula? Yet, seldom does he resist tackling such; rarely has he the courage to admit his limitations and insist that patients place themselves in the hands of men, to whom the operative field is familiar ground, and surgery there is easy, quick, painless and satisfactory.

The writer feels that proctology has earned its "place in the sun" and should be allowed to occupy that place. This Journal, from its inception, has given space to articles from leading proctologists. It plans to enlarge that space. Through the courtesy of its Executive Officers, arrangements have been made

whereby such papers as annually are presented before the American Proctologic Society and have been approved by the Organization's Publications' Committee will appear in this magazine. Further, it is proposed to print that most commendable feature of the Society's activities, the Annual Abstract of Literature as compiled by one of its members.

The current year's "Abstracts" have been made by Dr. Clement L. Martin, Chicago. A tedious task is the preparing of an annual abstract of the literature of any special topic, but when carefully done, the results are invaluable to those concerned. Dr. Martin's "Abstract" represents a most conscientious effort to visibilize proctologic advances as they are revealed by the World's literature. Apart from its value to proctologists, this feature, of itself, should assist greatly the general surgeon and the internist to a realization of what real progress is being made by trained, earnest proctologists every where and should teach much to those of our profession who are yet capable of being taught and are willing to learn. Its publication may induce certain "die-hards" even to visit a modern clinic which is devoted to proctologic diagnosis and treatment!

Frank Smithies.

## ABSTRACTS

### GENERAL

In detailing the "Progress in Rectal Surgery" *Gordon-Watson* emphasizes the following:

The mechanics of the operation for fistula in ano remain about the same as they are in the 14th Century as practised by John Arderne. He believes he has evidence to prove that fistula in ano arises in ano-rectal glands which probably represent mucous glands of the primitive cloaca which persist in some adults and communicate with the anal canal.

Much progress has been made in treatment of Cancer of the Rectum and sigmoid in the last 25 years. He mentions the Miles and Lockhart-Mummery operations.

He associates rectal adenomata and cancer very closely. He believes that the sequence: hyperplasia, adenoma, cancer, is "clear cut and established" on the basis of the work of Dukes. As a cancer progresses any associated adenomata seem to be inhibited and regress.

The mortality following colostomy has been reduced from 69% in 1869-78 (lumbar) to 9% (on a five year average) at present.

He notes that the explanation of vesico-colic-fistula on a basis of diverticulosis was not made until present century. Recto-sigmoidectomy is advocated for prolapse and presacral sympathectomy for megacolon.

*Daniels* reviews the fundamentals in rectal diagnosis. He requires a simple history considering tuberculous infection and the use of alcohol. There should be a careful examination including palpation of perianal, anal, and rectal regions, and careful inspection with and without instruments. Every patient should be sigmoidoscoped and multiple lesions looked for, especially adenomata and carcinomata. The differential diagnosis of fissure in ano, tuberculous anal ulcer, chancre of anus, and epithelioma of anus is important.

Durst directs attention to the proper use of the proctoscope, noting among other points that digital examination

should precede the use of the instrument, that the proctoscope should be passed without the use of air inflation if possible, that it should not be advanced until the bowel is well seen and the direction of the lumen noted.

Gabriel enumerates the following as the recent advances in the treatment of rectal diseases: low spinal anesthesia, dettol (a new antiseptic), surgical diathermy, sclerosing substances in the treatment of hemorrhoids and prolapse, anesthetics in oil, recto-sigmoidectomy for prolapse, Frei test in rectal stricture, perineo-abdominal excision for cancer, presacral sympathectomy, intraspinal injection of alcohol for pain, sigmoidoscope with proximal light, and diathermy forceps.

Goldberger (1) states: While using the ordinary proctoscope one gets only a diagonal or oblique picture of the field and the view is never larger than the transverse section of the tube.

There are three faults of the ordinary proctoscope:

1. An exact and correct view may only be obtained while withdrawing the proctoscope and the viewpoint is limited.

2. Fecal masses are difficult to circumvent and sometimes can not be passed at all.

3. Sharp turns, ulcerative processes, distant strictures and stenoses are serious hazards.

With this in view the Author has constructed a new instrument which may be introduced higher in the colon and shows a larger and better field, magnified if necessary.

This new instrument is called the Diapetan Rektoskop.

It permits inspection of the bowel with air or water and is similar to the cystoscope. The light can be turned so the side walls can be seen or may be turned so the inspection is forward. This new Rektoskop is very narrow measuring 12 m.m. in diameter and carries at its point a high powered lamp. The inner part of the tube is divided

1. Goldberger, J.: Endoscopy of rectum and sigmoid with new method of unfolding organ. *Med. Klin.*, Berlin, 30:738 (June 1) 1934.

into two portions for the inflow and return of the water. The tube also has a handle to operate the light carrier and may be turned 360°.

### HEMORRHOIDS

The indications and limitations of injection procedures are becoming more generally known and on the other hand it is perhaps more generally recognized that not every patient having hemorrhoids necessarily requires an operation. Kleckner's article is a concise sound consideration of the subject, as are Cartwright's and Silvers'; Hayes discusses the important factors in minimizing post-operative pain.

Discussion of the Whitehead operation continues, chiefly in foreign journals.

Two book shelve been brought out on the subject in the last year, one by McAusland, the other by McNamara.

### FECAL IMPACTION

Norbury reports the case of a mentally defective girl 18 years of age who had an operation soon after birth for

imperforate anus with recto-vaginal fistula. At 16 years of age she had a very large fecal impaction extending up to the umbilicus which was broken up manually under anesthesia and the bowel cleared by enemas. Two years later the condition recurred but relief was not successful by the same method and the patient died several weeks after the attempt to relieve the impaction under anesthesia. Necropsy showed fecal impaction with the hypertrophied rectum measuring 9 inches in diameter and the colon 5 inches in diameter. The thoracic contents were pushed up and compressed by the diaphragm which rose high into the abdomen. "Supposed cause of death--Asphyxia and syncope."

### FECAL IMPACTION

Stewart and Illick cite a case of obstruction from four large fecaliths and show in their article an excellent reproduction of the roentgenogram.

Dr. Clement L. Martin, Chicago, Illinois.

## SECTION IX—Book Reviews

(This section is open to contributions from any medical reader, whether or not a member of the Editorial Council).

*Vegetables and Their Significance in the Physiology of Digestion.* An experimental and Clinical Study by Dr. N. T. Leporsky, Professor of Medicine, University of Voronej. 345 pp. (Russian), Voronej, U.S.S.R., 1934.

THE ancients attributed great importance to a vegetable diet. They not only ascribed to it nutritive properties but successfully used many vegetables as curative and preventive agents in disease. However, the advances of modern chemistry gave ground for the belief that proteins, carbohydrates and fats are the basic foods, whereas vegetables, having a low caloric value, were regarded, till recently, as auxiliary foods of gustatory and not of nutritive importance. This may explain why, along with fundamental physiological investigations concerning the effect of proteins, carbohydrates and fats on digestion, there had been no similar study of the rôle of vegetables.

The discovery of vitamins, however, revealed the importance of vegetable foods in the diet. About the same time, the investigation of the effect of vegetables on digestion was begun in Professor I. P. Pavlov's laboratory. In the book under discussion, the Author summarizes the results of his seventeen years' experience along the lines of the work which he began in Professor Pavlov's laboratory. His experiments on animals are supplemented by clinical observations on patients and healthy individuals. Numerous protocols, diagrams (37) and tables (125) included in the text illustrate the exhaustiveness of the study and give a clear conception of the technique employed. The book is a valuable contribution to the physiology of the gastro-intestinal tract. It also contains many data useful to the gastro-enterologist and to the general practitioner. The following vegetables and their juices, and soups and *purées*, also fractional extracts, prepared from them, were employed: cabbage, beet, radish, turnip, cucumber, lettuce (*Lactuca sativa*), carrots, as well as mushrooms.

Beginning with the buccal cavity, it is shown that, regardless of the mode of preparation, vegetables provoke a greater salivary secretion than do meat, bread or milk. The effect of vegetable juices, soups and other preparations on the gastric secretion is still more pronounced. All kinds of vegetables, whether cooked or raw, are shown to activate a far greater secretion of gastric juice than extracts of meat (3.0 per cent) and fish. It is shown that vegetables and their juices act as chemical exciting agents which provoke an early "second phase" of gastric secretion. Unlike other chemical agents, such as meat extract, vegetables provoke a secretion exclusively by coming into contact with the mucous membrane of the pyloric part of the stomach and are ineffective when introduced into the intestine. Secretion commences soon after the administration of the vegetable food (the latent period not exceeding 45 minutes), rapidly reaches its height and remains abundant, lasting usually about two hours. The gastric juice obtained under these conditions is of high acidity and digestive power. A detailed analysis revealed that raw vegetables and their juices produce a comparatively greater secretion than do cooked or dried vegetables. Soups prepared from fresh vegetables are more active than are those prepared from dried vegetables. Salted and pickled vegetables, however, exhibit a very pronounced effect, but this must be ascribed to the addition of salt, vinegar and spices and not to the properties of the vegetables themselves. Experiments with different fruits and their juices gave similar results; these may be included in the same category as vegetables.

The addition of vegetable juices to meat extracts increased the secretory effect of the latter by 200 to 300 per cent. When meat and vegetables are administered together, the amount of gastric secretion is greater than is the sum of the secretions produced when meat and vegetables are given separately. The explanation lies in the fact that the addition of vege-

tables facilitates the digestion of meat and that during the process of digestion of the meat products are formed which are themselves "activators" of still further secretion of gastric juice.

The addition of vegetables to carbohydrate foods has a very similar effect to that produced on the digestion of proteins mentioned above: the secretion of gastric juice is much greater than when carbohydrates are administered alone and also it is greater than the sum of the secretions obtained when carbohydrates and vegetables are given separately. The secretion provoked by bread, potatoes and other carbohydrate foods is chiefly of a reflex nature, the chemical phase being insignificant. In view of this fact, the addition of vegetables to carbohydrates is of special importance in cases in which the "first phase" of gastric secretion is excluded (as happens, for example, with loss of appetite or in hurried eating of unpalatable food). The increase in the volume of the secretion in these cases amounted, under experimental conditions, to as much as 520 per cent.

The conditions become more complicated when vegetables are combined with fats. As is known, fats at first inhibit gastric secretion, and it is only after they are converted into soaps that they act presumably as secretagogues. The addition of vegetable juices to a fatty diet provokes a long continued secretion of gastric juice. It reaches its maximum in the first hour, which means that the vegetables are capable of counteracting the inhibitory effect of the fats. On the whole, the period of secretion activated by a combination of vegetables and fats is only slightly longer than when fats are administered alone, but the *total* amount of gastric juice secreted is greater (up to 100 per cent) and the juice is more acid and of higher peptic power.

The effect of vegetables on the pancreatic secretion also was studied. Concentrated vegetable juices and soups under normal conditions were found to inhibit pancreatic secretion, but when diluted from five to ten times the same agents activated secretion. The more strongly a concentrated vegetable juice inhibited the pancreatic secretion, the more powerfully did it stimulate when diluted. This was found to be true, also, as regards the duration of the secretion, as well as the digestive power of the pancreatic juice. With slight variations these conditions were shown to hold both in dog and man.

It is interesting to note that, in patients exhibiting achylia gastrica, the conditions were found to be reversed: thus, concentrated vegetable juices stimulated the pancreatic secretion, whereas diluted they had an inhibitory effect. Also, the content of enzymes was found to be higher in the pancreatic juice of patients who exhibited achylia gastrica.

Concerning the influence of vegetables on the secretion of bile and its discharge into the duodenum, it is shown that, for about three hours after the ingestion of a vegetable meal, the *secretion* of bile is doubled. Concentrated vegetable juices administered by themselves or along with proteins and carbohydrates inhibited the *discharge* of bile into the duodenum. However, when taken with fats they increased the discharge of bile into the duodenum by 50 per cent. When diluted ten times, the vegetable juices acted by themselves as powerful cholagogues and were success-

fully used by the Author in duodenal intubations for the treatment of cases of angiocholitis.

These observations led the Author to infer that vegetables act not only on the glandular apparatus of the gastro-intestinal tract but also on its neuromuscular apparatus. This view is substantiated by an experiment in which the administration of 300 c.c. of a salt-containing fraction of vegetable juice to an animal quickly precipitated defecation.

In an attempted analysis of the active principle of the vegetables studied, the Author comes to the conclusion that the salt-containing fractions are the most active, whereas other fractions grow less potent in proportion to the decrease of the concentration of salts in them. The vitamin content of various vegetables and preparations made from them received little attention in this investigation. Therefore no definite conclusions in regard to the nature of the secretagogue substances present in the vegetables can be made.

The last chapters of the book contain a brief discussion of the application of vegetables in the treatment of various gastro-intestinal ailments. Vegetables are considered to be "regulatory" agents in the process of digestion. Their importance as stomachics, cholagogues and cholagogues is stressed and their use in gastric achylia is emphasized.

George W. Stavraky, Montreal, Canada.

*Child Psychiatry*, by Leo Kanner, M.D., Associate Professor of Psychiatry, The Johns Hopkins University, with prefaces by Adolph Meyers, M.D., L.L.D., and Edwards A. Park, M.D., of The Johns Hopkins University. 510 pages; published 1935 by Charles C. Thomas, Springfield, Ill., and Baltimore, Md., price \$6.00, postpaid.

NO aspect of pedagogy, particularly as applied to children and youth, is receiving greater attention by teachers of the first rank than is psychiatry and its application to the pupil in respect his capacity for receptiveness, his limitations, the *why* of those limitations and the topics suited best to him as influences towards the development of his future usefulness in business, the professions or, broadly considered, a member of our complex society.

In the Middle West, those interested are familiar with the excellent contributions upon Child Psychiatry from the viewpoint of the teacher which, during the past decade have emanated from such representative institutions as the School of Education (The University High School), University of Chicago and from the Francis W. Parker Private School. At these schools, for more than twenty years, genius, delinquency, low grade intelligence, exhibitionism, habits—all have been analyzed, not alone from the standpoint of the various formulae presumed to indicate natural ability, capacity or limitations to learning, but by cooperative clinical investigations by many persons. Of these persons, the physician, whether a psychiatrist, a pediatrician, a laboratory worker or a physical diagnostician, more and more, has served to elucidate pedagogical problems which had not been solved strictly from research into heredity, family, environment, study habits and the multitude of avenues so commonly explored previously by those interested in the art and the science of teaching.

Now comes from one so advantageously and uniquely placed as is Dr. Leo Kanner, a treatise titled "Child Psychiatry." In the reviewer's opinion, really this is a book most importantly concerned with pedagogy. It is not just a book but probably the most important book in its field which yet has been offered to teachers. While the work may not have been written with that object—it may have been meant for pediatricians, for aught we know!—our opinion is that no institution seriously interested in pedagogy, its true significance, the lines of its advancement and in the individual being taught, can afford not to take Dr. Kanner's book very much to heart. It should be read and analyzed through its every page and there should be adopted into every day practice the information imparted. In a large degree, such should shape programs for the investigation and the management of children and adolescents upon the basis of medico-psychiatric analyses and the deductions presented.

To the pediatrician, of course, these studies grouped from the extensive and carefully tabulated material at Johns Hopkins, are invaluable: that is, if appreciated. At present we still have too vast a horde of pediatricians to whom the specialty means little more than height-weight-age-sex-calories-diapers-food formulae-stools-bellyaches-exanthemata-running ears and noses-and walking the floor at night! If the specialty, pediatrics, ever is to mean anything, in a broad sense, teaching it and practicing it along the lines set forth in Dr. Kanner's work are imperative. Otherwise, hospital waste-pails will continue brimfull of needlessly removed tonsils and adenoids, appendices, loops of gut, remnants of the newspaper-made-famous "upside-down" stomachs;—and parents and institutions will continue to be dizzied and bankrupted with alphabetically christened and numbered vitamins, hog-washes, "accepted" foods, pocket-book flattening organ-extracts and a thousand "new" agents supposed to rebuild, re-vivify and make lovely.

Space does not permit page-by-page review of Dr. Kanner's book: it is encyclopaedic, yet, withal, where "sampled" rather thoroughly, it appears not only complete but rational. The "light-reader" or "skipper" will find little comfort in this publication. Each page is packed with most substantial *pabulum* which requires leisurely digestion. Those who long have sought

a work from one in authority will adopt Dr. Kanner's book without questioning and come to regard it as one of the few "key" volumes in their libraries.

Of special interest to the readers of this Journal are the chapters dealing with "The Endocrinopathies," "The Digestive System," "Habitual Manipulations of the Body," "Faulty Feeding Habits" and "The Attack Disorders." As is the case with each section, these chapters exhibit a wide range of knowledge, proper perspective, balance, the avoidance of faddism and startling statements introduced for their effect upon the curious or the impressionable. Newer investigations in physiology (as the "conditioned reflexes" of Pavlov, etc.), neurology and anatomy are introduced in orderly fashion and where they form real contributions to the topic under discussion: they are not exhibited as mere evidence that the Author has "read up" and desires that his reader be aware of that fact. Excerpts are correctly and honestly credited; deductions are made from a background of well assimilated evidence. Indeed, the section dealing with digestive disorders, as manifested by children, sufficiently is adequate to warrant place in a treatise compiled by a gastroenterologist. It is refreshing to find such thorough consideration of so-called "specialism" in a book purporting to be but a general survey of a many-sided topic. No gastroenterologist can afford not to read and ponder over the sections being discussed: his diagnostic and therapeutic horizons will be widened—on right lines, too!

As is usual with a "Charles Thomas" publication, one finds Dr. Kanner's book properly, nay, elegantly, ordered and dressed. Binding, paper, type-fonts and index, all are attractive, complete and accurate (the index proved its worth on twenty-five random tests). It must be a source of great satisfaction to an Author who has labored diligently and intelligently to have the results of his efforts presented to the public in the "Thomas" way. To the reader, the publisher's nice custom of giving facts regarding the technical aspects of a book is both educational and unique. We like it. We are of the opinion that those who are concerned with the actual planning and building of a volume must derive a lot of pleasure from having set forth in summary the steps leading from manuscript to finished tome.

Frank Smithies.

## ABSTRACTS

RICHTER, H. M.

*Gastric Resection for Peptic Ulcer; Technique. S. G. O., Vol. LIX, No. 3, pp. 337-343, Sept., 1934.*

The Author presents his idea of the objective to be obtained in wide resection of the stomach for peptic ulcer, and gives a short description of the more important steps in technique. The objective, he states, is not to alter the acidity or alkalinity of the stomach or duodenum, but is to remove the ulcer bearing area of both the stomach and duodenum. Recurrence of ulcer is probably most frequently due to a failure to accomplish a sufficiently wide resection; certain technical errors such as

spur formation, badly arranged gastro-jejunal anastomosis, etc., probably play a part.

The operation described may be used as an emergency procedure within a short period after perforation, but usually there is adequate time to prepare the patient. Hemorrhage can usually be controlled by various measures, including, first and foremost, adequate blood transfusion. Severe starvation and dehydration may be corrected in part by the administration of water, salt and glucose, intravenously, hypodermically and rectally. The Levine nasal tube is passed the evening before operation in cases of retention, and is

allowed to stay in place; toward the end of the operation it is pushed down into the jejunum to facilitate early post-operative administration of liquids.

The choice of incisions is a personal one; each has certain advantages and disadvantages. After routine exploration the anterior surface of the stomach is grasped with two heavy forceps at two points along the long axis of the stomach. By using those forceps as handles the stomach is pulled down, and the bloodless gastro-hepatic omentum is pierced with two fingers. That maneuver allows the transverse colon to fall away from the stomach by admitting air into the lesser peritoneal

sac. The stomach is now raised, and the gastro-colic omentum is grasped in bunches between forceps, and cut. The left gastro-epiploic vessels are divided far toward the left at the site of the intended transection of the stomach on the greater curvature. The gastro-colic omentum is now separated toward the right. The pancreas is freed by blunt and sharp dissection. This step is made more difficult if there is an ulcer on the posterior wall of the duodenum. Actual penetration of the ulcer into the pancreas may necessitate opening into the ulcer in the process of separation. If such an ulcer is opened, its base should be swabbed with iodine and a tag of omentum fixed in it with sutures. In certain cases in which it is deemed impracticable to open the ulcer, the stomach may be resected proximal to the pylorus, and inverted. If the ulcer has been elevated from the pancreas, the duodenum is grasped between forceps, severed, and inverted by a Parker-Kerr suture using fine catgut reinforced with silk. The choice of the site of division of the stomach has varied with different surgeons. The Author believes that subtotal removal of the lesser curvature and spur formation by partial closure of the stoma with the vertical position of the stoma in the standing position are correct. He divides the stomach downward and toward the left for the purpose of removing more of the greater curvature than was recommended by Finsterer, but he maintains the vertical position of the stoma by suturing the opening in the mesocolon above the anastomosis. The sacrifice of a greater amount of the greater curvature makes it technically easier to anastomose the stomach and jejunum without spur formation at the greater curvature end of the anastomosis. The Author recommends anastomosis made near to the point of origin of the jejunum; he believes that the long loop anastomosis with or without the Braun anastomosis adds a substantial danger of gastro-jejunal ulcer, and should be avoided.

In conclusion he states that spur formation at the lesser curvature border of the cut end of the stomach reinforced by the attachment of the jejunum, and the avoidance of spur formation at the greater curvature of the stomach, are necessary features in the technique.

Nine figures illustrate the technique described.

WHIPPLE, ALLEN O., M.D., F.A.C.S.,  
AND RAIFORD, THEODORE S., M.D.

"The Type and Grade of Gastric Carcinoma in Relation to Operability and Prognosis." *S. G. and O.*, Vol. 59, No. 3, pp. 397-410, Sept., 1934.

In this article, the Authors analyze the operability and prognosis of gastric carcinoma on a basis of the types and grades of malignancy involved. The

work is based on a series of ninety-five gastric resections for stomach malignancy operated at the Presbyterian Hospital during the past twenty-four years, and a follow-up study of sixty-three cases which survived operation.

Carcinomas of the stomach are divided into three main types:

1. The vegetative or fungating type which tends to grow into the lumen of the stomach and is found most frequently in the pars media.

2. The ulcerative type, growing both into the lumen and into the wall of the stomach, may be found in all parts of the stomach but usually in the antrum.

3. The infiltrating type, infiltrating the coat of the stomach and having very little tendency to ulcerate, is usually found in the antrum and pylorus.

Carcinoma of the stomach is graded into four groups based on the degree of malignancy. In determining the grade of malignancy, the following criteria of microscopic pathology were used.

1. The degree of cell differentiation, marked deviation in the normal glandular arrangement of the cells indicating a more malignant grade.

2. Cellular activity, indicated by the variation in shape and size of the cells and their nuclei and the variation in cell types in the same tumor.

3. The invasiveness of the tumor cells, whatever their arrangement or differentiation.

4. The lack of cohesiveness in the tumor cells, whatever their arrangement. This is considered indicative of extreme malignancy in gastric cancer.

5. Metastases in lymph nodes. Absence of lymph node involvement greatly enhances the prognosis.

The vegetating type most often shows the less malignant grades 1 and 2. The infiltrating type most frequently falls in grade 4. The ulcerating type may fall in either grade 2, 3 or 4.

The incidence of carcinoma found associated with true chronic ulcers in resected stomachs is low. They found in this series of 95 cases only six instances. The carcinomata thought to have developed on an ulcer basis, were invariably of grade 4 malignancy.

The pre-operative determination of the type of tumor and grade of malignancy is difficult. The duration of symptoms in grades 1 and 2 in their series was 7 and 8 months. The grade 3 group averaged 6 months duration and the grade 4 group 4 months duration. Those patients giving a history, suggestive of a gastric ulcer lasting over several months, and failing to abate after conservative treatment, likewise are apt to fall in the grade 3 and 4 groups.

Physical examination does not help greatly in differentiating these types of tumors. The large fungating tumors were more apt to be palpable and the large ulcerating carcinomata were more easily recognized by the radiologist than the others.

The percentage of achlorhydrias was inversely proportional to the ascending grade of malignancy. The percentage of achlorhydrias was greatest in the fundating type, least in the carcinoma-on-ulcer type, and greatest with tumors located in the pars media and least in the pylorus.

In considering the X-ray interpretation of these lesions, the Authors point out the difficulties frequently encountered in making accurate diagnosis of the pre-pyloric lesion without repeated examinations.

Regional lymph gland involvement does not necessarily contra-indicate resection, but it seriously enhances the probability of a cure. In their series, 53 per cent of the resected carcinomata had extended to the lymph glands. None of this group had lived more than 29 months after operation. On the other hand, in their patients who had lived five years or more after operation, none of them had had regional metastases.

A table is shown giving the end results in this group of cases. Twenty-six cases are alive at the present time. Seven of these have been followed ten years following operation, and two additional cases five years following operation. Thirty-five cases have died from recurrences of the tumors. Thirty-two cases died following operation before leaving the hospital. Tables are shown showing the influence of grades upon the results and also the influence of metastases upon the results.

In concluding this article, the Authors feel that the division of these cases into the degrees of malignancy and into the three gross types help materially in determining the operability and the operative procedure and in estimating the prognosis.

CONNELL, F. G.

*Partial Gastric Fundusctomy in Treatment of Peptic Ulcer.* *S. G. and O.*, Vol. LIX, No. 5, pp. 786-788, Nov., 1934.

The Author proposes the operation of partial fundusctomy (aiming at a diminution of the acid secreting surface rather than the removal of the alkaline secreting "ulcer bearing area") as a compromise between gastroenterostomy and subtotal gastrectomy. The indications for the operation are: peptic ulcer of the duodenum; peptic ulcer of the stomach (supplemented by local resection); peptic ulcer of the jejunum after gastroenterostomy.

A double wedge-shaped section of both the anterior and posterior fundal walls with a common base at the middle third of the greater curvature is removed.

The Author feels that the results of this operation suggest a definite field of usefulness for it in suitable cases.

A table presenting 7 cases, and one figure, accompany the article.

N. M. Percy, Chicago.

## SECTION XII—"The Clinic"

### Large Epiphrenic Diverticulum of the Esophagus

(Report of a Case)

By

B. D. ROSENAK, M.D.

INDIANAPOLIS, INDIANA

THERE is no call for an exhaustive article or a comprehensive review of the literature on the subject of diverticula of the thoracic portion of the esophagus as this material has been adequately presented in recent years in the papers of Vinson, Heacock, Barrett and others. The more restricted subject of diverticula of the lower third of the esophagus, so called "epiphrenic diverticula," has been studied and reported by Granet. He found 49 cases reported in the available literature to the year 1933. Of these, only 31 were authentic cases proved by post-mortem or by roentgen examinations. Of the 31 proved cases only 17 had direct esophageal symptoms and only 3 diverticula were situated on the left side of the esophagus.

The present case is of interest because of the size and location of the diverticulum and because of the manner in which the esophageal symptoms became manifest.

#### CASE REPORT

The patient, a white man, aged 71, was first seen in February, 1935, during an attack of choking, dyspnea and vomiting which suggested an esophageal obstruction. He was treated by elevating the foot of the bed and by the administration of opium and belladonna in a suppository. He soon became quiet and rested throughout the night. On the following day he was able to visit the office where a stomach tube was inserted into the esophagus with great care until fluid began to pour out. Thereafter his symptoms were greatly relieved. Examination of the aspirated fluid showed much undigested food-residue, pus, desquamated epithelial cells and streaks of old blood.

The patient gave the following history: Seven years ago he had frequent

attacks of dizziness and weakness which were ascribed to a possible cerebral arteriosclerosis. These symptoms were entirely relieved by a period of bed rest. Six years ago, the patient suffered the loss of his wife and was very much disturbed emotionally. During the period of mourning this man began to experience a sense of pressure in the epigastrium, associated with difficulty in swallowing and with dyspnea. Thereafter he had frequent attacks of dysphagia and choking with profuse perspiration and pallor. A few months later he began to vomit shortly after his meals. He soon learned that his epigastric discomfort as well as most of his other symptoms could be relieved by self-induced vomiting, which practice he has carried out for about four years. About six months before he was first seen he began to vomit particles of blood. He also began to lose weight at that time and has lost about 25 pounds. His appetite remained good, his bowels were always regular and there were no other significant symptoms except a constant coldness and blueness of the fingers.

On physical examination the patient was found to be in fair general condition with the exception of his obvious loss of weight, some evidence of dehydration and the disturbance of the peripheral circulation as evidenced by his cold cyanotic fingers.

On roentgenoscopy (Fig. 1) the barium was seen to enter a smooth sac as large as an orange, situated to the left of the distal portion of the esophagus and apparently resting on the left leaf of the diaphragm. Its orifice was about 3 cm. in diameter and was about 4 cm. above the cardiac opening. There was only a moderate degree of dilatation of the esophagus and no evidence of delay at the cardia. These features were demonstrated on the films. It was learned that X-rays of the esophagus had been made one year after the onset of the esophageal symptoms. These older films were obtained through the

courtesy of his physician in another city and an identical picture was seen, there being very little evidence of increase in size of the diverticulum. In addition there were two small diverticula of the second portion of the duodenum and multiple diverticula of the colon.

The mechanical factors which may explain the symptoms of esophageal obstruction in this case apparently do not include cardiospasm as the principle one, although this phenomenon occurred in 6 of the cases reported by Granet. The obstruction would seem, from the X-ray study, to be due to the direct pressure of the filled diverticulum upon the short terminal portion of the esophagus which is directed to the left and downward as it enters the stomach. A moderate degree of cardiospasm may also exist, but was not seen roentgenographically.

The symptoms of these diverticula are usually less abrupt in their onset and vary according to the size and situation of the diverticulum and the presence of such complications as cardiospasm or carcinoma. A large proportion of the cases found in the literature were asymptomatic and were discovered either at post-mortem or in the course of routine roentgen examination. The onset of the symptoms in the case herein reported was sudden and bore a definite relationship to emotional and nervous shock. This strange and perplexing circumstance often is seen and, though lacking a suitable explanation, there is an undoubtable association between psychic trauma and the reaction of an individual to visceral pain sensations. This fact recently was demonstrated in two cases of large, obviously old, pene-

# A Quarter Century of Research Relating to A Light Smoke

Since 1911, the Research Department of The American Tobacco Company has been engaged in the solution of an extraordinarily complex problem.

The objective may be stated as: *the perfection of a cigarette with a minimum of respiratory and systemic irritants, and with a fully preserved character, i.e., a perfected acid-alkaline balance—a cigarette in which rich, full-bodied tobaccos have been successfully utilized to produce "A Light Smoke."*

A glance at the chart below—representing the excess acidity of the smoke of other leading brands of cigarettes as compared with Lucky Strike Cigarettes—demonstrates graphically how successfully this balance between acidity and basicity has been worked out in Lucky Strike Cigarettes. It shows the results of current tests, and indicates that the other popular brands have an excess of acidity over Lucky Strike Cigarettes of from 53% to 100%.

*a light smoke*

OF RICH, FULL-BODIED TOBACCO

trating ulcers of the lesser curvature of the stomach which were entirely without symptoms until each of the patients was subjected to a severe emotional disturbance. Something happens in these circumstances which seems to lower the individual's threshold to pain sensitivity. The situation in our patient with the diverticulum is even more astounding in that this doubtless long-standing lesion, not only began to produce pain and other subjective symptoms following a profound emotional up-

heaval, but actually began to manifest mechanical obstruction. The most apparent explanation in this case is that the psychic disturbance superimposed the element of cardiospasm upon a moderate but asymptomatic obstruction due to the presence of the diverticulum. It is not tenable to dismiss the possibility that the sudden onset of symptoms might have been due to a coincidental esophagitis.

Diverticula in this situation probably are congenital in the vast ma-

jority of cases. The present case, in which there is an associated diverticulosis of both the duodenum and the colon is an example of multiple congenital diverticulosis. Carman states that the majority of such cases are examples of congenital diverticula. Certain mechanical factors, namely, the negative intrathoracic pressure and the increased intra-esophageal pressure during deglutition and vomiting, are adequate to explain the gradual increase in size of these lesions. Desseker has emphasized a theory which has been advanced in explanation of the etiology of pharyngo-esophageal diverticula, in a form modified to apply to the lower end of the esophagus. He points out that, in reaching the stomach, the esophagus turns to the left in its terminal portion and is oblique rather than vertical in direction. This angulation causes food to impinge on the right wall of the esophagus in this region. This view is supported by the fact that, of the 31 cases collected by Granet, 28 were on the right side. However, were this factor of definite etiologic significance the incidence of diverticula in this situation certainly would be higher. The preponderance of evidence indicates that the congenital occurrence of these diverticula is the important etiologic factor.

*Treatment* of the patient herein described, has consisted of periodic lavage of the diverticulum. The patient has gone from 10 to 14 days without recurrence of symptoms following a lavage. The obvious danger of this type of treatment must be borne in mind. No attempt is made to enter the diverticulum by use of hard, curved sounds. A very soft stomach tube is used and is passed until its eye is at the level of the orifice of the diverticulum, then water is allowed to flow in under low pressure. The end of the tube is then lowered and the fluid is allowed to return by syphonage. This procedure is repeated until the flow is clear. This mode of treatment probably is the safest that could be devised.

The great danger of this condition, in which a large area of the esophageal wall is markedly thinned and weakened, is rupture of the esophagus. The usual causes of rupture of the esophagus are instrumentation and vomiting. It has been doubted, since the time of Zenker, that a normal esophagus could be ruptured spontaneously, but there are numer-

## FRANK ANSWERS TO QUESTIONS ON BRAN

MILLIONS OF PEOPLE know of Kellogg's ALL-BRAN, so it is natural that questions are raised from time to time. To discover the scientific facts about bran, the Kellogg Company has sponsored years of research in leading nutritional laboratories. Here are some of the results of these studies, in question and answer form:

### 1. Is the "bulk" in bran irritating to the intestines?

**ANSWER:** No, not for the normal person. There are some individuals with highly sensitive intestines who should not eat "bulk" in any form—either in fruits, vegetables or in bran.

### 2. Is bran effective in relieving constipation due to insufficient "bulk"?

**ANSWER:** Laboratory tests in universities with adult people substantiate the effectiveness of Kellogg's ALL-BRAN.

### 3. Does bran continue to be effective over a period of months?

**ANSWER:** Yes. Moreover, dosage does not have to be increased, as with cathartics. In four laboratory studies on a group of healthy women, in which four tablespoonfuls of bran per person were eaten daily, the laxative effect was as satisfactory in the second month as in the first.

### 4. Is the "bulk" in bran more effective than that found in fruits and vegetables?

**ANSWER:** Yes, with many individuals. Laboratory tests indicate that, with certain people, the "bulk" in fruits and vegetables breaks down in the intestinal system. So bran is often more effective.

### 5. Is all bran more effective than part-bran products?

**ANSWER:** Yes. It's the actual amount of bran in the cereal that provides the "bulk" to promote regular habits. The greater amount of "bulk" in Kellogg's ALL-BRAN makes it more effective.

### 6. Does the medical profession approve the use of bran?

**ANSWER:** Kellogg's ALL-BRAN is accepted by the American Medical Association Committee on Foods.

Kellogg's ALL-BRAN provides gentle "bulk" to correct common constipation. Also vitamin B and iron. Sold by all grocers. Made by Kellogg in Battle Creek.

ous reports of cases in which a diseased or otherwise weakened esophagus has been ruptured. Most of the cases of rupture are ascribed to vomiting.

The passage of a soft rubber stomach tube and gentle lavage, in the absence of cardiospasm or other obstruction below the level of the diverticulum, certainly is attended by less increase in intra-esophageal pressure than occurs during the act of vomiting; hence there is less danger of rupture of the esophagus when this treatment is carried out properly.

Two cases are reported in the literature who were treated surgically by trans-thoracic excision of the sac. Both of these patients died. The risk of this operation seems too great to warrant its execution on individuals who can be relieved by the simple procedure described above.

## ABSTRACTS

LADD, WILLIAM E., M.D., AND GROSS, ROBERT E., M.D.

*Intussusception in Infancy and Childhood. Arch. Surg., Vol. 29, No. 3, pp. 365-385, Sept., 1934.*

This article is a report of 372 cases of intussusception, treated at the Children's Hospital of Boston between 1908 and 1932.

Eighty-seven per cent of these cases were under two years of age and seventy per cent were between the ages of four and eleven months. Sixty-one per cent were boys, and thirty-nine per cent were girls.

In only five per cent was there a demonstrable etiological factor, Meckel's diverticulum being the most common. Benign tumors of various kinds caused most of the others. Seventy-five per cent of the cases were invaginations of the ileum into the colon.

The important and most frequent symptoms were attacks of abdominal pain, pallor, sweating, vomiting and

bloody stools occurring in a previously healthy child. The prominent physical findings were shock, dehydration, a palpable abdominal mass (84 per cent), blood from the rectum (50 per cent). X-ray studies were characteristic when made, but the Authors do not feel that this is necessary in the average case of acute intussusception.

The treatment was by operative reduction and resection when reduction failed. In thirty resections done, only two were successful. However, the Authors point out that in the last five years, in 90 patients only two resections have been necessary. The mortal-

ity in this group has steadily dropped through the years, being 59 per cent in the 1908-1912 group, and 14 per cent in the 1928-1932 group. In the last five years, 60 cases which were operated upon during the initial thirty-six hours of the disease recovered without any mortality.

The removal of a Meckel's diverticulum or other cause of intussusception should be deferred, if possible, for a second operation. Reducing the time between the onset of symptoms and the operation was the most important single factor in reducing the mortality in this group of cases.

### *The World's Most Famous Natural Alkaline Water*

## PRESCRIBED BY PHYSICIANS THE WORLD OVER

VICHY CÉLESTINS, the most famous of natural alkaline mineral waters, is indicated in stomach and liver affections and digestive disorders in general; in gout, arthritis associated with uric acidemia, uricemia, and nephrolithiasis of uric acid origin. During convalescence, it eases and expedites the journey back to health. Vichy Célestins is obtainable everywhere.

AMERICAN AGENCY OF FRENCH VICHY, INC., 198 Kent Ave., Brooklyn, N. Y.

Pre and postoperative care of this group of patients is discussed.

The incidence of recurrent intussusception in this group of patients was 1.8 per cent. Because of this fact, the Authors do not feel that time should be wasted at the primary operation in attempting procedures designed to prevent recurrence.

N. W. Swinton, Boston.

GAITHER, ERNEST H.

"Gastric Carcinoma: A Clinical Research. Preoperative Course and Post-Operative Results." *South. Med. Journ.*, 28:107-114, Feb., 1935.

In an analysis of 245 cases of operatively demonstrated gastric carcinomas some depressing findings are recorded but there is offered the following revision of symptomatology which may

aid in earlier diagnosis. The onset of symptoms was usually not gradual but the subsequent course may be abrupt or gradual. There was no characteristic cancer pain. The presence of pain rather than simple discomfort is suggestive enough. It may resemble ulcer pain, be constant or intermittent and while usually in the epigastrium may be any place in the abdomen. Anorexia was frequently an outstanding symptom but many will not complain of loss of appetite. *Hamatemesia* was rare but of coffee-ground type when it occurred. Nausea and vomiting were found more marked and prevalent than expected. 70 per cent of the patients were constipated. Tarry stools were reported in but few cases probably because of the patient's faulty judgment but the presence of occult blood was generally constantly present and of considerable diagnostic importance. Practically every patient shown an appreciable loss in weight and in the majority of cases it was enormous.

There was an almost total absence of complaints of soreness while localized tenderness was frequently found. Anemia was present in the majority of cases and often quite marked with no evident ill-effects. Family history for carcinoma was practically nil. Positive Wassermann reactions were present in 8 per cent of the cases but apparently unrelated to the carcinoma. Achylia or hypochlorhydria were usual but even hyperchlorhydria was demonstrated in some cases. Cachexia was detectable in very few cases. Even large masses were frequently not palpable. The average age was 55 and 83 per cent were male.

Only 25 post-operative patients could be gathered for study. Even those who had only a palliative operation were greatly relieved symptomatically. Unless absolutely contraindicated operation should always be undertaken. Periodic health examinations and a revaluation of symptoms should make possible earlier diagnosis which is the great need now.

J. Duffy Hancock, Louisville.

H. E. S. STEVEN.

*Diverticula of the Jejunioileum. Lancet*, 227, pp. 704-705, Sept. 29, 1934.

Diverticula of the jejunioileum are extremely rare only 60-70 cases being reported in the literature.

A farm worker, aged 40, was sent into the Cairo hospital with a diagnosis of appendicitis. The history was suggestive of chronic incomplete intestinal obstruction and it was considered advisable to investigate the case before operation. A bismuth meal was given. This precipitated a crisis and laparotomy was performed.

Volvulus of the upper part of the jejunum was found and multiple diverticula were observed extending down the jejunum and ileum. They varied in

WHIPPLE, ALLEN O., AND RAIFORD, THEODORE, S.

*The Type and Grade of Gastric Carcinoma in Relation to Operability and Prognosis. S. G. and O., Vol. LIX, No. 3, pp. 397-409, Sept., 1934.*

In attempting to explain the great variation in mortality rate and interval results in the surgical treatment of carcinoma of the stomach, the Authors mention the importance of limiting gastric resections to individual surgeons of mature experience with permanent assistants, pre-operative care and post-operative care. They believe that the interval results depend on those factors, and on the type and grade of the carcinoma. Three types of carcinoma of the stomach are recognized:

1. The vegetative or fungating type which shows a tendency to grow into the lumen of the stomach more than to infiltrate the walls.

2. Those that grow into the lumen, and into the walls showing a tendency to ulcerate.

3. Those that grow into and infiltrate the coats of the stomach with less tendency to ulcerate.

The vegetative type was found most frequently in the pars media; the ulcerating type most commonly in the antrum, while the infiltrating type was found most frequently in the antrum and pylorus.

Grading of the malignancy of tumors is at best only relative and involves a certain personal factor. The Authors recognize four grades of malignancy. The grade is determined according to the following criteria:

1. The degree of cell differentiation.  
2. Cellular activity-variations in the size and shape of the cells, and their nuclei.

3. The invasiveness of the tumor cells; this is noticed by the presence in adjacent tissues.

4. The lack of cohesiveness in the tumor cells.

5. The presence or absence of metastases in the lymph nodes.

There is a fairly definite relation between two of the types and grades; the vegetative type is most often less malignant, that is, in grades 1 and 2. The infiltrating type is usually in grade 4. The ulcerating type may be grade 2, 3, or 4.

The duration of symptoms before medical aid is sought bears an interesting relation to the grade of the tumor.

In grades 1 and 2 the average duration of symptoms was seven or eight months, while for grade 3 it was six months, and for grade 4 it was four months. A case showing a palpable tumor mass with a filling defect in the pars media without great loss of weight and strength, without a severe anaemia, and with achlorhydria would be considered as a probable fungating type of grade 1 or 2. A case showing rapid loss of weight and strength, an anaemia, free hydrochloric acid, and X-ray findings showing an infiltrated wall in the region of the pylorus would

be considered as an infiltrating type of grade 3 or 4. The Authors do not consider adherence of the tumor mass to adjacent organs as a contra-indication to resection because such adherence may be inflammatory; they cite two cases in which the colon was resected, and in which the results were excellent.

In the series of cases reviewed by the Authors the percentage of deaths from recurrence rose in direct proportion to the grade of malignancy of the tumor.

In conclusion the Authors suggest that these cases be studied clinically and pathologically by a combined group

of physician, surgeon, roentgenologist and pathologist. They suggest a modification of the plan first suggested by Scott. Their plan embodies a clinical classification in which the malignant cases are definitely segregated from the benign. Such a classification contains four groups as follows:

1. Ulcer suspect.
2. Ulcer verified.
3. Ulcer verified, carcinoma suspect.
4. Ulcer verified, carcinoma verified.

Group 1 includes a large number of cases whose histories suggest an ulcer, but in which there is no confirmatory evidence. Treatment in this group is palliative.

Group 2 contains those cases in which the clinical impression of ulcer has been confirmed by roentgenological studies. Conservative treatment is advised in these cases. Each case should be carefully followed for recurrence. It is important to follow these cases carefully for it is not uncommon for an ulcerating carcinoma to apparently improve temporarily on such treatment. If symptoms are not markedly abated, or if they become worse, the patient must pass on to group 3.

Group 3 contains the group in which ulcer is verified, carcinoma suspected. Treatment of this group varies with the individual physician or surgeon. It

is in this group that exploration should be done. When the presence of carcinoma is verified, the patient passes on into group 4.

The Authors quote the criteria of Lahey and Jordan for the limits of conservative treatment in group 3. They require that, within a period of three weeks, symptoms be completely relieved; that the lesion, by repeated X-ray studies, must show a definite decrease in size; and that blood disappear from the faeces and gastric content.

Nine figures and nine tables accompany the article.

JUDD, E. STARR, AND WALDRON, GEORGE W.

*The Present Status of the Surgical Treatment of Peptic Ulcer.* S. G. and O., Vol. LIX, No. 3, pp. 350-353, Sept., 1934.

The Authors state that the surgical treatment of peptic ulcer is not entirely satisfactory in certain nervous, high-strung individuals in whom the symptoms seem to parallel the degree of nervous strain, and in young persons. The best that one can accomplish for such patients is to keep the symptoms under control a part of the time. In another group of patients in whom the symptoms are atypical, and in whom the laboratory tests fail to show the presence of an ulcer, surgical treatment is unsatisfactory. Surgical treatment in such cases should be confined to a local operation, that is, the removal of the cap of the duodenum with the ulcer and the anterior two-thirds of the pyloric sphincter, making closure by a gastro-duodenostomy. This re-establishes the continuity of the gastro-intestinal tract, and eliminates all possibility of spasm due to sphincter action.

In cases in which the duodenum cannot be mobilized without undue risk, and in which a gastro-jejunostomy is not a feasible procedure, it has been found satisfactory to make a lateral anastomosis between the pyloric end of the stomach and the first portion of the duodenum, leaving the pyloric sphincter undisturbed. This operation is of greatest use in cases in which it is necessary to take down an old gastro-jejunostomy because of the development of a jejunal ulcer, and in which the lumen of the duodenum is inadequate because of scar tissue contraction.

In elderly patients with marked obstruction, and low gastric acidity, gastro-jejunostomy is still the most satisfactory procedure. Gastric resection is necessary in less than five per cent of the cases.

The Authors contend that without microscopic study it is impossible to determine whether a gastric ulcer is benign or malignant, and for that reason it should be treated surgically. V-excision of the lesion with gastro-jejunostomy was given the most satisfactory results in many cases. In some

## DR. TWISS' DUODENAL TUBE

Designed by Dr. John Russell Twiss, New York City

**A** RADICALLY new tube with bucket and terminal swivel weight that guides tube and bucket easily through pylorus into duodenum without kinking or curling.

The use of slightly larger and more resilient tubing tends to prevent looping in stomach.

The small diameter of solid terminal tip makes engagement in pylorus easier and the smaller size tubing attached is drawn after it by peristaltic action on the terminal ball. Thus the small size bucket which is attached by the means of swivel connection between terminal ball and bucket permits torsion of terminal ball without affecting duodenal tube and bucket or causing it to loop in the stomach.

Construction of slots in bucket allow free flow of fluid. Concavity prevents adherence to visceral walls. Terminal

ball and bucket by silk thread, but without use of knots.

The rubber tube has the standard one, two and three ring marking, but in addition the tube is calibrated in inches from the two-ring marking to a point four inches beyond the three-ring mark. This calibration is advantageous where drainage is to be repeated, because the three-ring mark represents only the distance where bile may be obtained in the average patient. Since there is a variation of length required, the correct length may be recorded for reference.

For descriptive folder giving full technical details, usages and advantages, address:

I. SKLAR MANUFACTURING CO.,

BROOKLYN, N. Y.

instances the technical procedure is simplified by taking out the pyloric part of the stomach with the ulcer.

The Authors believe that two procedures tend to correct the etiological forces more than any others; they are: (1) lateral gastro-duodenostomy, and (2) excision of the ulcer along with the cap of the duodenum and the anterior two-thirds of the pyloric sphincter, closing by gastro-duodenostomy. Those operations they believe should be employed more often.

BALFOUR, DONALD C.

*Indications for the Surgical Treatment of Carcinoma of the Stomach. S. G. and O., Vol. LIX, No. 3, pp. 543-560, Sept., 1934.*

The Author states that when the diagnosis of carcinoma of the stomach has been made, or when a lesion which may be malignant has been demonstrated roentgenologically, the basic indication for treatment is that unless definite metastasis can be demonstrated, surgical exploration of the growth is warranted. The conscientious surgeon should view the situation from the standpoint that cure may sometimes be brought about in cases which, preopera-

tively, appear to be too far advanced for cure.

Fortunately early distant metastases occur in the supra clavicular lymph nodes and in the peritoneum of the rectal shelf. Nodules in either site denote incurability but not always the undesirability of exploration. In rare instances biopsy will show that the supra clavicular glands are inflammatory rather than malignant. If they are malignant operation is precluded even though marked obstruction may be present. The patient who is in good general condition, but who has an antral lesion which is producing obstruction, may be greatly benefited by operation. Metastases to the liver, or to the region of the umbilicus, are contra indications to operation regardless of other circumstances. The presence of fluid in the abdomen, or of extra-gastric masses, definitely contra-indicate operation. (Smithies' "signs of inoperability"). Other things being equal, the younger the patient the more clear the indication for operation, and it is on relatively younger patients that the most extensive operations are justified. Fluoroscopic and roentgenographic examination by a competent roentgenologist will give more definite char-

acteristics of the growth than all other methods combined.

Exploration of the abdomen is carried out under local anaesthesia alone, or combined with a general anaesthetic. If peritoneal implants are found, the surgical treatment cannot be considered as curative. Occasionally the primary growth may be so situated that it is advisable to perform a resection to protect the patient from the early onset of obstruction. An apparently isolated, small metastatic nodule in the liver may not be a contra indication to resection. Widespread involvement of the regional lymph nodes is a very unfavorable prognostic sign. Involvement of the supra, and infra, pyloric nodes is of more serious prognostic value than involvement of the nodes along the greater and lesser curvatures. If the growth is found to be adherent to the pancreas, or the liver, but free from other structures, resection should be carried out as the adherence may be entirely inflammatory. Definite involvement of practically the entire lesser curvature is usually a contra indication to radical operation. The exception, however, is in those rare cases in which the entire stomach is involved; in this type of case total gastrectomy is most likely to be

## EVERYTHING FLORIDA OFFERS

At Exceptionally Attractive Rates

**H**OTEL Charlotte Harbor is one of Florida's finest and loveliest resort hotels. In a beautiful setting, directly on the water at Punta Gorda on the West Coast. Own facilities for bathing, golf, tennis and trap shooting—wonderful quail shooting and fishing. Unique swimming pool of mineral water for warm, healthful bathing. All Florida offers—yet rates are only

Weekly \$42 to \$56 Single and \$84 to \$112 Double Including Meals and Private Bath.

All rooms face the water and front grounds, all with private bath. Suites may be arranged. Special attention is given to the table and service for which the hotel has long been noted. On Tamiami Trail, 100 miles south of Tampa, or by railroad to Punta Gorda. Select Christian clientele.

Now open, special rate concessions up to January 1st. Wire reservations collect or send for booklet to the manager, Mr. Floyd Alford, Jr.

feasible. Accurate determination of the extent of the infiltrating type of growth is difficult, while determination of the extent of the ulcerative and colloid types of growth is usually accurate by palpation. The largest tumors which may still be operable are of the colloid type.

If resection seems to be justifiable, there are many variations in the methods by which it may be accomplished. No attention need be paid to a consideration of gastric acidity. The stomach should be anastomosed to the jejunum by a suitable method. The Billroth I method of resection is inadvisable, in that recurrence of the growth will be so situated as to produce obstruction early.

So far as palliation by resection is concerned with the exception of resection, the Author believes that exclusion of the growth is the most satisfactory procedure. Gastro-enterostomy too frequently fails to accomplish what it is hoped to do as a palliative procedure.

*The Symptom Complex of Complete External Pancreatic Fistula. S. G. and O., Vol. 59, No. 4, pp. 590-598, Oct., 1934.*

This article discusses the symptom complex of complete external pancreatic fistula, its diagnosis and treatment, and reports a typical case.

## SYMPATHETIC RELATIONS

of the gastrointestinal tract are effectively allayed while the fundamental organic trouble is properly treated, in the adjunct use of

## TAUROCOL Bile Salts Tablets

A combination of bile salts, extracts of cascara sagrada, phenolphthalein and aromatics. TAUROCOL is a cholagogue widely prescribed by physicians for more than a quarter of a century. Clinical Record Forms for the asking. Samples and information on request.

The Paul Plessner Co.

Detroit - - - Michigan  
J. D. 12-35

Various experimental and clinical studies are reviewed and it is shown that complete exclusion of pancreatic juice from the intestines is lost by external fistula, produces a highly characteristic clinical syndrome consisting of striking anorexia, nausea, intermittent vomiting, steatorrhea, extreme exhaustion, anhydremia and emaciation, with a rapid lethal determination.

A typical case is presented. A woman aged 61 developed this typical syndrome following a cholecystectomy and died five weeks post-operatively. At autopsy a pea size adeno-carcinoma of the ampule of Vater, causing complete ob-

struction of the common and pancreatic ducts, was found.

In treating this condition a low carbohydrate, high-alkalin diet should be given. Ereptone by mouth or by enema has been used advantageously. Sheep's pancreas in amounts of over one-quarter pound daily are beneficial. The feedings of fistula bile and intestinal juice by stomach tubes improve these patients. Operative procedures are either designed to extirpate the fistulous tract, if the fistula is incomplete, or to anastomose the pancreas to the stomach or duodenum.

N. W. Swinton, Boston.

## Viable Bacteria Reduced To Zero (Or Near Zero)

In 15 series of samples of the defecate from a number of human subjects. The subjects were not injured by the medication, as determined by thorough clinical and laboratory examinations immediately after cessation of medication and for a number of months subsequent thereto.

The medications employed were two saponaceous glycerites of Alpha Naphthol designated:

## ALPHA NAPH CO AND JELLY OF ALPHA NAPH CO

The Alpha Naph Co was taken in water and orange juice. The "Jelly" was administered in enteric coated capsules opening in the intestinal tract.

A resume of the reports, and adequate supplies for clinical test, will be gladly sent to any physician interested, with our compliments.

## SECTION I—*Clinical Medicine: Diseases of Digestion*

### Psychogenic Factors in Ulcerative Colitis\*

By

ALBERT J. SULLIVAN, M.D.†

NEW HAVEN, CONNECTICUT

A CONVINCING method of demonstrating the importance of psychogenic factors in the symptomatology and therapy of chronic ulcerative colitis would be to relate the detailed histories of each of our cases. Unfortunately, the space at our disposal makes this impossible. In first calling attention to this relationship in 1930, Murray (1, 2) presented impressive case studies. In 1932 we (3) reported in detail the first six of this series of fifteen cases which have been seen at the New Haven Hospital during the past five years.

The purpose of this report is to emphasize the frequency with which psychogenic factors are etiologically associated with this disease, the surprising number of personality traits that these patients have in common which seem to be of significance and the excellent and often dramatic results obtained from psychotherapy.

In Table I are arranged the data pertaining to the colitis at the time the patients presented themselves at the hospital. These are offered as evidence to indicate that we are dealing with real organic disease and not merely functional diarrhea. No attempt will be made to give the average duration or the average febrile reaction, for averages mean little in a disease as varied in its manifestations as is ulcerative colitis. Our cases range from the acute fulminating type of one month's duration to the more usual one of six or seven years' duration with numerous remissions and recurrences. Most of the patients had been hospitalized elsewhere and therapy in each case had usually included diet, irrigations, anti-amebic therapy, blood transfusions and vaccines.

One of the most interesting facts revealed by Table I is that with the exception of three cases, the disease began between the 20th and 30th years of life. This is considered of significance by psychiatrists because it is in this decade that most individuals are called upon to assume adult responsibilities. The average individual establishes himself both financially and sexually during this decade.

Many commentators have called attention to the frequency with which vegetative nervous system imbalance is found in patients with ulcerative colitis. Unfortunately, in our cases, most of the signs and

symptoms of *autonomic imbalance* were not recorded. In Table II are given the data which were most frequently recorded. Most striking is the frequency of dilated pupils and an elevated pulse rate. In only two cases did the accelerated pulse seem to be associated with an elevated basal metabolic rate.

*Bowel habit* previous to the onset of colitis is included in Table II because of its obvious relation to the vegetative nervous system and because it may give an inkling of the mechanism responsible for this type of ulcerative colitis. In five cases there was a story of previous constipation, apparently of the spastic variety. Three gave a history of always having had a tendency to pass two or three soft or loose stools a day. Three patients told of loose or diarrheal stools whenever they were excited or emotionally upset. Case 14, for example, would have two or three diarrheal stools while waiting to go to a dance or to the theatre.

In Table III are given factors concerning the *personality* of the patient and the patient's social relations which seem to us to be of significance.

*Occupational and Intellectual Endowment.* It seems to be of no little significance that only two of the fifteen patients were of low intelligence, three of average intelligence and that ten were of high intellectual capacity. This is especially striking when it is emphasized that thirteen of the fifteen were ward or dispensary patients.

*Sense of Neatness.* It is interesting to note that so many of these patients were inclined towards introjection. Most of the housewives in the series were of the "neat and fussy" variety. The males were prone to express themselves by their care in personal appearance and dress. One of the patients became highly disturbed if anyone disarranged her toilet articles. One can only speculate as to whether the diarrhea is a subconscious symbolic method of expressing one's resentment at a neat and clean world which has betrayed one.

*Emotional Tension.* By this we refer to an inability to throw off the effects of an emotional episode. This mental characteristic is best expressed by one patient who said, "I wish I could get over my troubles and forget things as soon as they are over as most people can. When I get into a quarrel or some other unpleasant thing comes up, I stew it over for three or four days." Ten of our patients observed this type of

prolonged emotional reaction. Strangely enough they showed few outward signs of this bottled-up emotion. They seemed to suppress the usual methods of expressing anger, despair, triumph, and were often considered to be rather nonchalant by their friends.

**Financial Worries.** Eight of the group of 15 cases gave histories of financial troubles; in one case it took

the colon in a few hours. This fortunate circumstance allows one to concentrate on the emotional adjustments just prior to the attacks. Rarely, if ever, is the fundamental problem discussed by the patient at the first or second interview. Usually several weeks of daily talks with the patient are necessary before real progress can be expected. It has been an interesting

the form of embezzlement and in another of theft. In these two cases and in four others, money matters played a rather prominent role in the total problem presented.

**Marital or Sex Difficulties.** Marital incompatibility or maladjustments of sex life clearly were present in all but two cases. There were marked individual variations in the problems presented.

**Abnormal Attachments.** Five of the young men had what appeared to be abnormal emotional attachments to their mothers. In five other cases there appeared to be marked attachments to some close relative.

**Relation to Childbirth.** In two wives and one husband the onset of the diarrhea was related to pregnancy or child-birth. In two other patients there was a chronological relationship but no clear psychological connection could be made out.

All the above data usually are obtained readily from the patient and are of significance in showing us in what kind of people this disease develops. However, only rarely is the specific psychological problem which is of etiological importance obtained with ease. Usually weeks must be spent in getting the confidence of the patient, talking over his problems and investigating his emotional reactions to all the factors of his environment. This would lead one into the endless investigations of the psychoanalyst if it were not for one fact: *there is an amazingly close chronological association between emotional episodes and the onset of bloody diarrhea.* In eleven out of fifteen cases the bloody diarrhea began within 48 hours of the emotional upset. In the other four cases the coincidence was not quite so dramatic in the original attack because the emotional episode was a prolonged one. However, in following the latter group it was clearly shown that exacerbations of the diarrhea were as closely dependent on the emotional state as in the first group; in fact the emotional disturbance would be reflected in

observation that the patient may show an exacerbation of symptoms during the period of several days when the fundamental problem is finally discussed. The diarrhea increases, the temperature may rise several degrees and vomiting may enter the clinical picture.

As an illustration of the difficulty in obtaining a proper history of emotional conflicts let me cite Case 13 of this series. The patient was seen in the Dispensary during some of his earlier attacks in 1931, 1932, and 1933. No psychogenic factors were discovered. In the Fall of 1934 he was admitted on the wards. Questioning by the medical students, internes, residents and myself for three weeks revealed nothing ex-

cept that the patient considered himself a little nervous. During this period the colitis had not improved, but on the contrary was getting worse. A psychiatrist, Dr. W. T. Brown, was called in. At the end of a week

the patient had unfolded an amazing series of episodes including gun play, forgery, a frame-up for theft, and repeated marital infidelities. These various episodes were directly associated with attacks of his colitis. Psychotherapy consisted chiefly of this unburdening and confession. Within two weeks the patient was discharged, having two or three soft-formed stools a day. In the next six weeks he gained 35 pounds and he has remained well. This case is not unusual; in fact the unfolding of the emotional background was accomplished more easily than in many of our cases.

### INCIDENCE OF PSYCHOGENIC FACTORS

During the five year period in which these 15 cases were seen, there were 10 other cases of ulcerative colitis seen in the New Haven Hospital. This would give an incidence of 60 per cent of psychogenic ulcerative colitis. Amazing as this figure may seem, it is probably too low. Seven of these 10 cases were not investigated as to possible emotional factors, as most of these were on the surgical wards. One case had four carcinomata of the colon which had developed 14 years after the onset of his colitis. There were some suggestive emotional disturbances in the background but these were not exhaustively studied. One case was a child of seven, in which psychiatric studies were extremely difficult but which is now being investigated by a children's psychiatrist. The other was a grave case complicated by severe pellagra. The patient suffered constantly from delusions, hallucinations and paranoid ideas and was labelled a schizophrenic. Because of the lack of an adequate history and because of the fact that the psychosis might have been due to the pellagrinous deficiency we could not assume that the mental state was a causative factor in the colitis. It is our opinion that about 75 per cent of cases of chronic ulcerative colitis are of psychogenic origin.

### PSYCHOTHERAPY AND ITS RESULTS

Most of these people were hospitalized three or four weeks before psychotherapy was begun. Frequently that amount of time was necessary for the discussion of the patient's problems before the real emotional disturbances were revealed. During this period, the usual extensive laboratory procedures necessary to rule out other causes of colonic ulceration were carried out. All the patients received a low residue diet with additional vitamins. All received some symptomatic therapy such as bismuth, kaolin and belladonna. Occasionally opium was necessary. A few received irrigations or oxygen by rectum. None of these therapeutic procedures seemed to give more than slight symptomatic relief. The disease usually was unchanged or even aggravated until the patient decided to talk over the fundamental psychological maladjustment.

In Charts I and II the course of the disease in these fifteen patients is graphically shown. No attempt is made to chart the attacks previous to the one which brought the patient to us. Data on the duration of the disease and the number of attacks at the time the patient entered the hospital are given in Table I. The vertical arrows indicate the point at which psychiatric investigation was begun. In most cases this coincided with the institution of psychotherapy—for the two go hand in hand. In other cases, although the emotional factors were obvious to us, the patient refused to accept or discuss them and hence there was no psycho-

therapy. The solid black areas indicate severe symptoms; the alternate black and white areas indicate periods in which the patient was having slight to moderate symptoms and the clear areas indicate complete freedom from symptoms with not more than two or three stools without blood a day.

*Brief Case Histories and Follow-up. (See Footnote)\**

*Case VII.* This case we consider of great interest. The patient's first attack of bloody diarrhea occurred when she decided to be married, her second when she had been married, and her third when she began to reside with her in-laws. She was under our care for three weeks only, in December, 1931. During this short period she refused to admit other than a chronological relationship between these events and her diarrhea. The patient thus serves as a sort of control, a case of ulcerative colitis of psychogenic origin who received no psychotherapy. A few months ago we attempted to find out what had become of her. Her course has been typical of a patient with severe colitis. There have been at least six hospital admissions in three different Massachusetts hospitals. She has been almost hopelessly ill on several occasions. She has developed some unusual skin lesions which have been reported by Dr. Brooks of Worcester (4). Her problem has never been considered from the psychogenic standpoint and she has received no psychotherapy.

*Case VIII.* This was a rather mild form of colitis of four months' duration which did not require hospitalization. The diarrhea began on her honeymoon. There were no deep psychological maladjustments, merely a few surface difficulties of a 29 year old woman, who had previously earned her own living, in adjusting to the physical and social responsibilities of marriage. Improvement was rapid and the patient has lived a normal life and has had a child. There has been no recurrence.

*Case IX.* This patient was left an orphan at 2. Her foster-father died when the patient was 12, and her foster-mother committed suicide on his coffin. There is a long history of vague fears and "the fear of being afraid" and a history of nervous indigestion. Attacks of colitis were definitely linked up with a fear of pregnancy and worry over failure of contraception devices. No deep psychological study was made. Talking over her worries seemed to banish them. Response was rapid and there was no diarrhea for nearly a year. In February, 1935, there was a short bout of diarrhea which affected all the members of the family. The patient responded to treatment in two days, the family in ten days.

*Case X.* This was a school teacher with a psychopathic personality who was subject to terrifying dreams and who was greatly worried about salary cuts. Frank discussion resulted in prompt cure of the diarrhea. He writes, "If I am subjected to an unusual excitement I have a return of diarrhea that lasts for from 24 to 48 hours."

*Case XI.* This patient, a law student, was first seen at the beginning of his third attack. These attacks and two subsequent ones began in the week preceding examinations. It was first thought that frank discussion of the rôle played by his worry over examinations would be enough to clear up his difficulties. His examinations in May, 1934, brought on another acute attack, however. Psychiatric studies by Dr. Fry revealed that the reaction to examinations was merely the apex of a broad pyramid of emotional conflicts. The patient had been placed on a pedestal by his family and much was expected of him. His diarrhea may be a method of making restitution or it may be only an excuse to justify his inability to live up to his

\*Case 1 to 6 were reported in detail in the *Yale Journal of Biology and Medicine*, Vol. 4, No. 6, July, 1932. The later cases will be reported in more detail, particularly from the psychiatric standpoint at some future date. It is suggested that the interested reader consult the *Yale Journal of Biology and Medicine*, so that he may observe the complete stories of this type of patient. Results on cases 1 to 6 from 1932 to 1935 are indicated on Chart I.

family's expectations. Dr. Fry feels that the patient represented the emotional hold that his family had upon him and desired to break free. Good work in law school meant a good job, which in turn meant freedom. He does not believe that the diarrhea is a form of "restitution." Many of the psychological reactions in this case are suggestive of those discussed in the studies of Franz Alexander (5).

a transfusion. The failure of an expected visitor to arrive would greatly upset her for two days and her colitis would be aggravated. She fought attempts to get a complete psychiatric history. Questions on sex would result in cramps and a call for a bed-pan. It became evident that the psychiatric problem was going to be a very intricate one, probably with a homosexual component. It was de-

In January, 1935, several days before midyear examinations the diarrhea again returned. For two days he had as many as fifteen stools a day with considerable blood. Frequent interviews and much reassurance checked all the symptoms by the day of the first examination. A week after examination, while at home, he again became upset over the family situation and the diarrhea returned.

**Case XII.** A very severe colitis who was on our wards for nearly eleven weeks before the psychogenic factors could be elicited. After many of us had failed, Mr. Yochelson, a medical student, gained her confidence. To him she admitted a self-induced abortion which she previously had kept a secret even from her husband. She had the fixed idea that she had poked a catheter from the vagina into the rectum and would menstruate per rectum for the rest of her life. There were many disturbing factors in the marital situation but after four months of careful psychotherapy by her family physician, she became symptom-free in February, 1935.

**Case XIII.** This is the patient previously referred to who had been seen in the Dispensary in 1931, 1932, and 1933, and who, after weeks of careful questioning in the hospital in 1934, finally admitted attacks of diarrhea coinciding with episodes involving gun play, forgery, and theft. Within two weeks he was nearly cured. He has gained 35 pounds and has from one to three stools daily, except on one occasion when he had an argument with his brother-in-law. For two weeks thereafter he had five stools a day.

**Case XIV.** For seven weeks attempts were made to get to the bottom of this patient's mental disturbances. There were many convincing evidences of the effects of emotion on her colon. She would have three or four stools during

cided to transfer the patient to the psychiatric ward where she could be isolated and more carefully studied. The patient refused this and left the hospital against advice. Two weeks later she was subjected to an ileostomy at another hospital and died.

**Case XV.** This patient's chief difficulty is his strong attachment to his mother and the difficulties this brought into his marital life. The patient's father committed suicide a few days before the patient was to be married. His first attack of diarrhea came during his wife's first

Chart 1

pregnancy when tension first developed between wife and mother. The second attack came the day his wife returned from the maternity hospital. In October his mother left on what was to be an extended visit. The patient insisted that she return. On November 15 he received a letter that she would return and on that day his most severe attack began. Most of the history was obtained from the wife

Chart 2

and mother who both agreed with our interpretation. The patient resisted and for ten days his condition grew much worse. He then swung around and admitted that the mother-wife situation was directly the cause of his diarrhea and stated that he wished he were not married. Psychotherapy which is being carried out by Dr. Brown, will probably be a long and difficult job. The diarrhea persists and probably will until he accepts or dissolves his marital status.

### DISCUSSION

In the fifteen cases presented we believe that psychogenic factors are prominent in the etiology of the ulcerative colitis. It is our opinion that psychogenic disturbances are frequently the main causative factor in the disease. We believe as a result of the follow-up study of these cases over a period of one to four years that psychotherapy is of utmost importance in the treatment of chronic ulcerative colitis.

The mechanism by which emotional disturbances can produce ulcerative colitis and by which the ulcers can be made to disappear by psychotherapy is, in the light of present knowledge, a matter of speculation. Our own working hypothesis is that the disease is closely related to "neurogenic diarrhea," a syndrome frequently seen by the gastro-enterologist. Emotion, through the vegetative centers in the diencephalon, whips the liquid contents of the small intestine down into the colon. In these particular individuals the enzymes in this liquid intestinal content may be of a higher digestive power than the normal or the natural protective powers of the mucosa of the colon may be lowered. At any rate, surface digestion of the mucosa of the colon occurs, bacterial invasion is made easy, and acute ulceration results. Because the emotional difficulty remains a chronic one, either because the situation cannot be solved or the patient is unable to face his problem, the hypermotility of the intestinal content persists and the constant irritation results in a chronic colitis. The natural reparative processes of the colon at times get the upper hand but often fresh emotional disturbances arise and we have a series of

remissions and exacerbations in the organic disease. Psychotherapy attacks the disease at its source, the nervous diarrhea. When the emotional conflict is solved, the intestinal motility returns to normal, the chief irritative factor is removed from the colon which can now take care of its bacterial invaders and the disease may promptly disappear. We offer this only as a possible explanation of the mechanism of the dramatic results obtained by psychotherapy in a few of our cases.

### CONCLUSIONS

1. During the past five years the psychiatric background in eighteen out of twenty-five consecutive cases of ulcerative colitis has been investigated. Three of these cases had some psychological difficulties which were not completely studied. In fifteen cases the emotional disturbances appeared to be of definite etiological significance.

2. In many cases the specific psychological episodes were related by the patient only after long and persistent questioning.

3. Psychotherapy in most of these cases produced striking results when many other forms of therapy had failed.

4. Brief case histories and follow-up studies on these fifteen cases are given.

### DISCUSSION:

DR. GEORGE EATON DANIELS (New York, N. Y.): For the last five years I have been doing considerable clinical psychiatry on the wards of the Presbyterian Hospital in New York City. About the time I started this work, Dr. Murray published his work on ulcerative colitis, so that I became interested in the problem at that time. This interest became increased through seeing patients of this type on the ward. These cases I have followed for about the same length of time as Dr. Sullivan has followed his, so in a sense they make a parallel series.

I have twelve cases of ulcerative colitis that seem to be pretty definitely on a psychogenic basis, or in which psychogenic factors are extremely important.

Now, my series of cases, I discovered in reading Dr. Sullivan's paper, had a great many similarities. One very striking thing which Murray and Sullivan have emphasized is an abnormal attachment to a relative, usually the mother. In four cases of my series the death of this relative seemed to be of great importance in the onset of the disease. One of these patients saw her mother return to her frequently in her dreams. Another made the statement that all her luck left her when her mother died.

In another case an attack of colitis appeared with the serious illness of the patient's brother, who subsequently died, and during a later attack she had very severe exacerbations of symptoms when the anniversary of this death was approached.

Another girl had an attack of ulcerative colitis whenever she was about to make the step of leaving her older sister

and her sister's son, who had made very considerable demands on her financially and in other ways.

Engagement, marriage, and child-bearing were of significance. Sexual difficulties were found in practically all the cases which is what one would expect with the type of emotional immaturity which these patients show.

I should like to add one factor which I think is of considerable importance and that is that these patients, to a large extent, are of the rather egotistic or narcissistic type. For that reason they would withstand very poorly emotional deprivations, such as the loss of someone close to them, and have very little tolerance for giving of themselves as required by marriage or the rearing of children.

In several cases the frustration of personal, professional or social ambition seemed to be an important factor in bringing on the disease.

DR. CHESTER M. JONES (Boston, Mass.): Dr. Sullivan's paper seems a most timely one, and while I am not so sure as he that psychic trauma may be the direct etiologic agent in so large a percentage of cases of non-specific ulcerative colitis, I am absolutely sure that his point of view is a very fundamental one.

There is not the slightest doubt that not infrequently emotional disturbances act rapidly as an immediate cause of acute exacerbations of the disease. There is also not the slightest doubt in my mind that mental and physical rest alone is sufficient to quiet rapidly many cases of moderately severe ulcerative colitis. Hospitalization, confidence in a given physician with an enthusiastic personality, and the use of various new therapeutic procedures, frequently are considered only from the point of view of specific or nearly specific therapy, and little or no attention is paid to the fact that such measures are often effective largely because of their psychological effect on the patient.

In going over 100 cases that Dr. Urmey and I have been following for several years at the Massachusetts General, we have tried to evaluate the various factors that entered into the causation and continuance of the disease. In easily two-thirds of the cases psychogenic disturbances were obviously responsible for bringing on exacerbations, and in the whole group we felt that acute upper respiratory infections, emotional or nervous upheavals, and possibly pregnancy, were the most obvious elements entering into the onset of the disease. That there is infection of the colon is obvious, but that it represents a specific disease due to a single organism is still, I believe, far from obvious. At any rate, the conception that Dr. Sullivan has presented should be very seriously considered.

In our cases at the Massachusetts General Hospital particularly those on the private wards, psychotherapy of a

moderate or intensive type has helped exceedingly in individual instances.

DR. JOHN L. KANTOR (New York, N. Y.): Before going on to this topic proper, I should like to state that this disease is not the same as an "unstable colon," although, of course, people with unstable colons may develop chronic ulcerative colitis (idiopathic colitis, *colitis gravis*).

I think one ought to distinguish between what chronic disease does to people emotionally, and what one can claim for psychogenic factors as being the etiologic agents in a chronic disease.

As long as Dr. Sullivan and his associates are willing to emphasize the fact that *exacerbations* may be caused by emotional upsets, we are all willing to go along with them, as Dr. Chester Jones did, but if they step over the ground and say that the *initiation* of this obscure disease is of emotional origin, then I would differ.

Let me point out that any chronic recurrent, nagging, upsetting, and demoralizing disease will produce an individual with plenty of material to keep a psychoanalyst busy for days and even weeks. On the other hand, any of us, if sufficiently investigated might show psychic findings similar to those described in the ulcerative colitis cases.

Dr. Chace was good enough to tell me of a case of severe colitis in a woman who had great emotional upsets from marital difficulties and who was treated along psychic lines for months and months. Ultimately, she was found to have amebic dysentery.

As long as our friends, the psychoanalysts, will study what the disease does to people emotionally, they will probably give us information of value and may thus help us prevent recurrences, but I seriously doubt whether they are on the right track to find the original etiologic factor.

DR. ALBERT J. SULLIVAN (closing the discussion): Dr. Kantor has brought up the problem that has worried a good many of my friends when I have talked with them about this disease, and the effects of emotion on the disease. Some psychiatrist once said a psychopathic personality is any personality that has been thoroughly studied, and that may be true.

I didn't have time to bring out (I wish I could have gone over these cases individually) what I feel is the most striking thing, and that is that in twenty-four or forty-eight hours before the first attack of ulcerative colitis comes on, there is some very striking and emotional insult. That is just as true, and perhaps more true, of the first attack than of later attacks.

In these cases, if they are of psychogenic origin, there is a striking emotional problem coming just before the diarrhea begins.

## Gastroscopy with a Flexible Gastroscope\*

By

RUDOLF SCHINDLER, M.D.†  
CHICAGO, ILLINOIS

IT is well known that while gastroscopy has been carried out in an ever-increasing number of cases from 1922 on, the method has not been accepted as a routine procedure in hospitals and clinics or by the gastroenterologists themselves. This has been due,

primarily, to the difficulties and the dangers which attended the use of the rigid instrument. In 1932, however, the invention of the flexible gastroscope effected a sudden change whereby the method became at once safe and simple.

Many investigators have used it with success and have published reports. On March 29th, 1934, Benedict in this country reported a series of cases exam-

\*Presented at the 38th Annual Session of the American Gastroenterological Association, Atlantic City, N. J., June 10-11, 1933. Approved by the Publications Committee of the Association.  
†Visiting Professor of Medicine, University of Chicago.

ined with the flexible gastroscope. A few months later Chevalier Jackson, in a paper on gastroscopy, described his experience with this instrument.

Mikulicz first knew, in 1881, that diagnostic gastroscopy could not be made merely with open tubes, but that it had to follow the laws which govern the examination of large cavities in the interior of the body. He saw that gastroscopes would have to be built after the model of cystoscopes, and that the tip of the instrument would have to be equipped with an electric lamp which would radiate its light onto the mucous membrane of the stomach. The reflected rays could be collected by the objective of an optical system, turned by a prism to an angle of  $90^\circ$  and led to the ocular, through which the examiner was looking. Because of the length of the esophagus, the optical problems of such a system were much more difficult than in cystoscopy. A certain perfection of the optical system was reached by the instruments of Loening-Stieda and Elsner (1911). Chevalier Jackson (1907), however, tried to retain the principle of the open esophagoscopical tube. It was easy to show that this was the only possible way for the extraction of foreign bodies through the esophagus. This necessity arises, however, extremely rarely in the practice of the gastroenterologist. The greater need is that of a method which will enable him to diagnose even the smallest lesions of the mucous membrane of the stomach. The open tube is unsatisfactory for this purpose because it is too dangerous and because it does not permit adequate visualization of the interior of the stomach. The difficulties encountered were such that the development of the method was given up in 1911. When I began my work in 1921 there was no longer anyone in the world who used gastroscopy as a diagnostic method.

I used straight, rigid tubes at first. Fig. 1 shows the standard instrument which has been used since

Fig. 1. Rigid gastroscopes. Schindler of 1922. A—Outer tube with air channel and obturator. B—Outer tube with optical tube.

then by many workers. A, is the outer tube with the obturator bearing a rubber finger; B, shows the outer tube after the removal of the obturator and the introduction of the optical tube. With the air balloon, the stomach could be inflated with air. The drawing shows the small holes of the outer tube through which the air passes into the stomach, the mucous membrane of which had to be at least 1 cm. from the objective in order to be seen through the optical system. The astonishing results obtained with this instrument were published in 1923 in a text book and atlas of gastroscopy, based on 400 examinations.

It was nevertheless rather soon apparent that this instrument never could be routinely used. There were two decisive objections. First, the introduction of a rigid tube was never without danger. It was found, in fact, that the introduction of open tubes was even

more dangerous than that of closed tubes with rubber obturators. Rupture of the esophagus was possible. The second objection was that, in 10% of all cases, it was not possible to pass through the diaphragmatic portion of the esophagus. A further difficulty was the fact that, in 40% to 50% of all cases, it was not possible to introduce the instrument into the lower depths of the stomach, and hence three very important portions of the stomach, the "angle," antrum and pylorus could not be observed.

It was evident that in order to overcome these difficulties it was necessary to build an instrument, the lower part of which, from about 3 cm. above the cardia up to the distal end of the tube, remained flexible during the examination. This instrument had to be capable of being bent in several planes with an angle of at least  $30^\circ$ . This seemed to be impossible. Nevertheless, in cooperation with Wolf of Berlin, we succeeded finally in the construction of such a tube.

Fig. 2 shows this instrument. Its distal end can be bent. The picture seen through the objective is quite sharp and

Fig. 2. Flexible gastroscopes. Schindler-Wolf, 1932. A—Rubber Finger; B—Lamp; C—Objective; D—Flexible part; E—Rigid part; F—Ocular; G—Electric cable; H—Air balloon.

clear unless the tube is bent to an angle of  $34^\circ$  or more. The rubber finger (A) leads the instrument.\* The lamp (B) and the objective (C) are constructed in the usual manner. (D) is the flexible part, which is covered by two thin rubber tubes, between which air can be injected into the stomach. In the newest model the rigid part (E) has a diameter of only 8.5 mm. (F) is the ocular. The optical system (Fig. 3) contains twenty-six lenses and is naturally extremely complicated. For this reason the instrument must be handled very carefully. Danger in this method does not concern the patient, but only the instrument.

The experience of an extended private practice has shown me that gastroscopy can become without any difficulty a routine method of the gastroenterologist, that it can be carried out in the office, that it is without real discomfort to the patient when a good local anesthesia is given, and that the patient may go immediately after it to his work. It is, however, difficult and must be learned conscientiously.

The few *contraindications* must be considered carefully. The most important ones are: Aneurysm and obstruction of the esophagus, especially of the cardia, and varices of the esophagus. When an Ewald stomach

\*A rubber sponge as used by Henning is unnecessary and not safe.

tube can be passed without difficulty, then the gastroscope can also be introduced safely.

My own experience has been derived from something over two thousand gastroscopical examinations. Approximately seven hundred of these were performed with the flexible instrument, three hundred and fifty

*sphincter antri*" (Fig. 6). The waves of peristalsis begin in the antrum beyond this point. The *musculus sphincter antri* has nothing to do with this peristalsis.

Hemorrhages and pigment spots are often seen in an apparently normal mucous membrane, but I believe they should be considered as pathological. They are

Fig. 3. Scheme of the optical system of the flexible gastroscope. (In the newest model the angle of the visual field has 85° instead of 60°).

in Munich and as many in Chicago. In many instances there were several observations in the same patient. The greatest number of gastroscopies carried out in one patient in Munich was sixty-five, in Chicago, ten.

The fundament of all of our findings has been knowledge of the normal stomach, which was studied carefully and repeatedly in many healthy persons of various ages. We found that the normal gastric mucous membrane is always uniformly orange red in color, glistening and bright. The folds of the mucosa apparently do not correspond with the well known rugous folds of the X-ray relief technic, because they are generally not parallel, but crossing and net-like. In Fig. 4 there is shown a photograph of the folds made through the rigid gastroscope. The *incisura angularis* appears as a fold. Beyond it, in at least 80% of all cases, the pylorus is seen (Fig. 5). Its activity is interesting. In the Figure, made after a colored picture, it is open. Often a small piece of the antrum remains hidden from view. In the region of the angle

frequently seen together with an ulcer or before the beginning of an ulcer, after the healing of an ulcer, or together with small hemorrhagic erosions (Fig. 7). In chronic gastritis, on the other hand, the hemorrhages seem never to change into pigment spots. These smaller changes cannot be shown by photography because the most sensitive films do not render the differences between yellow, orange red and red. This fact shows the limits of photography in endoscopy. For several years I hoped that gastrophotography would prove to be a method of value. During that time, I made endless attempts both with the "gastrophotor" and with a photographic attachment for the objective of the gastroscope, as recommended by Henning, but all to no avail. At the present time, gastrophotography has, in my opinion, no diagnostic value at all.

Ulcer of the pyloric region or of the duodenum cannot be seen with the gastroscope. Here the X-ray examination is much superior. Gastric ulcer, however, is usually well seen (Figs. 8 and 9). We have

Fig. 4. Photograph through the rigid gastroscope, showing the anterior wall of a healthy adult.

a very characteristic formation is observed, a high fold which runs over the anterior wall, the greater curvature and the posterior wall. It is cord-like and separates the cavity of the antrum from the cavity of the body. I think it is the same fold which has been described by Cole, and we may call this the "*musculus*

Fig. 5. Normal pylorus. In the upper part of the picture the lesser curvature is seen; the sickle-shaped fold is the angle. Beneath it at the end of the antrum the pylorus appears.

observed penetrating ulcers in which the convergating folds were swollen and inflamed. Under treatment they quickly became shallower, smaller and the edge reddened (Fig. 10), a sign of healing, finally disappearing and leaving a very small gray scar.

Fig. 6. Musculus sphincter antri, separating the cavity of the antrum (above) from the cavity of the body (in the lower part of the picture). The cordlike aspect is typical.

At the present time the theory of the gastritic origin of ulcer is widely advocated, at least in Germany. We find gastroscopically that in many cases of ulcer the mucous membrane is identical with that seen in quite healthy persons. In many instances, the area surrounding the ulcer is distinctly swollen and reddened. In some cases, gastritic changes in the upper parts of the stomach are seen. The so-called "gastritis of the antrum" does not occur in cases of gastric ulcer. By this it becomes evident that our gastroscopical observations do not support the gastritic theory.

In Munich we found in 2% of the cases examined gastroscopically benign tumors which had not been found previously by X-ray relief technic. Fig. 11 shows the only case of *polyposus ventriculi* which I have ever observed.

*Carcinoma* of the stomach shows the greatest variety of forms. The submucosal infiltrative lesions are seen as grayish rigid areas; the adenomatous types appear as nodular elevated tumors of various colors. The ulcerated lesions are seen as ragged, irregular, dirty brown or violet areas surrounded by a thick red wall. (Fig. 12).

Fig. 7. Lesser curvature, showing numerous pigment spots and one small hemorrhage (paler, in the middle part). In this case, in the lower parts of the lesser curvature a chronic gastric ulcer was found.

Fig. 8. Large longitudinal benign chronic gastric ulcer of the lesser curvature. (In the upper left quadrant just the margin of a second ulcer is seen).

Gastroscopy is of great value for the *differentiation of benign and malignant lesions*. The latter do not have the sharp edge and the yellow floor of the benign ulcer. Microscopic examination of the resected specimen has proved the exactness of the gastroscopic diagnosis in every instance thus far.

Gastroscopy also allows a better judgment with regard to the *operability of a tumor* than does X-ray examination. It enables one to observe the location of the lesion and the type and extent of involvement of the gastric wall, and thus to decide if it is likely whether or not a radical operation may be performed.

The most important field for gastroscopy is that of *chronic gastritis*. For thirty years this disease had disappeared almost completely from our conceptions of gastric pathology, although chronic inflammation in all the other mucous membranes is their most frequent disease. Gastroscopy has settled this question. There is no doubt that we find very often in patients, suffering from abdominal pains, changes in the mucous membrane which correspond with the inflammatory

Fig. 9. Benign chronic gastric ulcer of the lesser curvature just above the angle. (At the right side the dark cavity of the antrum is seen, on the origin of the muscular sphincter antri a dark pigment spot. The ulcer occupies the middle of the picture. A part of its edge is undermined).

Fig. 10. Large benign chronic gastric ulcer, above the angle, healing. At the right side of the whitish ulcer is an edematous inflamed fold of the posterior wall. Under this the antrum with the dark hole of the pylorus appears.

processes of other mucous membranes. We should distinguish, in my opinion, three forms:

1. *Superficial gastritis*. Here red, apparently hyperemic spots of various sizes are seen, with layers of mucus and occasionally small erosions. Generally, this condition heals. It may develop, however, into the second form.

2. *Atrophic gastritis*. Here small gray-greenish spots are first observed. There are often hemorrhages, but erosions are rare. A complete atrophy may develop, as is indicated by the way in which the branching blood vessels of the submucosa may be seen through the mucosa. (Fig. 13). The relationship of atrophic gastritis to pernicious anemia and to the origin of tumors is an important consideration.

3. *Hypertrophic gastritis*. In this condition the mucous membrane is swollen, velvetlike, often verrucous, nodular, with creases and ulcerations. This hypertrophic ulcerative gastritis is a very severe condition and never heals completely. In one case, a fatal termination resulted from hemorrhages from very small ulcerations. The picture shown in Fig. 14 was found in a stomach with a gastric ulcer. A resection

Fig. 11. Polyposus ventriculi. In the middle of the picture the pylorus and antrum are seen. In the body there are three small, stalactite-like prominences, which are benign polyps.

Fig. 12. Ulcerative carcinoma with thick reddened wall.

was made, and so it became possible to control the observed area microscopically. The fixation was made immediately after resection. Fig. 15 shows the microphotography with an extended interstitial cellular infiltration of the mucosa.

It is very interesting to observe *post-operative stomachs*. In those cases in which the new opening develops a pylorus-like rhythmic action, the patient remains healthy. If such an adaptation is missing, the patient develops pains which are apparently caused by either jejunal ulcer, which is seen often, or by a severe gastritis with a bad prognosis, or by silk sutures which are found to have cut through the mucous membrane. In Fig. 16 the opening into both loops of the intestinal coil is seen.

In conclusion, may I express the hope that this brief report will suggest the great value of gastroscopy in the various types of gastric disease.

#### SUMMARY

1. The invention of the flexible gastroscope has made it possible to view the interior of the stomach with safety and with relatively little discomfort to the patient.

2. Gastrospectical observation shows that the anatomical conception of the necessity of subdividing the cavity of the stomach in two parts is correct. An almost unknown formation, a high fold, between the

Fig. 13. Complete atrophy of the mucous membrane; at the left in a case of combined cord degeneration; at the right, in a case with purely psychoneurotic symptoms. The mucous membrane is so thin that a net of thick, prominent blood vessels is seen.

Fig. 14. Severe hypertrophic gastritis (observed in a case of gastric ulcer). The mucous membrane is swollen and nodular. At the left side a hemorrhagic spot is seen.

two cavities, the body and the antrum, is regularly seen.

3. In persons who suffer or who have suffered from gastric ulcer, hemorrhages and pigment spots of the gastric mucous membrane are often seen; these are not found in healthy persons.

Fig. 15. Microphotography of a section through the mucous membrane shown in Fig. 14. Extended cellular infiltration of the interstitium of the mucosa.

Fig. 16. Large operative opening between stomach and intestine. Both loops of the intestinal coil are seen; in the right one a peristaltic contraction can be observed.

4. Gastroscolical observations contradict the theory of the gastritic origin of gastric ulcer.

5. Gastroscoly allows the differential diagnosis of benign and malignant ulcer better than any other method.

6. Gastroscoly furnishes direct evidence of the progress of benign lesions and of the degree of involvement in cases of neoplasm.

7. Gastroscoly has rediscovered the frequency of chronic gastritis, which has to be considered as the most frequent lesion of the stomach. On the basis of our gastroscolical observations, it is subdivided into three great groups: superficial gastritis, atrophic gastritis and hypertrophic gastritis, which differ in their course.

8. Gastroscoly often reveals the reasons for complaints of patients after gastric operations. An ulcer or a very severe gastritis, or an irritation from silk suture may be found.

#### DISCUSSION:

DR. WILLIAM A. SWALM (Philadelphia, Pa.): You have just witnessed something which I believe will be the beginning of a new era in gastro-enterology. Dr. Schindler has studied this subject for many years and to one who has had the privilege of visiting him and watching him work in this field, it is more or less of a revelation.

True, he cannot see every lesion in the stomach. He cannot see the lesion just below the cardiac end of the esophagus, and without hesitation he tells us that he cannot observe an ulcer at the pylorus, although that may be worked out later, but in the rest of the stomach we saw the very things at which you were just looking.

In conjunction with the Doctors Jackson, especially Dr. C. L. Jackson, I have had the privilege of doing at least one hundred of these gastroscolies, and I have had the privilege of correlating gastro-enterological findings with gastroscoly. We heartily agree with Dr. Schindler that this method is here to stay.

DR. CHEVALIER JACKSON (Philadelphia, Pa.): When Dr. Swalm spoke about Dr. Jackson, he was referring to my associate, Dr. C. L. Jackson, and not to myself, though I have many times had the pleasure of looking through the flexible gastroscope, and can corroborate all the statements made by Dr. Swalm, and all of those made by the essayist. A few minor points still admit of discussion.

Dr. Schindler stated foreign body cases are not seen by the gastro-enterologist. That is absolutely true. Patients with foreign body in the stomach come to the laryngologist. It is curious, but such is the case. We have had four instances of foreign body in consultation with gastro-enterologists; in each instance the patient was the child of a gastro-enterologist, who brought the patient to us to remove the foreign body from the stomach.

I agree with the essayist on the matter of hemorrhagic spots and pigmented spots. We have been observing them for years and they do appear in an apparently otherwise healthy stomach, and yet we feel just as the essayist feels, that the stomach is not really normal.

I agree also with the essayist in regard to the differential diagnosis of malignant disease and ulcer, so far as the late cases are concerned. I think in the very early cases we will require biopsy in most instances to differentiate between ulcer and malignant disease, and also between benign growth and malignant disease, but that probably would apply chiefly to the early cases. I think no one is likely to mistake the appearance of a late and advanced carcinoma. The early ones, I think, will require biopsy.

I heartily agree with the essayist in regard to gastritis; his classification into the superficial, atrophic and hypertrophic, will do for the present; but there will be subclasses made to the number of about twenty-five or thirty different varieties of gastritis, classified on the basis of objective appearances, not on the basis of function.

Another point is that of the gastroenterostomy patient who has been disappointed with the results of gastro-enterostomy, and they are numerous; this is one field in which the gastroscope will help enormously in the relief of the patient. The patient who has had gastro-enterostomy done and has not been relieved of the symptoms, and perhaps has had symptoms added, requires local examination with the gastroscope.

I was disappointed that the essayist did not mention the subject of hernia of the stomach, trans-hiatal hernia of the stomach. That is one very important field, it seems to me, for the gastro-enterologist.

I do not feel that the gastro-enterologist should do as he has done in the past, abandon the stomach as part of it gets through the diaphragm, or abandon that part of the stomach that gets up through the diaphragm, and especially so because that part of the stomach is accompanied by symptoms that are gastric and not esophageal. Trans-hiatal hernia of the stomach is one of the relatively common things that has been overlooked.

I am not going to follow the essayist as to the cause of gastric ulcer. For forty-odd years, forty-five or more, I have looked on at the battle between the surgeon and the gastro-enterologist and the research worker as to what is the cause of gastric ulcer, and the end is not yet. There may be cases caused by gastritis, but they are probably cases that have other causes. It is still an open question. There is one point, however, on which I must differ with the essayist; an historical fact. The essayist said that when he took up the work in 1921, it had been abandoned all over the world. If he had not said "the world," I should not have disagreed with him. There was a small part of the world where there were done, between 1907 and 1921, over 1700 gastroscopies that are duly recorded. Many of them were incomplete gastroscopies, however, incomplete as compared to the work of the flexible gastroscope.

Another very slight point of difference with the essayist is in regard to technique, in regard to the use of a rubber guide attached to the distal end, a mandrin attached to the distal end of the rigid tube. To my mind that introduces a danger. He said that he found it less dangerous. I wish to issue a word of caution. When you are looking through an open tube, you can see what is ahead of you and, if you see tissue, you do not push on the tube. You wait until you find the lumen. To be safe one must find the

lumen before advancing the tube. You can not see through a rubber guide to find a lumen ahead, and, if the guide does not find it, you may go fatally astray. This refers to the open tube gastroscope.

In regard to the dangers: the dangers of any kind of gastroscope, are concerned altogether with the esophagus, not with the stomach. There is no danger to the stomach. Anyone competent to deal with the stomach at all, will never injure it with a gastroscope. There need be no hesitation whatever, but, as Dr. Swalm has pointed out, we must be sure that the esophagus is normal.

We can trust the roentgenologist in 95 to 96 per cent of the cases when he gives a negative opinion on the pathology of the esophagus, and 95 or 96 per cent is a very high average. I doubt if many other departments of medicine approach 96 per cent perfection, but there is that remaining element of 4 or 5 per cent against which we must be on our guard. Occasionally small lesions in the esophagus are overlooked.

I would not say that every patient ought to have an open tube gastroscope before he has the flexible gastroscope passed; but I think before putting down a flexible tube one ought to be sure no pathology exists in the esophagus; and sometimes the only way to be certain is with the open tube gastroscope.

We are using constantly in the Bronchoscopic Clinic, the flexible tube gastroscope described by the essayist, and we find it a great addition to endoscopy, the greatest addition that has been made for many years. But I wish to say that if the endoscopist is to do a gastroscopy he must have at his elbow, a gastro-enterologist to complete the diagnosis when the endoscopist gets through looking at the stomach, and also to do something for the patient after the diagnosis is complete. The endoscopist is merely a mechanic for the purpose of looking at the mucosa. When it comes to the functional tests and treatment of gastric disease he cannot measure up to the requirements of modern gastroenterology.

In conclusion, gastroscopy is an *addition* to and *not a substitute* for any other method of examination of the stomach. All other diagnostic methods are needed just as much today as they ever were. We have added to our means an additional method that will be invaluable in the study of the problems in general as well as the problems in the particular patient.

The gastroscopy will give the gastro-enterologist when he looks in the stomach, what he has never had before, living pathology, not the pathology of some previously dead patient on whom he has done an autopsy, but the living pathology in that particular patient, but it will not tell him anything about the function of the stomach. That remains just where it always has been, a matter for investigation by the gastro-enterologist, supplemented with gastro-intestinal study by the roentgenologist.

DR. EDWARD B. BENEDICT (Boston, Mass.): I want to compliment Dr. Schindler very highly for his work on gastroscopy and the development of the flexible gastroscope; I think we owe a great deal to him in the diagnosis of stomach conditions.

For the past two years at the Massachusetts General Hospital in Boston we have been conducting frequent gastroscopic examinations in connection with the Gastro-Intestinal Clinic, and are finding it a very useful procedure.

I have been interested in gastroscopy from a surgical standpoint, and Dr. Chester Jones from a medical standpoint has also been very much interested.

(Slide) This is a carcinoma of the stomach, a typical nodular growth that was well seen by the gastroscope, an advanced condition which was also seen by X-ray.

(Slide) This is a polypoid tumor of the stomach which proved on removal to be a malignant adenomatous polyp.

(Slide) In regard to early carcinoma, the gastroscope may make the diagnosis before the X-ray. This patient, a forty-five-year-old man, had gastric complaints for three months. The X-ray showed enlarged rugae and the roentgenologist made a diagnosis of gastritis on that basis. We may, however, have hypertrophic rugae without gastritis, or gastritis without hypertrophic rugae.

Gastroscoy in this case showed many large elevations and depressions which suggested malignant disease very definitely. The patient was not operated on at that time, but did not respond well to treatment, and four months later the X-ray suggested malignant disease. Operation was done and the lesion proved to be inoperable carcinoma.

(Slide) This is a benign gastric ulcer as seen by gastroscopy. The rugae may be seen characteristically converging toward the lesion. As Dr. Schindler pointed out, the smooth margins and clean-appearing base are typical of a benign lesion. A malignant lesion would show nodular margins and a dirty base. I think in these cases the gastroscopic differentiation is of importance.

(Slide) Then, hypertrophic gastritis; we have the verrucous, warty appearance of the mucosa as contrasted to the smooth rugae in the normal stomach.

(Slide) The bleeding cases: This patient complained of gastro-intestinal bleeding. The gastric X-ray and barium enema were entirely negative and the source of the bleeding was revealed by gastroscopic examination as coming from the eroded area seen on the slide.

(Slide) Then we have atrophic gastritis seen especially in pernicious anemia with the blood vessels clearly seen shining through a very pale, thin mucosa, entirely different from the normal.

(Slide) That particular patient also had a benign polyp clearly seen through the gastroscope. The X-ray had questioned malignant disease. Gastroscopy made the diagnosis almost certainly a benign polyp, frequently associated with pernicious anemia.

(Slide) After liver therapy and operative removal of the polyp the color improved and the normal rugae began to return, the appearance in general returning to normal.

In conclusion, I want to emphasize the importance of the gastroscope in diagnosis and localization of early

carcinoma, in benign ulcer of the stomach, and particularly in gastritis.

DR. RUDOLF SCHINDLER (closing discussion): I think that the Chairman would not be very satisfied if I were to discuss all these questions which have been brought up in discussion. They include, really, the whole pathology of the stomach. I wish to thank you all for the great interest which has been shown in this paper, and especially I want to thank Dr. Chevalier Jackson.

When I read the literature, I am accustomed to read over and over two classical papers, those of Mikulicz in 1881, and Chevalier Jackson in 1907. They were the pioneers. The observations of 1907, made through an open tube, by Chevalier Jackson are astonishing, and it would be difficult for me to make them in this way. That Dr. Jackson now has accepted the method with the flexible tube, and that he is able to follow in the new ways, shows how young he still is.

One remark that he made was of great interest to me, about the classification of the gastritis, because I was writing a paper on this subject in collaboration with Dr. Ortmyer, which will appear soon. Classification is a difficult problem. Shall gastritis be subdivided in accordance with only the gross gastroscopies as Moutier in Paris does. I have the impression it should not. The best way at this moment is to follow the development of the different pictures, and after the course and prognosis to subdivide gastritis in these three forms which I have described. Perhaps we can later subdivide gastritis according to the etiology, but we are not yet at that point.

I agree with Dr. Swalm completely that gastroscopy allows gastro-enterology to enter a new era, the era of morphologic diagnosis, naturally not without X-ray. X-ray examination and gastroscopy are cooperative methods. They help each other.

The question is: Who will carry out the gastroscopies? You know that in Germany gastroscopy is a routine method of the gastro-enterologist. I don't know whether it will be so in this country. I was happy when a young physician of Jacksonville, Florida, told me that after what he had seen he believed that the gastroscope will in a short time be part of the equipment of every gastro-enterologist. That is my opinion also.

## Bacteriological Findings in Disease of the Biliary Tract\*

### An Improved Method of Obtaining Cultures of Bile by Duodenal Drainage

By

JOHN RUSSELL TWISS, M.D.

and

CHARLOTTE H. PHILLIPS, M.D.

NEW YORK, NEW YORK

**E**VIDENCE of biliary tract infection obtained by duodenal drainage is of diagnostic value only if the specimens of bile procured are free from extraneous contaminations. As shown by Hanssen and Yurevich (1), many varieties of organisms cultured from duodenal bile are not found in the biliary tract at operation. It is the purpose of this paper to indicate the sources of these contaminating organisms,

and to describe a method of taking duodenal cultures which for the past 2 years has given results more in accordance with the conditions actually found at operation than those obtained by methods heretofore in use.

The actual incidence of contamination was shown by Hanssen and Yurevich (1) in a complete bacteriological study of 104 operative patients. Evidence of infection was found in some part of the biliary tract in 33% of the cases, 20% of the gall bladder bile cultures being positive. A single infecting organism was found in 95% of the cases. Forty-eight of these

\*From the Departments of Medicine and Surgery of the New York Post Graduate Hospital.  
This work has been aided by a grant from the Oliver Rea Fund.  
Submitted July 8, 1935.

patients had sterile drainages before operation, positive cultures were obtained in 69% of these drainages. This finding compares favorably with other published reports. However, only 33% of these patients showed infection at operation. 42% of those whose biliary tracts were sterile at operation had a mixed growth of organisms in the drainage bile.

An analysis of possible sources of contamination suggests the necessary manipulation of the duodenal tube. Contamination may occur at the syringe end of the tube by contact with unsterile fields, hands, or by

ers the fasting stomach sterile. Patients having a normal or increased acid content usually show no organisms, those with achlorhydria almost invariably have positive gastric cultures. According to Bartle and Harkins (2), only gastric contents with free hydrochloric acid of over 20° have bactericidal power.

The third likely source of contamination in performing a drainage of the biliary tract is the mouth and throat, for as many investigators have shown the tonsils, teeth, and pharynx harbor innumerable organisms. Boardman (3) has shown that attempts at

Fig. 1. The single drainage tube, showing: A. The three-way stop-cock and bile container, supported by a ring-stand. Bile for culture is obtained in a test tube from the side-arm, the bile being diverted for this purpose when necessary. B. The metal bucket and leader of the tube, with and without the keratin-coated capsule in place.

a syringe with contaminated tip. With the usual method of drainage contamination may occur through the bucket end of the tube by the introduction of infected materials from the mouth, throat, or stomach. Finally, contamination may result from inadequate sterilization of the drainage tube, bile containers, or solutions.

Another probable source of contamination is the stomach. Organisms from the food, saliva, tonsils, teeth, sinuses and various parts of the upper respiratory tract are unquestionably swallowed. The presence of the free hydrochloric acid, plus possibly the action of the pepsin, normally constitutes a protective mechanism which destroys swallowed organisms and rend-

sterilization of the mouth have had no apparent effect in reducing the bacterial flora, cultures taken before and after these procedures showing identical growths.

There is obviously a discrepancy between the sterile cultures or the single type of organism usually found in the biliary tract and the many types of organisms which have been commonly reported as present in the duodenal bile. Various methods of obtaining sterile cultures of duodenal bile have been described, notably that of Lyon (10). MacNeal and Chace (5), as well as Whipple (6) have used tubes sealed off to preserve sterility. A small tube for sterile cultures, contained in an outer tube, has been devised by Buttiaux. There are, however, inadequate data based upon comparative

bacteriological studies and findings at operation to confirm the practicability of these methods. A different method has been devised and has been in use for the past two years, with very satisfactory results, in the Clinic for Diseases of the Liver and Biliary Tract of the New York Post-Graduate Hospital.

### METHOD

The principle of our closed or encapsulated drainage in eliminating contaminations is the sealing off of a Twiss duodenal tube (7) by means of a keratin-coated gelatine capsule (Figure 1). The usual type of single Twiss tube may be used when its position can be checked by the use of the fluoroscope. The double tube as shown in Figure 2 is, however, an advantage, for

Fig. 2. The double duodenal tube: A. Bucket end of tube, showing (a) metal bucket covered by keratin-coated capsule, which is held in position by wide rubber bands. (b) opening of pilot tube, for the purpose of obtaining gastric and bile specimens not cultured. B. Syringe end of tube, showing (a) tube through which bile for culture is obtained. (b) pilot tube.

one tube serves as a pilot tube for the taking of gastric or biliary specimens and for determining the position of the tube in the duodenum as shown by the character of fluid obtained, thus obviating the need of a fluoroscope. A further advantage of this arrangement is in showing, at all times, the type of bile being discharged, so that cultures may be taken when indicated. The second tube, which is for the purpose of procuring bile for culture only, has the slotted metal bucket, over which the capsule is held in place by wide rubber bands. The tube and rubber bands are sterilized by boiling, the capsule is sterilized in absolute alcohol and applied with sterile precautions. If the double tube is not available, or its passage through the stomach is difficult on account of a persistent pylorospasm, a single encapsulated Twiss tube is used.

That the sterile capsule maintains its integrity until reaching the alkaline medium of the duodenum has been demonstrated in the following way: The duodenal tube was filled with barium solution and the capsule applied. The tube was then swallowed by a patient and passed to the duodenum, as checked by fluoroscopic inspection. A roentgenogram taken at this time showed the barium retained in the tube. The capsule was then removed by pressure applied by a syringe, a second roentgenogram showed the barium distributed in the duodenum.

A further attempt has been made to eliminate contamination at the syringe end of tube. A three-way stop-cock (8) is attached to the end of the duodenal tube, the stop-cock and bottle for bile being supported by a large ring-stand (Figure 1). The drainage of

bile and the introduction of stimulating fluids is conducted through the direct pathway. Cultures are taken from the side-arm only, the bile being temporarily diverted for this purpose. Both the tip of the side-arm and the mouth of the sterile test-tube are flamed before taking the cultures.

The drainage is done with the patient having had no food for at least 12 hours; the mouth and throat are sprayed with 10% silver nucleate, followed by a gargle of the same solution, before passing the tube. After the single tube is passed into the duodenum, its position is verified by fluoroscopic inspection. The capsule is then removed by the instillation of hot sterile water by a syringe, the duodenum being thoroughly lavaged with sterile water before beginning the drainage. The complete equipment and its sterilization, as well as the method of performing the drainage, are elsewhere described (9).

Specimens of bile are collected before and after stimulation with sterile magnesium sulphate or olive oil, the dilute or duodenal bile and most concentrated specimens only being cultured. Bacteriologic studies of bile specimens were made under the direction of Dr. Adele Sheplar of the Department of Bacteriology. Details of the laboratory methods employed may be found in our Clinic Manual (9).

### RESULTS

For the purposes of illustrating the results of this type of drainage a series of 165 consecutive drainages is reported on 50 patients referred to this clinic with a tentative diagnosis of disease of the gall bladder. Fifty patients were drained 87 times by the closed or encapsulated method, 31 of the same patients were drained 78 times by the open or usual method. Throat cultures were taken in 20 patients immediately preceding drainage by both the open and closed methods.

A study was made of the organisms found in the throat cultures and in the duodenal bile specimens obtained by both methods, the results are shown in Table 1. The usual or open method gave sterile cultures in

Table I. A comparison of the bacteriological findings of the throat and duodenal bile, as obtained by the open or usual method and the closed or encapsulated method.

13% of the drainages, organisms similar to those found in the throat were present in 60%. In the same patients, drainage by the encapsulated tube method showed sterile cultures in 38% of the cases, only 23% had organisms similar to those of the throat. These results indicate that with the encapsulated method fewer contaminating organisms from the throat and mouth are found in the duodenal bile.

We have also made a study of a series of patients, who had for the most part repeated drainages and

in some cases repeated throat cultures (Table 2). Patients drained by the open method, were found to have sterile cultures in 10% of the cases, only one or

Table III. Percentage of patients showing sterile cultures and various types of organisms in the cultures of the throat and in the cultures of bile obtained by the open and closed methods.

dominating organisms of the throat are seen to be the streptococcus of the non-hemolytic, hemolytic, and green types, as well as the *M. catarrhalis*. There is a relatively high incidence of *B. influenzae*. Patients drained by the open method showed predominately these organisms, for example the non-hemolytic streptococcus, *Micrococcus catarrhalis*, *staphylococcus albus*, and diphtheroids occurred from 2 to 10 times as frequently as in those patients drained by the encapsulated method. Patients drained by the encapsulated method show a decreased incidence of all organisms. The non-hemolytic streptococcus was again found to predominate, most of the other organisms found in

higher percentages are of types found in the biliary tract at operation.

In a further study, a series of gastric cultures was taken immediately preceding drainages by the open method. The same types of organisms were found in the stomach as in the throat. Staphylococci, however, which were seldom found in the throat cultures, were usually present in the gastric contents with diminished or absent free hydrochloric acid. In all patients one or more types of bacteria found in the gastric specimens were present in the duodenal bile.

## CONCLUSIONS

The results of these investigations indicate that the organisms found in the biliary tract and not usually in the stomach or throat are found in higher incidence and more frequently in pure culture in the duodenal bile obtained by means of the encapsulated method here described. These include the *B. coli communis*, *B. acidii lactici*, the *lactis aerogenes* group, *B. proteus*, *B. Welchii*, and *B. typhosus*. On the other hand drainage bile obtained by the usual or open method was found to show more frequently mixed growths of those organisms indicating contamination, such as the *micrococcus catarrhalis*, Friedländer groups, diphtheroids, diplococci, and pneumococci. For these reasons we consider all findings more reliable when the bile is obtained by the encapsulated method.

A further study is in progress at the present time in which a series of patients with biliary tract disease are being drained preoperatively by the encapsulated method. The results of the cultures are then being compared with the bacteriological findings at operation. A report of this investigation will be made at a later date.

## SUMMARY

1. Bacteriological studies of the biliary tract at operation in practically all cases have shown sterile cultures or a single type of organism.
2. Cultures of bile obtained by means of the duodenal tube have shown in most cases a variety of organisms, many of which are found in the mouth, throat, and gastric contents.
3. Specimens of duodenal bile obtained by present methods in many instances are contaminated and cultures can not be considered diagnostic of biliary tract infection.
4. A method of taking sterile cultures of duodenal bile by means of an encapsulated tube is described. This method has given a higher percentage of sterile cultures and a higher incidence of pure cultures of bacteria significant of biliary tract disease than the one previously used. Studies have further shown a lower incidence of mixed growths of organisms, especially in those types of contaminating organisms found in the throat and stomach.

The Authors are indebted to Dr. Carl H. Greene for assistance in the preparation of this article, as well as for suggesting the use of the double duodenal tube.

ABELL, IRVIN.

*"The Diagnosis and Treatment of Duodenal Ulcer."*  
*South. Med. Jour.*, 28:138-141, Feb., 1935.

In an unbiased and thorough manner the Author presents the difficulties encountered in the diagnosis and treatment of duodenal ulcer, utilizing his own case records for his observations.

The diagnosis is frequently obscure in the absence of many of the classical symptoms: hunger pain with food relief; fullness, discomfort, or sour eructations some time after ingestion of food; seasonal variations; hemorrhage in stool or vomitus; and vomiting of food or gastric secretion when pyloric obstruction occurs. Actual pain may be absent or very acute and severe. The symptoms may be of such short duration and with such long periods of remissions that they may be attributed entirely to dietary indiscretion. Evidences of gross hemorrhage will be lacking in 80% of the cases. Since, however, all the later complicated pathological changes in the ulcer and surrounding tissues have their origin in what is first a simple ulcer thorough examination, including laboratory and X-ray studies are indicated in all cases of "stomach trouble."

The treatment is primarily medical, consisting of diet, antacid medication, elimination of focal infection and institution of other general health measures. Persistence and adequacy of this regimen are essential.

The Author reserves operation for patients presenting one or more of these conditions: perforation, repeated or long continued hemorrhage, pyloric obstruction, and intractable chronicity. In the majority of cases perforation is best treated by simple closure of the leak without additional plastic procedures. Single massive hemorrhages rarely require operation but when hemorrhage of any kind does demand surgical treatment the ulcer should be destroyed. Simple pyloric obstruction is well cared-for by gastroenterostomy but in the small percentage of those cases showing multiple, extensively-calloused or posteriorly-placed ulcers, with perforation into or fixation to the pancreas, resection of the duodenum and pylorus seem indicated. Those intractable chronic cases best are treated by pyloroplasty with excision of the ulcer or gastroenterostomy with destruction of the ulcer. The radical ablation of the acid-bearing portion of the stomach seems an unnecessarily extensive operation and the continued subsequent absence of hydrochloric acid should make one consider the possibility of serious secondary changes resulting from disturbed body chemistry.

In spite of proper surgical treatment of the ulcer, including also the removal of an infected gall bladder or appendix, and proper postoperative diet, the patient is a potential ulcer prospect for life. Recurrence is probably due to our incomplete knowledge of the etiology. Team

work by internists, surgeons, pathologists, research workers and roentgenologists is essential for the solution of the problem.

GRAY TURNER.

*Recent Advances in the Treatment of Carcinoma of the Esophagus From the Surgical Aspect.* *Jour. of Laryngol. and Otol.*, XLIX, pp. 297-311, May, 1934.

The patient in this case was a man fifty-eight years of age, who complained of serious difficulty in swallowing of eight weeks' duration. Solid food appeared to stick at the lower end of the sternum, and he could swallow only foods of the consistency of porridge. He had lost 42 pounds in eight weeks. Roentgenoscopic study revealed the characteristic shadow of a neoplasm in the middle of the esophagus.

Gastrostomy was performed and exploration failed to reveal secondary deposits in the liver. Twenty-three days later, the abdomen was re-opened through an incision in the median line which was carried high up between the left costal margin and the xyphisternum. The left lobe of the liver was detached from the diaphragm and turned to the right. The peritoneum over the esophagus was incised and enucleation was commenced with the forefinger introduced through the hiatus and worked up as far as possible around the tube. When no further separation could be accomplished, the abdominal region was covered with sterile towels and the field of operation was transferred to the neck. A transverse or oblique incision was made just above the left clavicle, dividing the sternomastoid muscle. The cervical esophagus was exposed by blunt dissection and separated as far down as the finger could reach; the esophagus was then surrounded by a silk ligature at as low a point as it could be tied. It was cut across with the cautery and the lower end and parts around freely smeared with bipp (bismuth iodoform paraffin paste). The proximal end, which had been controlled by a light clamp, was then brought out of the incision. A return was made to the abdomen and traction made on the esophagus. The esophagus, including the neoplasm, was freed from its bed, ligatured at the cardia, and cut away from the stomach. The stump was securely buried by purse-string sutures. The open esophageal tunnel in the diaphragm was repaired by suturing the left lobe of the liver over its mouth and the abdomen was closed.

Nine weeks after gastrostomy, in a series of operations, a new esophagus was constructed by making a tube from the skin over the front of the chest, and the gap between the skin tube and stomach was bridged by an isolated loop of jejunum. Six weeks after the last stage of the operation, the gastrostomy tube was removed and the patient was able to take all food by mouth.

## SECTION II—*Experimental Physiology*

### V. The Effects of Drugs on the Motility of Isolated Segments of the Intestine of Man<sup>\*</sup>

By

J. ARNOLD BARGEN, M.D.†

and

JOHN S. GUTHRIE, M.D.‡  
ROCHESTER, MINNESOTA

IN recent years, this Clinic has offered a unique opportunity for intensive study of functions of the large intestine. Patients who have had various kinds of intestinal disorders have been segregated on one floor of a hospital, under combined medical and surgical management. In this way, fifty to seventy-five patients, most of whom had disease of the colon, have been under observation the year around. Some of them consented to the performance of certain harmless, painless investigations, by which we hoped to learn facts which would be of benefit to them and to others. Consequently, many problems for clinical research have suggested themselves.

These patients were under the care of specially trained nurses and workers. This fact has been of great help in the execution of our research. This is the fifth report of a series of problems. The next study, now well under way, concerns the functions of the small intestine of colectomized patients. Colectomies have been done only for extensive polyposis or advanced chronic ulcerative colitis with serious complications. The results will be reported in the near future.

#### REVIEW OF PREVIOUS STUDIES

Members may recall that, at the meeting of this Association, in 1929, results of the first series of investigations were reported. These investigations were made on dogs. They established the fact that, in dogs, selective absorption and excretion of various drugs took place in the isolated colon. The colon of the dog was isolated by sectioning the distal part of the ileum, and the colon, as near to the anus as possible, and making end-to-end anastomosis of the proximal part of the ileum and the distal part of the colon. The distal end of the ileum was then brought to the outside of the abdominal wall, on the right side, and the proximal end of the colon was treated likewise on the left

side, thus leaving the colon in the abdominal cavity, with nerve supply and blood supply intact.

The second and third studies concerned the motor and secretory activities of these isolated segments of colon. It was established that secretion of mucus is a normal function of the mucosa of the bowel and that mucus serves as a lubricant and protects against penetration of harmful bacteria. There was a strong suggestion that the mucus acted as a regulator of absorption. It was found that the amount of mucus secreted varies directly with the amount of colonic irritation; the source of irritation may be central as well as peripheral. Great loss of nitrogen occurs by excessive secretion of mucus. Mucus is not a product of inflammation.

The motor activity of segments of the colon varies. In the cecum, there is mixing and churning, and thus absorption is aided. In the distal portion of the dog's colon, the activity is largely one of propulsion.

With these studies on dogs as a background, similar studies on man have been undertaken. Some have been completed. The fourth study was reviewed in "*Surgery, Gynecology and Obstetrics*," March, 1935. It concerned the absorption and excretion of various substances in isolated segments of the colon of man.

A surprising amount of conflicting experimental evidence exists concerning absorption of substances, other than water, by the large intestine. Colostomized patients are ideally suited to elimination of the usual fallacies inherent in investigations of colonic absorption. Instead of studying the colon of carnivorous or herbivorous animals, as has been done in the past, we could make observations on the isolated colon of omnivorous man. The divided colon has the added advantage of preventing error from regurgitation of the clyisma into the absorbing ileum. Short distal segments can be thoroughly evacuated, thereby eliminating any errors attributable to failure to recover unabsorbed fractions, and finally, such segments can be cleansed, thus preventing error attributable to fermentation by bacteria.

By a study of such isolated portions of the colon of man, it was found that even in the distal seg-

‡Fellow in Surgery, The Mayo Foundation.

ments there is absorption of methylene blue, atropine, sucrose, arsenic as neoarsphenamine and glucose. Distal segments of the colon of man do not excrete methylene blue, glucose, or sucrose. Arsenic, as "trep-arsol," is excreted by the distal segments.

#### PRESENT STUDY CONCERNING THE EFFECTS OF DRUGS ON MOTILITY

Many drugs have been used in the past to combat and prevent postoperative intestinal distention, such as that which occurs with paralytic ileus from various causes. So far, knowledge regarding the ability of drugs, as extract of the posterior lobe of the pituitary body ("pituitrin"), physostigmine, acetylcholine, or "peristaltin," to influence intestinal tone and motility, has been founded principally on the results of experimentation with animals and on impressions acquired by clinical observations of the effects produced following administration of these drugs to patients affected with postoperative intestinal distention.

We undertook to evaluate the effects of these drugs on patients on whom colostomy had been performed. Patients who have undergone colostomy or ileostomy, at various levels, afford opportunities to study accurately the action of these drugs on intestinal segments. The intestinal stomas in the cases studied, had been made as steps preliminary to eradication of intestinal neoplasms, so that in each case ample normal colon was at hand after surgical resection.

For our experiments, patients were selected whose intestinal motility had been disturbed to the least possible extent. Hence, they were chosen with the thought that colostomy had not been performed longer than two weeks before the experiment was undertaken. The patients were all in excellent general condition and their bowels and colonic stomas were functioning well. No interference with intestinal function had taken place for several days before each experiment. During each experiment, the patient was supine on a couch, in a room that had been especially set aside for the carrying out of this study. Hence, the subject was free of extraneous influences which might cause reflex nervous irritation.

The apparatus used for these experiments was a closed air-balloon system, connected with a tambour and recording lever, this, in turn, writing with an ink point on smooth kymographic paper fastened to a revolving drum.

The drugs, whose action on the intestine of man we investigated, were (1) surgical pituitrin, (2) physostigmine sulphate, (3) "peristaltin" (Ciba), or soluble extract of cascara sagrada, grains  $2\frac{1}{2}$  (0.15 gm.) per ampoule, prepared for hypodermic use, and (4) acetylcholine. All the drugs were administered intramuscularly. The effect of each drug on various segments of the intestine was recorded.

**THE TRANSVERSE COLON.**—*Pituitrin*: After administration of pituitrin, powerful contractions of the transverse colon began within three to five minutes. These contractions occurred every three to five minutes, and the effect of the pituitrin lasted for forty-five to ninety minutes.

*Physostigmine*: Doses as large as  $1/35$  grain (0.0018 gm.) caused no effect on this segment of colon.

*"Peristaltin"*: In some cases,  $2\frac{1}{2}$  grains (0.15 gm.) of this drug caused slight and irregular contractions. The contractions occurred every one and a half

minutes to seven minutes, for an hour. At other times no effect from this drug was recorded.

*Acetylcholine*: Doses as large as 6 grains (0.4 gm.) caused no effect on this segment of colon.

**THE SIGMOID COLON.**—*Pituitrin*: This drug caused, on the sigmoid, reactions identical with those which it had exhibited on the transverse colon.

*Physostigmine*: Small to medium-sized contractions resulted from administration of this drug; the contractions occurred every one to eight minutes, for an hour.

*"Peristaltin"*: A few small contractions occurred at irregular intervals.

*Acetylcholine*: Slight elevation of tone of the sigmoid occurred between six and nine minutes after administration of this drug, and small contractions occurred at irregular intervals for about forty-five minutes.

**TERMINAL PART OF ILEUM AND SIGMOID COLON.**—With balloons in the terminal part of the ileum and in the sigmoid colon of a single individual, simultaneous recording of contractions could be made.

*Pituitrin*: Contractions occurred simultaneously, in both sections of bowel, every one and a half to three minutes.

*Physostigmine*: On some occasions, no effect on the ileum could be recorded after administration of this drug; on others, increased ileal tone occurred, associated with small to medium-sized contractions every one and a half minutes to five minutes. The contractions occurred, although they gradually decreased in magnitude, for 105 minutes. In the sigmoid, slight contractions occurred every two to four minutes, beginning about ten minutes after administration of the drug.

*"Peristaltin"*: On some occasions, no effect was observed on either the ileum or the sigmoid; on others, when administration of the drug was repeated, and in similar amounts, thirty minutes after the initial dose had been given slight increase in ileal tone occurred, but no effect on the sigmoid was noted.

*Acetylcholine*: Slight increase in tone of the ileum occurred for twenty minutes.

#### CONCLUSIONS

1. These experiments would compel the conclusions that pituitrin alone is a constant motor stimulant of the large and the small intestine of man. It increases motility without effect on intestinal tonus. Its action is rapid and powerful.

2. The action of the other three drugs is inconstant and uncertain, when amounts are given that will not cause other systemic effects.

3. These experiments open new avenues of valuable clinical physiologic research on man.

#### DISCUSSION:

DR. M. B. DREYER (Halifax, Nova Scotia): As a pharmacologist, I have to listen to a good many heresies. I don't want to take Dr. Bargaen to task at all, but if one is going to use doses, use heroic doses. Secondly, "peristaltin," while it may be an excellent drug, should be considered from the point of view of kidney damage. Its indiscriminate use may lead to kidney damage.

I am more particularly interested in the use of pituitrin. The effect of it varies with the portion of the gastro-intestinal tract selected. The colon is particularly sensitive

to small doses, in that small doses of pituitrin (and I am speaking of the effects on cats) showed two effects: increase in tonus and increase in number of contractions per minute. All doses as I have used them were given intravenously.

Now, in the small intestine, strange as it may seem, in the cat and the dog (these results have been confirmed by Grüber), pituitrin causes relaxation of the small intestine. The effect of pituitrin varies on the pylorus and cardiac portions of the stomach. In the pylorus, pituitrin causes strong contractions, and at the cardia it causes a relaxation. To show that it is a real effect, one can compare that with the effect of histamine in the gastro-intestinal tract, where the histamine has a stimulating action on the colon but causes relaxation of the small intestine. Like pituitrin, it is followed by a period of increased activity. There is a well known tolerance produced by pituitrin, but it is less marked for the colon and most marked for the pylorus.

If one repeats the injections of pituitrin too rapidly, the pylorus will not respond and the large intestine will. That is similar in many respects to the effect of pituitrin on the uterus. The uterus is the organ in the body most tolerant to the action of pituitrin.

The fraction of pituitrin responsible for these motor effects on the intestine is "pitressin," and not "petressin" as such, but the interesting point is this, if you increase your dose of "pitocin," because it is 96 per cent pure, as you increase that, you eventually find that the large intestine will respond to pitocin but the small intestine will not respond at all.

Perhaps one should say there is some difference in the large intestine as compared with the small, which will make it respond to pitressin.

Another thing about the large intestine which might be considered is that it is an extremely sensitive portion of the intestine and its mucosa is considerably more sensitive to purgatives than is that of the small intestine, as shown by the recent work of Straub. He found that infusion of senna (10 per cent) will cause increased movements in the small intestine, whereas 0.1 per cent of infusion of senna will cause marked movement in the large intestine and will be ineffective on the small intestine.

Another point which perhaps might be stressed is this: Dr. Barger said that bismuth is absorbed from the large intestine. Now, as a student, each of us was probably taught if there is one thing in which the large intestine differs from the small, it is that it acts as an excretory organ, and if you take bismuth and give it, you will get a blackening of the mucosa. One doesn't deny it might be absorbed from the large intestine.

Now, to utter one violent heresy, the large intestine, as you know, has three longitudinal bands and a lot of circular muscles. If you look at the large intestine when you produce a peristaltic wave, you find that the peristaltic wave confines itself almost exclusively to the circular coat and that the longitudinal bands are there merely for support of the circular coat; and, secondly, produce retraction to allow the circular muscle in contracting to pass the movements on better.

I should like to ask Dr. Barger to observe when he gives morphine to a human being, say with the barium, in the large intestine, whether there are any increased reversed peristaltic waves following the use of morphine and some of the other drugs he uses.

DR. WALTER A. BASTEDO (New York, N. Y.): We like to see experiments such as these made on the human animal because, in the last analysis, that is our guide for the use of drugs in medicine. I have done animal experiments on the bowel with some of these drugs, particularly physostigmine, but also with pituitrin and atropine.

As to the four drugs mentioned, we have to think of pituitrin as acting on the muscle essentially. That puts it in quite a different category. Physostigmine, or eserine, acts essentially by enhancing and prolonging the influence of vagus stimulation. Acetylcholine has the effect of vagus stimulation if you can put it in the right place, but acetylcholine by hypo is very quickly destroyed by the tissues of the body or in the blood stream. Cascara, (represented by "peristaltin")—well, there isn't any active principle of cascara that has ever been isolated that will produce the same effect as cascara; and although you can get some action by hypodermic material made from cascara, unless one gives a great deal, much more than one would have to give by mouth, one can't get any effect on the bowels.

As far as the dose of eserine is concerned, a number of years ago I tested patients, post-operative, with physostigmine by hypo in doses of 1 milligram and two milligrams, and found it very inefficient. Sometimes we would get a little action and sometimes we wouldn't get any, even from two milligrams, that is, a thirtieth of a grain.

Martin and Weiss obtained very good results from double that dose, four milligrams, a fifteenth of a grain, but when one reaches that point of dosage, as Dr. Barger has pointed out, one begins to get the toxic symptoms of physostigmine, which, as you know, are nausea and salivation, and, very strikingly, cramps in the bowel.

We found that physostigmine tends to increase peristalsis in the small intestine and to increase the tone waves into spasm or cramp. This effect can be completely overcome by atropine. We don't want cramps, and cramps result from physostigmine in dosage just a little larger than that which tends to stimulate peristalsis.

Of course, when we talk about peristalsis in the large bowel, I don't think we know much about it. We know a lot about the small bowel because that organ is so much more easy to work with, as its actions are rapid. We must think of the large bowel as an organ that holds back material instead of pushing it on, the small bowel emptying liquid into the large bowel all day long, and the large bowel expelling solid material only once or twice a day. The colon's job is to hold things back, not to push them along, except at very rare intervals; therefore, we have to be careful not to transfer the results of experiments on the small intestine to the large.

Just one more point: Drugs that stimulate the vagus—I mean that enhance the action from vagus stimulation—depend for their action, as vagus stimulation does also, on the state of the bowel at the time. If the bowel is contracted, if it is hypertonic, stimulation of the vagus causes it to relax—again I have made a mistake—we shouldn't say "vagus," but rather parasympathetic, for the vagus does not supply the colon in man. If the colon is in a relaxed state, parasympathetic stimulation tends to cause its contraction. This apparently contrary action, according to whether the bowel is in hypertone or hypotone, is a new idea to us medical men, but a fact established by a great many experimenters at the present time.

DR. J. ARNOLD BARGER (closing the discussion): The suggestions of Professor Dreyer and Dr. Bastedo are very much appreciated. The opportunity for further intensive study of other drugs is constantly at hand. We chose the four drugs mentioned because they are the ones in common usage among surgeons and clinicians in the control of paralytic ileus of various kinds. We realize that the work of the last few years has but opened the field. We hope that these discussions will stimulate others sufficiently so that more intensive studies of this type will be undertaken.

# Some Normal Variations in the Emptying-Time of the Human Stomach (Using a Carbohydrate Meal)\*

By

EDWARD J. VAN LIERE, Ph.D., M.D.

and

CLARK K. SLEETH, A.B., B.S.

MORGANTOWN, WEST VIRGINIA

IN the course of some experimental work upon the emptying-time of the human stomach (1) considerable data pertaining to the normal emptying-time was obtained. Some rather interesting variations were noted in connection with these data, and led us to believe that this report might prove of interest to gastroenterologists and to experimental physiologists.

It is well understood that many factors may influence the rate of gastric emptying, and that even when every attempt is made to control all of these factors and to produce uniform experimental conditions, a careful evaluation of results is necessary.

## METHOD

Nine normal young adult male medical students were selected for this work. They were given a standard meal, which was prepared as follows: 15 grams of farina and 1 gram of salt were added to 350 c.c. of boiling water and the mixture was cooked until the total volume was 200 c.c. This semi-solid preparation was kept in an electric refrigerator overnight. The next morning 50 grams of barium sulphate were added, and the meal was eaten at 8:30 A. M.

After the subjects had eaten the meal they were asked to lounge about the laboratory, and for the main part to keep seated in comfortable positions. They were allowed

at about what time gastric evacuation would occur, for, as is pointed out later, the emptying-time of the stomach for each individual remained singularly constant from day to day. This method of estimation prevented undue exposure to the Roentgen ray.

## RESULTS

Nine subjects were used, and a total of 77 tests was run. The arithmetic mean (average) of the emptying time of the stomach of the 9 individuals was 2.07 hours. The arithmetic mean of the 77 tests was 2.08 hours. The extremes of the emptying time for the subjects were 1.03 and 2.81 hours, respectively. The extremes for the tests were 0.75 and 3.50 hours, respectively.

## DISCUSSION

It is interesting to observe that the emptying time of any individual varied but little from day to day. Even in such cases as subjects number 4 and 9 respectively, where there is considerable difference between the extremes, the mode and the median check closely with the average emptying time. A similar constancy has been observed in previous work upon animal subjects (2).

It must be noted that our standard meal consisted almost entirely of carbohydrate. It is doubtless true that a meal with a higher protein content would be retained longer by the stomach, since such a meal would be subjected to a certain amount of gastric digestion before it would be allowed to leave the stomach. The meal we used was chosen for ease in preparation and administration, and to conform with standards previously set up by other workers on the emptying time of the stomach (3).

It is seen that the emptying-time of the stomach of subject number 1 is considerably shorter than the average. This subject reported that when in perfectly normal health he had 2 or 3 bowel movements every day. Subjects number 8 and 9, each with a rather long emptying time, were high-strung individuals.

These points of information are not given in an attempt to explain why the emptying time in these cases varied considerably from the average, for it is certain that in a series of persons chosen at random a number of just such individuals would be encountered. We feel, therefore, that the subjects used in this work represent a fairly accurate cross section of their group.

Owing to the small number of subjects used in this work no attempt was made to correlate our objective

TABLE I

Table I gives the details of the results obtained

| Subject Number | Emptying Time in Hours |         |                       |      |        | Number of Tests |
|----------------|------------------------|---------|-----------------------|------|--------|-----------------|
|                | Shortest               | Longest | Arith. Mean (Average) | Mode | Median |                 |
| 1.             | 0.75                   | 1.50    | 1.03                  | 1.00 | 1.00   | 7.              |
| 2.             | 1.25                   | 2.00    | 1.58                  | 1.50 | 1.50   | 9.              |
| 3.             | 1.75                   | 2.25    | 1.96                  | 2.00 | 2.00   | 7.              |
| 4.             | 1.50                   | 2.50    | 2.00                  | 1.75 | 2.00   | 11.             |
| 5.             | 1.75                   | 2.50    | 2.17                  | 2.25 | 2.25   | 10.             |
| 6.             | 2.25                   | 2.25    | 2.25                  | 2.25 | 2.25   | 7.              |
| 7.             | 2.25                   | 2.75    | 2.40                  | 2.25 | 2.25   | 7.              |
| 8.             | 2.25                   | 2.75    | 2.50                  | 2.50 | 2.50   | 10.             |
| 9.             | 2.25                   | 3.50    | 2.81                  | 2.75 | 2.75   | 9.              |
| Average        |                        |         | 2.07                  |      |        | 8.5             |

to spend part of the time in reading light fiction, such as may be found in current non-scientific periodicals. In short, they were asked to relax, physically and mentally, as much as possible, without making a studied effort to do so. Every precaution was taken to shield them from extraneous influences.

The emptying-time of the stomach was determined fluoroscopically. After a few determinations had been made upon any individual it was relatively easy to estimate

\*From the Department of Physiology, West Virginia University.  
Submitted August 19, 1935.

findings with weight, physique, mental makeup, or any other characteristic.

### SUMMARY

The normal emptying time of the stomach of 9 young adult males was determined fluoroscopically, under carefully controlled conditions. The standard meal used consisted chiefly of carbohydrate; the preparation of the meal is described in the body of this paper.

A total of 77 tests was made. The arithmetic mean (average) of the emptying time of the 9 subjects was 2.07 hours. The arithmetic mean for the 77 tests was

2.08 hours. The extremes for the subjects were 1.03 and 2.81 hours respectively. The extremes for the tests were 0.75 and 3.50 hours respectively.

It was found that the emptying time of the stomach of any individual remained strikingly uniform from day to day, but that great individual variations exist.

## ABSTRACTS

RIEGEL, CECILIA, RAYDIN, I. D., MORRISON, PHILIP J., AND POTTER, MILTON J.

*Studies of Gall Bladder Function. XI: The Composition of the Gall Bladder in Pregnancy. J. A. M. A., 105:1343, Oct. 26, 1935.*

Gall bladder disease follows pregnancy too often to be considered a mere coincidence. It has been thought that this results from some alteration in the bile during pregnancy. It has been shown that alterations in the chemical composition of the bile accompanies biliary tract disease and previous studies have demonstrated that damage to the gall bladder wall is accompanied by marked changes in the composition of gall bladder bile. It therefore becomes very interesting to know what the gall bladder bile removed from pregnant patients at term with no history of gall bladder disease would reveal. Data from the studies of thirty-four specimens of such bile removed from living women at term during the course of cesarean section revealed that the composition of such bile was changed from the normal. Chemical examination of this bile revealed that the cholesterol concentration is increased while the bile salt concentration is below normal. These changes in the pregnant gall bladder bile are in the direction that one would expect to precede stone formation.

*An Investigation of the Nervous Control of Defaecation. Brain, 58, 256-310, 1935.*

The defaecatory process in healthy man and the automatic defaecation resulting from destructive lesions of the sacral cord were studied.

(1) Where the sacral innervation of the rectum and anus has been destroyed, there occurs contraction of the rectum with reciprocal relaxation of

the anal sphincter. This reciprocity is nervous in mechanism, being related solely to the peripheral (intramural) nervous plexus. The adequate stimulus for relaxation of the anal sphincter is tension upon the wall of the rectum. Changes in tension are more efficient than passive tension.

(2) In "reflex defaecation" (where the sacral portion of the spinal cord is intact and is in nervous connection with the rectum and anus) the process is that of progressive and fused rectal contractions.

(3) The automatic and reflex responses are not mediated by the hypogastric nerve (i.e., they are not under the control of the sympathetic nervous system).

(4) Voluntary control over defaecation extends only to the external voluntary sphincter ani. The external sphincter is not tonic, but it contracts synergistically with the abdominal parietes in the course of the flexion reflex.

(5) If delivery of faecal material to the colon is adequate, the mechanism of defaecation depends primarily upon the reaction of the rectum to distension.

ARNDORFF, J. R., BERGH, G. S., AND IVY, A. C.

*"Peptic" Ulcer and the "Anxiety Complex." S. G. and O., Vol. 61, No. 2, pp. 162-168, Aug., 1935.*

The Authors performed experiments designed to determine whether chronic peptic ulcers could be produced in the dog by:

1. A sustained stimulation of the motor activity of the stomach.
2. Maintenance of the secretory activity of the stomach at a high level.
3. Continuous motor stimulation together with a high acid level. Since even the wildest of jungle animals soon become accustomed to the unnatural conditions of captivity, and, according to those who are familiar with their

habits, show no signs of emotional stress, it was not possible to study the effect of that factor in the production of peptic ulcer.

Three groups of dogs were studied. The first group was given 2.5 milligrams per dose up to 37 days. The second group was given 2 milligram doses of histamine over periods varying from 63 to 66 days. The third group was given a mixture of pilocarpine and histamine in doses of 2 milligrams each for periods up to 58 days. Injections were given every two hours for 10 doses daily after which the dogs were given a "smooth" ground diet. Gastric analyses, throughout the 24 hour period, were made one to three times a week. At the completion of the experiments the animals were sacrificed, and careful autopsies were performed. Sections were made of the liver, kidneys, adrenals and stomach.

Most of the dogs in the first group showed no change throughout the intestinal tract except a slight injection of the duodenum in some cases. None of the dogs in the second group showed chronic ulcers in the intestinal tract at the completion of the experiment; some showed small superficial erosions. In all of the dogs in that group a high free acidity was found throughout the experiment. In one of twelve dogs in the third group a small erosion was found in the stomach. The intestinal tracts of the others were found to be normal. The liver, kidneys and adrenals were found to be normal in all dogs excepting those receiving obviously toxic doses of the drugs.

The Authors conclude that hypermotility of the stomach in combination with high acidity, as produced by pilocarpine and histamine, respectively, does not produce chronic peptic ulcers in the dog.

A large bibliography accompanies the article.

## SECTION VI—*Abdominal Surgery*

### Experiences with Postoperative Jejunal Ulcer and Gastrojejunocolic Fistula\*

By

FRANK H. LAHEY, M.D.†  
BOSTON, MASSACHUSETTS

THERE are probably no two subjects today about which there has been a wider divergence of opinion or a more diametrically opposed attitude than that of the advisability of employing subtotal gastrectomy in the surgical treatment of intractable duodenal ulcer‡ as opposed to gastro-enterostomy and the incidence of postoperative jejunal ulcer following gastro-enterostomy.

In a recent review of the literature on this subject, we found the incidence of gastrojejunal ulcer after gastro-enterostomy reported as low as 1.7 per cent (Walton) and as high as 24 per cent (Strauss, Bloch, Friedman) and after gastric resection as low as 0.4 per cent and as high as 10 per cent.

Such a wide variation in figures on the part of men with experience must of necessity be due to irregularities in methods of arriving at these conclusions such as, whether or not diagnoses of gastrojejunal ulcer were made by actual demonstration of the lesion at operation, in which case the diagnosis is established with certainty, or whether or not the diagnosis was made from symptomatology and by X-ray, in which event in at least a considerable number of cases, it has been our experience that the diagnosis must be in doubt. All of these figures represent just patients upon whom gastro-enterostomy has been done, with no attempt to separate (if it is a possible undertaking) those patients with recent ulcers from those with longstanding ulcers, the young people with high acids from the older individuals with lower acids, those patients with pyloric obstruction from those with a patent pylorus and those patients with repeated histories of bleeding and so the posterior wall eroding ulcers that are notably difficult to manage by any method of treatment. Likewise, these figures include impartially those patients who have had good postoperative dietary management with those who not only have had none but have resumed the habits of life which played a considerable part in the production of the ulcer.

The figures for recurrent ulcer following subtotal gastrectomy represent a massed group of postoperative results in which no segregated data is available as to whether the resection was a radical one calculated to be followed by a low gastric acidity or anacidity,

or what amounts to a pylorotomy, probably to be followed by a higher gastric acidity.

With the above stated variables present, it is only possible to arrive at what amounts to approximate conclusions concerning the incidence of this lesion; but as more and more time passes after the era during which there was an unreserved enthusiasm for gastro-enterostomy as a method of treating gastro-enterostomy, it becomes more and more evident to us that while one cannot state in accurate figures the percentage incidence of gastrojejunal ulcer after gastro-enterostomy, nevertheless so many patients are presenting themselves at our Clinic with this lesion, together with the accumulating data, (see particularly the recent report of seventy-nine carefully followed cases by Hinton with 16 per cent gastrojejunal ulcer, six by operation and seven by careful X-ray study) and the depressing experiences of Graham with forty-three carefully followed postoperative cases, that we are convinced that gastro-enterostomy is not a justifiable routine operation in the surgical treatment of duodenal ulcer. We are further forced to this conviction by our operative experiences with this condition.

We have operated upon thirty cases of gastrojejunal ulcer and gastrojejunocolic fistula with a mortality of 15 per cent. This mortality rate represents approximately the average mortality rate for this condition. With an increasing background of experience, this rate can perhaps be lowered somewhat but when one deals with a lesion as complicated as this one is, high in the upper abdomen where the risk of surgery is great, in patients often in poor condition, requiring complicated technical procedures that consume long periods of operating time and which are known to be followed by a high percentage of pulmonary complications, there will always be here, I believe, a disturbing mortality rate.

Of the thirty cases, ten had excision of the gastro-enterostomy together with the ulcer, anastomosis of the jejunum and reestablishment of the alimentary tract to its normal course, that is, without subtotal gastrectomy. In all of these cases, the original duodenal ulcer was found to be healed but following the excision of the jejunal ulcer and the gastro-enterostomy, either the original duodenal ulcer has been reactivated or a new one has developed in 40 per cent of the cases.

†Approved by the Publications' Committee of the Association.

‡Lahey Clinic, Boston.

§There is little or no conflict of opinion regarding subtotal gastrectomy for intractable gastric ulcer.

From this experience, together with that of Graham who reports that in three cases in which the gastro-enterostomy was taken down, the gastrojejunal ulcer removed and the stomach restored to its original state, all are now suffering severely from duodenal ulcer symptoms, it seems to us that this is not a satisfactory surgical procedure for the treatment of gastrojejunal ulcers. He also reports that in twenty-eight cases with pyloroplasty for duodenal ulcers, postoperative X-ray studies showed constant hypermotility and no brilliant surgical cures.

We have had eight cases of gastrojejunal ulcer proven by X-ray and histories that have been conditionally treated medically. Three are well, six, eight and twelve months after first being seen. One has gone four years but has had severe ulcer symptoms fairly controllable by treatment. One has been under observation but six months and is unable to work, one died of perforation two years after the beginning of his treatment, two are free from symptoms but have had hemorrhages, one two years after treatment and one four years after treatment.

While the outlook for medical treatment of gastrojejunal ulcer is far from satisfactory, it must be admitted that contrary to what used to be our opinion, it is possible to carry some patients with gastrojejunal ulcer along with fair satisfaction under non-operative forms of treatment.

It is of interest to know that in none of our demonstrated lesions was the gastrojejunal ulcer truly gastric, being jejunal but marginal in location in 75 per cent of our cases and completely jejunal in 25 per cent.

Starlinger reported from the literature, one hundred and fifty cases of perforation in gastrojejunal ulcer. On the basis of twenty-five hundred cases estimated by him to be in the literature, he considered the percentage of perforation after gastro-enterostomy as 5.6 per cent and after resection 3.3 per cent. The percentage of perforation in our series was 9 per cent and the percentage of hemorrhage in our series 13 per cent as opposed to 18 per cent in our patients with duodenal ulcer.

When one considers the causative factors of gastrojejunal ulcer, one must, I believe, consider hyperchlorhydria as the factor occupying a position of first importance. Gastro-enterologists are so acutely aware of the relationship of increased gastric acids to ulcer and particularly gastrojejunal ulcer that I do not need to do more than mention some of the evidences of its quite constant linkage with this lesion.

Gastrojejunal ulcer is rare in women who have lower acids than do men.

It almost never occurs in gastro-enterostomy for carcinoma of the stomach.

In our series of gastrojejunal ulcers, the lesion followed gastro-enterostomy for duodenal ulcer in 90 per cent of cases and for gastric ulcers in 10 per cent. This is quite suggestive in view of the high acids in duodenal ulcer and the lower acids in gastric ulcer.

Of further significance is the so often proven fact that the lower down the jejunum one places these anastomoses to the stomach and so the farther away from the segment which has adapted itself to receive acids, the easier it is to produce experimental ulcers.

until they can be quite regularly produced in anastomoses made to the ileum.

Surgical technique has often been reproached as a causative factor in gastrojejunal ulcer but in my opinion has little if actually anything to do with it and I will set down a few reasons why I believe this to be true.

It used to be said that the employment of silk or linen in the suture line of the anastomosis between the stomach and the duodenum because it acted as a foreign body, was the cause of these ulcers and this position was strengthened by the fact that strands of silk would be found hanging in the beds of those ulcers where erosion had taken place about the foreign body. Because of this feeling, all non-absorbable suture material has now for several years been given up and only catgut used by almost all surgeons and yet the percentage of gastrojejunal ulcer remains just as high. As has been said the silk or linen is not the true offender but just an innocent bystander.

It used to be said that gastrojejunal ulcers were caused by too tight gastro-enterostomy clamps but just as many ulcers now follow gastro-enterostomy done without clamps.

It used to be said that these postoperative ulcers followed operative trauma to the suture line, but the entire question of the relationship of operative trauma to gastrojejunal ulcer is largely eliminated by the fact that gastrojejunal ulcers occur fifteen to twenty years after gastro-enterostomies and so are quite definitely unassociated with any question of relationship to operative technique.

In a group of fifty cases of gastrojejunal ulcer taken at random, the average time of recurrence was two years and cases of gastrojejunal ulcer have been reported as occurring from a few weeks after gastro-enterostomy up to twenty-one years. The longer a patient with a gastro-enterostomy for peptic ulcer goes without a gastrojejunal ulcer, the less likely he is to have one. Nevertheless, the occasional development of such a lesion years after operation indicates that he is never free from the possibility of the occurrence of such a lesion.

There are certain signs and symptoms in patients who have had gastro-enterostomy for peptic ulcer which point strongly toward the diagnosis of this condition. If a patient has had duodenal ulcer and the symptoms have been relieved by a gastro-enterostomy and then recur and with greater intensity, one must be extremely suspicious that the symptoms are due to the occurrence of a gastrojejunal ulcer. As the result of our experience with these conditions, we are impressed with the fact that in practically every case in which we have had the opportunity to observe the original duodenal ulcer after gastro-enterostomy, it has been found to have healed. We are of the opinion as the result of these observations that it is very much more common for a gastrojejunal ulcer to occur following a gastro-enterostomy than it is for the old duodenal ulcer to be reactivated. If the original point of tenderness in the right upper quadrant following the recurrence of ulcer symptoms in the presence of a gastro-enterostomy shifts to the left of the umbilicus over the gastro-enterostomy stoma, it is strongly suggestive that this tenderness is the result of a gastrojejunal ulcer.

Symptoms of perforation in a patient who has had a gastro-enterostomy should make one extremely suspicious that the perforation is of a gastrojejunal ulcer and not the original duodenal ulcer. When a gastro-enterostomy has been functioning and then ceases to function and closes, one should be suspicious that this closure is the result of the inflammatory reaction associated with a gastrojejunal ulcer.

Hemorrhage late after gastro-enterostomy while less suggestive than some of the above mentioned factors, must nevertheless be considered distinctly a possible indication of the presence of a gastrojejunal ulcer.

While I have often employed the Hibernianism regarding the prevention of gastrojejunal ulcer, that the best prophylaxis against gastrojejunal ulcer is not to do a gastro-enterostomy, nevertheless, gastro-enterostomy must occasionally be employed, in which case the only prophylaxis is the realization by the patient of the real likelihood of his having such an ulcer, the real seriousness of such a lesion if he has it and the need for the rest of his life to modify his living, eating, smoking and drinking habits.

There are certain features about gastrojejunal ulcer which are quite universally accepted. The lesion is undoubtedly very apt to occur in young people, with duodenal ulcer, who have high gastric acids. Its incidence is increased if in addition to a gastro-enterostomy, the pylorus is occluded, thus preventing the return of alkaline duodenal contents into the stomach. It is likewise more apt to occur after a gastro-enterostomy if enterostomy is done between the two loops of the jejunum, thus sidetracking the alkaline jejunal contents and preventing their return into the stomach through the gastro-enterostomy stoma. While anterior gastro-enterostomy must be made with a long loop of jejunum up over the transverse colon, and so at a lower jejunal level more susceptible to ulcer, there are no really convincing figures to prove that this is so. Unconventional as the position may be, I must as the result of my experience with the gastrojejunal ulcer state that if I had to have a gastro-enterostomy for duodenal ulcer, I believe that I would feel safer with an anterior one than with a posterior one. I take this position because I feel sure that the surgical management of a gastrojejunal ulcer in an anterior gastro-enterostomy is safer and easier than it is in a posterior gastro-enterostomy.

As the result of our experience, I am more and more convinced that the best operation for gastrojejunal ulcer is the one which results in the lowest percentages of gastric acid postoperatively and that undoubtedly is subtotal gastrectomy.

While it is my conviction that many skeptics (and I have been one) will with increasing experience have, as have I, the above conviction forced upon them, still the problem remains an extremely serious one. The operation is a very difficult one technically. Familiarity and facility with its performance requires a considerable experience with it and even in spite of this, my own mortality is far from a comforting one. Patients who are candidates for such serious operations are often in poor condition, the operation is necessarily long and postoperative complications are inevitably associated with it. In spite of these non-reassuring observations, progress may still be accomplished in these patients. In another paper on this subject, I stated that I was a little disturbed to make the follow-

ing statement but the oftener I make it, the less self-conscious I am about it.

We must make clear to all patients, particularly with duodenal ulcer, that indirect operative procedures which have a relatively low mortality rate, are followed by a relatively high percentage of postoperative ulcers, that these ulcers are intractable to non-operative measures and have associated with them a relatively high mortality rate in their satisfactory surgical treatment; that the surgical operation which is followed by good results and a low percentage of recurrent ulcers has a relatively high mortality rate and that with the above in mind, doctors must advise and patients must adhere to an extremely strict non-operative ulcer regime. If this is done, and surgery becomes necessary, then the lesion simulates that of malignancy and the risk becomes unquestionably justifiable. If the regime is advised and adequate, but is not pursued, then the responsibility places itself squarely where it belongs. If on the other hand, patients are permitted to believe that peptic ulcers are not serious lesions, that the surgical treatment of this condition is quite satisfactory and that permanent changes in eating, drinking, smoking and living habits are not necessary, then the ultimate responsibility for the unhappy situations which are bound to arise in patients with ulcer will be largely upon the shoulders of the medical adviser.

#### DISCUSSION:

DR. L. J. AUSTIN (Kingston, Ont.): The last two papers combined must indeed make us feel extraordinarily unhappy. We are between the Scylla and Charybdis of obesity and dyspepsia, and, as far as we can see, the obesity has the advantage. There are some tremendous advantages in being eupeptic; I am.

We heard last night at dinner a discussion of the history, of the technique, of gastro-enterostomy, its variations, the different sorts of sutures, the dangerous, and some of the immediate rather than the remote sequelae of these operations, and I suppose there isn't a surgeon of today, even in a big clinic, who doesn't sometimes, occasionally hit up against an obstruction case, or, if you prefer to call it a vicious circle; and there is no question that gastro-enterostomy gives us furiously to think.

Now, when I was a student, I served my time under some of the pioneers of gastric surgery in London, Mr. Mansell-Moullin, who did not write much about it, Mr. James Sherren, who certainly was a pioneer in gastric surgery in England, and also under Mr. Albert J. Walton, who was only a few years senior to myself but had the good fortune to be on the staff while I was still an intern—there is a great deal of difference in that, you know—and he certainly was a beautiful technician, and is still a beautiful technician; and during the time in which I was a sort of junior staff man, what we called "registrars," I made a fairly intensive study of those cases operated on by my chiefs, and they didn't all come out quite so successfully as I had hoped.

You will remember when the plain gastro-enterostomy was introduced, it was thought to be a panacea for all stomach troubles—a little weeping hemorrhage, gastritis following several days of, you know, the night before, and for the relief of all forms of gastric and of duodenal ulcer; but, as Dr. Lahey has shown us today, surgeons and physicians have gradually come to the conclusion that that is a very mistaken idea, that gastro-enterostomy has but a limited application.

The first change I noticed was that it began to filter into the minds of some people that gastro-enterostomy, a plain gastro-enterostomy, would not be very successful

unless it was a degree of obstruction, and I think it was from some of the very successful cases of obstructed pylorus due to ulceration, and to the great relief obtained in many of the cases of carcinoma with obstruction, that the blocking of the pylorus was adopted, in a measure to make an artificial obstruction so as to insist upon the sterner work.

The technical difficulties of doing a gastro-enterostomy are not really, I think, to be lightly thought upon, and no surgeons who are growing up in any school should be allowed to dash off and do gastro-enterostomies, alone and by themselves without a certain amount of training. There is a danger of men, what you might call "gnawing up" patients, without adequate training. We all know that happens, and the attempt in the old lands, as you probably all know, is to build a specialized class of privileged surgeons, those who have the fellowship. I don't say that because a man has a Fellowship of the Royal College of Surgeons, he is naturally a God-given operator; he isn't, by a long ways, but it does mean that at one time in his life he knew his anatomy—I don't say he does now, but he did once. And even that is an advantage. It is because of the difficulty of standardization and of specialization, that both your medical association and our own Canadian association are very much troubled about this question of specialists, and we cannot expect the law to help us.

I have struggled myself very hard to find out what are the legal privileges of a doctor in the Province of Ontario. I can't find it out, but I know they are very restricted in the old land. When we were qualified in the College of Surgeons with a degree of Member of the Royal College of Surgeons and Licentiate of the Royal College of Physicians, an ordinary, qualifying, examination, we were taken into a big room, and there was a throne in it, and the President of the Royal College of Surgeons was there in his robes, and the Board of Examiners on each side of him, and after a very few remarks not lasting more than half a minute, congratulating the boys on having got through, he said, "The Secretary will now read to you the legal privileges of a medical man."

Then the Secretary got up and said, "The legal privileges of a medical man in England are four:

- (1) "You can sue for your fees in a court of law." (You all know what happens if you do that!)
- (2) "You cannot be called to serve upon a jury." And that certainly applies. We can't be called to serve upon a jury.
- (3) "You are not liable to the militia ballot"—and when the Great War came on, we were conscripted with the rest.
- (4) And this doesn't apply nowadays very much—"Your horse cannot be taken for a fire engine."

I had the permission of the Chairman to wander a little off the subject, and I wandered off deliberately because I have not had—and it is no good saying I have—enough cases to add to the statistical importance of Dr. Lahey's report. All I know is that the cases of fistula that I have had to deal with, are, I think, most of them, happily buried now, and there is no question that it is our bounden duty, I think, to see that our patients with duodenal ulcer have the really finest medical treatment possible before they are submitted to surgery.

Sometimes you can cure them, as our President does, with tubes, and then has one done on himself. Sometimes you can suffer and then finally decide to have tubes. But I think we must admit that medical treatment is the logical and reasonable thing to try, that gastro-enterostomy, applicable as it is in some cases, is more or less an adventure and carries with it certain grave and serious risks.

To say I am happy about doing gastro-enterostomy is absurd, and I think that my attitude towards the whole

matter might be summed up in the few words of Cardinal Woolsey, in Shakespeare's "Henry VIII":

"I have ventured,  
Like little wanton boys that swim on bladders,  
This many summers in a sea of glory,  
But far beyond my depth."

DR. PAUL W. ASCHNER (New York, N. Y.): It is with some sense of gratification that we hear Dr. Lahey express himself today as he did, as unwilling and unhappy when he has to do a gastro-enterostomy for duodenal ulcer.

Now it would be almost presumptuous to go into a discussion of the underlying fundamental cause of jejunal ulcer when we do not know the underlying fundamental cause of duodenal ulcer; however, there are certain factors that we do know from experience and study. One is that there is such a thing as gastritis and duodenitis; that it is in all likelihood the predecessor of ulcer and that even after we have attacked the ulcer surgically, it is quite possible for that process to go on in the remaining portion of the stomach which we leave behind when we have done a subtotal resection, or which we certainly leave behind when we do a gastro-enterostomy, and that, moreover, the same process may appear in the jejunum.

We also know from some of our studies that the disease of gastritis and duodenitis is one which has a tendency to undergo, in the course of time, a recession with diminution of the activity of the glands of the stomach, and lowering of the acidity. The cases possibly favorable for gastro-enterostomy are those which have a low acidity, and in which the obstruction of the pylorus is not due to an acute inflammatory edema about an active ulcer, but in which there has actually been such a recession of the disease that scar formation and cicatrization have taken place. In these cases we are no longer dealing with ulcer and ulcer disease, but rather a mechanical obstruction.

There is one thing of interest in this connection I want to point out. Jejunal ulcer does not occur when a gastro-enterostomy has been performed in a patient who did not have a duodenal ulcer, or a gastric ulcer to begin with; in other words, it is the underlying disease which predisposes.

The dangers of the secondary operation when jejunal ulcer has occurred—and I might say by the way, Dr. Lahey, that in our experience we find jejunal ulcer, much more common than marginal, and frequently multiple—the dangers are many, in the technique of operating these cases.

As to the mortality to be arrived at in secondary resections, Dr. Lahey once made a very fine suggestion. I don't know whether he is still following it. It was to divide this operation into two stages, to take down the gastro-enterostomy closing both sides as one stage, and at a second stage to do the resection of the stomach to prevent the patient's getting the duodenal ulcer he is certain to get if resection is not carried out.

DR. B. B. VINCENT LYON (Philadelphia, Pa.): The Chair would ask permission to make the following remarks:

You have noticed that in this year's program, we purposely dodged the acceptance of all papers dealing with peptic ulcer, gall bladder disease, and, to some extent, colitis, because of the continued confusion in properly handling the discussion of such topics.

I should like to point out, as all of you who go back thirty or thirty-five years will remember, that we were taught that peptic ulcer could be cured surgically by gastro-enterostomy alone, or medically by the Sippy method or other medical regimes. You have seen for yourselves what has happened in regard to this subject over that twenty-five, thirty, or thirty-five years.

This problem, gentlemen, is today just as unsolved as it was when we were given the answers to it in that day. I speak of this to point out to you the need of what I suggested yesterday, a national research institute devoted

solely to the solving of gastro-intestinal problems, by which scattered views can be assembled and a concentrated attack made on one common problem chosen in a proper way.

DR. FRANK H. LAHEY (closing the discussion): I appreciate that this subject of ulcer is a trite one. At any meeting, it always occasions a great deal of discussion. I appreciate also the muddle in which the entire peptic ulcer situation is, and I particularly appreciate how difficult it would be for anyone who has a duodenal ulcer after listening to this discussion, to arrive at some definite plan of approach.

I was very much interested to hear Dr. Lyon's personal experiences with gastro-enterostomy. It is nice of him to be willing to state them.

When Dr. Aschner discussed my paper, I presumed I was in a group of medical men, and so I asked Alfred Strauss if Dr. Aschner was a surgeon, and he said, no, he was a medical man which turns out not to be true. I was about to tell the story, if he had happened to be a medical man, about a colored man named Jake who worked for me in the South, where for several years I have had a shooting place.

One day a colored hobo arrived at the plantation via freight train and he was a type not uncommon in the South with long, thin legs, with no muscles, all bone, and in our part of the South that type is called a "shinbone nigger." He was sitting on the porch of the little country grocery store on a box, with his pantaloons pulled up, and his bare, thin shinbones sticking out, and Jake, sitting beside him in the sun, leaned over and looked at his legs and said, "Dave, has you ever had de dropsy?"

And Dave said, "No, Jake, I ain't never had de dropsy. What for does you ask me has I had the dropsy?"

And Jake said, "Well, I was going to say, has you ever had the dropsy, you're the cured-est nigger of it I is ever seed."

I was about to say if Dr. Aschner was a medical man, he is the surgical-est medical man I have seen.

Now, while I do not want to discuss surgical technique, there is one thing I would like to say: I would urge those of you who watch gastro-enterostomies, if they are ever done, to beg the surgeon to do a reasonably long loop gastro-enterostomy and he will thus make it easier for the next surgeon when he deals with a gastrojejunal ulcer.

I know of nothing which has caused me greater distress and which has resulted in more mortality than having to operate upon patients with gastrojejunal ulcer who have had a no loop gastro-enterostomy. This has compelled me

to do an end to end anastomosis on a jejunum with only a half an inch of that structure intraperitoneal.

As to subtotal gastrectomy, I make this as an admission, because I was an opponent of subtotal gastrectomy, I think all of us should frankly admit that we owe to Finsterer, Harberer, Strauss, Berg and others a debt of gratitude for adhering in the face of criticism to the position that subtotal gastrectomy is the best operation for patients with intractable peptic ulcer. It is true that we have assessed gastro-enterostomy after thirty years and, to be fair, we must likewise assess subtotal gastrectomy after thirty years, but at the present time, we surgeons who receive these patients from you when you have exhausted non-operative measures, must take a position; subtotal gastrectomy, as one acquires the technique of the operation, is, I am convinced a better operation than is gastro-enterostomy.

Sometimes my surgical friends say, "I don't have jejunal ulcers." That is wrong. The reason is that they do not have personal follow ups. Until you get a personal follow up by someone not interested in what the incidence is, and who is critical about the end results and who does accurate studies, you do not find out what your incidence of gastro-jejunal ulcer is.

There is one criticism of the medical man I should like to make and it is a mild one. We all hesitate to admit defects even in methods of treatment. I do not believe that the poor patient really gets a fair deal when you help him make the decision about what he will do with his ulcer unless you frankly tell him that medical treatment and surgical treatment are far from what we would like them to be, I mean in the terms of high percentages of cures and non-recurrences. About everyone at the end of five years today admits around 50 per cent good results, in the medical and surgical treatment with ulcer, excepting the patients with subtotal gastrectomies.

I think if you do not say to these patients, "Medical treatment is far from satisfactory and surgical treatment likewise," how can he ever take his responsibility as to the non-operative treatment of his ulcer seriously? Certainly he approaches the subject today from the point of view that it is not a serious lesion. The man with a duodenal ulcer takes it very lightly. He even takes his hemorrhages lightly and that is wrong. If he is going to die from these lesions as a result of perforation or hemorrhage, and he is, or as a result of jejunal ulcer or subtotal gastrectomy, and he is, then the just thing to do is to impress upon him first the seriousness of peptic ulcer, and the need for accurate medical management of his ulcer. If he then does not adhere to his regime, the responsibility for recurrence or a fatality is his.

## ABSTRACTS

*Cholecystectomy in the Absence of Stone. Editorial from Lancet, 227, p. 1112, Nov. 17, 1934.*

Cholecystectomy in the absence of calculus or severe infection is no longer a dangerous operation. Hence the question raised is not the mortality of the operation but the benefit to the patient.

In Mackey's analysis of 149 cases of cholecystectomy for disease of the gall bladder without calculus 41 were cured and 44 were improved. Cholecystography was shown to be of value in predicting the success of the operation only when it showed deformity. Where the patients had suffered from attacks

of colic the operation was of value as 76 per cent were improved. Cases suffering from gall bladder dyspepsia (flatulent dyspepsia, food selection, and constipation) were disappointing and Mackey doubts whether it is justifiable to refer such symptoms to the gall bladder. Where there is no gross lesion such as catarrhal or fibrinous inflammation cholecystectomy gave relief in only 11 out of 57 cases.

In cholesterosis where the "strawberry" gall bladder (i.e. the mucosa covered with deposits of cholesterol) is found, it has been argued that removal is justifiable on account of impaired

absorption. However, it has been shown that tying the cystic duct does not prevent the deposit of cholesterol on the inflamed mucosa of the gall bladder in rabbits on a high cholesterol diet, hence the fallacy in such reasoning. In conclusion Mackey sums up the situation by saying that cases with well defined symptoms are likely to do better after the operation than those in whom the symptoms are vague, and, similarly, the removal of a definitely pathological gall bladder is generally more productive of gratifying results than is the removal of a gall bladder in which the microscopic appearance is equivocal.

John T. Day, Montreal.

## SECTION VII—*Surgery of the Lower Colon and Rectum*

### Traumas Resulting from Sigmoid Manipulation \*

By

BURRILL B. CROHN, M.D.

and

BERNARD D. ROSENAK, M.D.†

NEW YORK, NEW YORK

**P**ERFORATING wounds of the rectum and pelvic colon occur either in association with penetrating or crushing wounds of the abdominal wall or through the purposeful or accidental introduction of instruments or foreign bodies through the anus. Wounds of the first type include traffic and industrial injuries as well as gunshot and stab wounds. This type of injury has been amply covered in the surgical literature.

Our interest at present lies in the second type of injury; that is, those produced by the insertion of an instrument or a foreign body into the rectum. These injuries are of importance, not because of their frequency in civilian life, but because of the professional usage (for diagnostic and therapeutic purposes) of introducing various instruments into the rectum and sigmoid. The possibility of injuring the rectum and colon in the course of such procedure has been widely rumored; hitherto no compilation of data on this subject has been available in the American literature. This type of accident does not cause the majority of cases of traumatic rupture of the intestines, as was shown by Cooke (1), who reviewed seven hundred odd cases of penetrating wounds of the intestine, practically all of which were due to crushing and penetrating wounds of the abdominal wall and perineum. Accidents due to therapeutic and diagnostic procedures do constitute an important minor portion of such injuries which have never received recognition or proper emphasis; a frank and open admission of such facts should lead to an appreciable reduction of the incidence of this lamentable mishap.

Amongst civilian injuries which may cause perforation of the colon are impalements, insertion of foreign bodies into the rectum, and pneumatic injuries.

*Impalements* are accidents in which the body falls vertically upon a sharp or pointed object, driving it into the rectum. These accidents are seen not infrequently in civilian life, occurring commonly among children. They are associated in most instances with considerable injury to the external parts as well as with laceration and perforation of the colon. Rumbaugh reviewed 147 cases of impalement injuries of

the rectum and colon. Of this number 44 were treated by laparotomy and 29 or 66% recovered. Of the remaining 102 unoperated cases, 43 or 41.7% recovered.

One not infrequently hears of serious lesions, often perforations of the colon, produced by the *insertion of foreign bodies* into the rectum. The variety of objects which have been introduced into the rectum is astounding. Bottles, broomsticks, projecting knobs of furniture, hardware appliances and many other devices may be found in the rectum under varying circumstances. The commonest occurrence of this accident is in instances of ano-eroticism, although it has occurred in cases of criminal assault and occasionally in so-called "pranks." The practice is doubtless widespread; the reported cases of serious traumatization are probably small in proportion to their actual incidence.

A not very frequent, but always well publicised accident is the pneumatic or air-hose injury of the rectum and sigmoid. Andrews (4), in 1911, reported 13 such injuries and many more have since been published. Some authors have attempted to determine the amount of air pressure required to perforate the colon. It will be shown later that this pressure need be no greater than that produced by a hand bulb. However, injuries produced by hose lines carrying air under great pressure are always more severe, the perforations being nearly always multiple, occurring for the most part, in the pelvic colon. The 13 cases reported by Andrews (4) were all fatalities. Since then many such cases have been saved by prompt surgery. Our own experience is limited to one case, an individual who, 5 years previously, by the mischievous insertion of an air-hose into his rectum, had suffered multiple perforations of his pelvic colon. At that time the injuries had been minimized by the physician called in the emergency and castor oil was freely administered; notwithstanding which, a laparotomy the succeeding day resulted in a protracted convalescence and eventually a complete restoration of function.

The force exerted on the bowel wall is always in excess of that required to penetrate it and the perforations are frequently multiple. Such perforations occur in the majority of instances at or about the recto-sigmoid angle because this point is more or less fixed

\*Presented at the 35th Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., June 10-11, 1935.

and because the colon here becomes an intraperitoneal organ. Lesions which diminish the mobility of the sigmoid, such as post-operative adhesions and localized peri-colonic inflammations have been regarded as contributing elements in the etiology of some cases of perforation.

#### INJURIES DUE TO DIAGNOSTIC AND THERAPEUTIC PROCEDURES

Professor Ad. Schmidt (5), of Munich, has said "One hears much of the skill and the ability of the physician and surgeon, but much less is heard or read of the misfortunes and accidents which occur in medicine and surgery, but from these we may often learn more." With this thought in mind we have attempted to determine, the approximate frequency with which injuries and perforations occur in the course of diagnostic and therapeutic manipulations within the rectum and pelvic colon; to learn, if possible, what factors in their execution are associated with threats of danger and what possible errors of technic may lead to the incidence of such injuries. The American literature contains very few references to perforations of the colon in the course of sigmoidoscopy, there being no instance of such a report by a man who himself was responsible for the accident. French and German physicians have been more frank and have freely discussed what technical errors to avoid in order to minimize the hazards of this procedure. They have also taught the means of early recognition of technical perforations of the sigmoid and have emphasized the prompt steps necessary to meet the situation when it occurs.

A general survey of the literature has been undertaken in order to emphasize the possibility of this trauma occurring at times in the hands of those best qualified to perform such examinations.

There have been 33 cases of instrumental perforation collected from the world literature. Of these, 18 occurred in the course of proctoscopy or sigmoidoscopy; several were due to dilatation of rectal strictures, others due to the introduction of enema tips and one to fulguration of polyps. Most of the sigmoidoscopies were done by physicians; some by qualified experts, others by inexperienced general practitioners or assistants, and others were done by irregular practitioners of little experience. Anyone who does sigmoidoscopies may perforate the bowel. However, relatively few of the cases reviewed were done by experts and these were for the most part in patients who had diseased colons. Proper training under the guidance of one qualified in this field, and considerable personal experience are essential to make one a safe sigmoidoscopist. It is not true that every medical graduate is qualified to do this work or that owning a sigmoidoscope makes one a sigmoidoscopist.

In addition to a survey of the literature direct contact by questionnaire was made with 27 recognized proctologists and gastro-enterologists in the United States. A total of 21 perforations due to sigmoidoscopy were reported by this group. Of this number 5 were actually done by these specialists, 7 by assistants, and 5 perforations were seen in consultations. No data was submitted in the 4 remaining cases, except the bare recital of the occurrence. In most of the cases, the colonic wall had been weakened by the existence of carcinoma, ulcerative colitis, or diverticuli-

tis. In one of the cases reported by questionnaire and followed, the perforation was due to the fulguration of a polyp.

In addition, one of us, (B. B. C.) has had personal experience with two perforations and has indirect

knowledge of two more. The first instance occurred in the course of a routine sigmoidoscopy in which there was no disease of the colon; the patient was co-operative, the sigmoidoscopy was performed with ease and without strain. The perforation occurred while using no undue force. The other instance occurred during the fulguration of a polyp. In this last case the perforation was not at first recognized, so that several enemata had been administered before the true situation was appreciated; free air under the diaphragm and a localized peritonitis removed any doubt as to the occurrence of the trauma. Both patients recovered.

The answers to the questionnaire indicate that perforation occurs more easily in the presence of a diseased colon. This is not uniformly true, many men having seen perforations in the presence of a perfectly normal colon. It is true that the amount of force or air pressure required to rupture a thinned-out, weakened or ulcerated bowel wall is much less than that necessary to rupture the normal bowel. However, numerous cases in the literature and personal experience in one case, (B. B. C.) are convincing that no great amount of force need be exerted to push the end of the sigmoidoscope through the colon, at or above the fixed point at the recto-sigmoid angle. A case quoted by Dick (6) illustrates the ease with which a manual perforation may occur.

The greatest number of perforations reported by qualified sigmoidoscopists have occurred with the use of air inflation apparatus. The use of a hand bulb, though helpful, has not been entirely safe. Originally condemned by French authors, it is now generally considered dangerous.

The importance of passing the sigmoidoscope under direct vision has been emphasized by Buie (7) and other writers. They have cautioned that the obturator of the instrument be removed as soon as the anus is passed; the progress of the instrument must be guided entirely by the eye. Failure to observe this funda-

mental rule, has without doubt, caused many perforations.

The need for a sound knowledge of the anatomy of the rectum and pelvic colon, and the importance of directing the sigmoidoscope along this anatomic course is a requisite factor to the performance of these examinations.

Experts have long regarded blanching of the mucosa as a sign that too much pressure is being exerted and as a warning that the instrument should be withdrawn from this point and reintroduced. Ultra-cautious physicians refuse to administer a barium enema or any type of enema following a sigmoidoscopy because of the danger of a possible unrecognized perforation. The prognosis for life is always much graver if an enema has been given following perforation. However, in the routine of many offices and clinics it is customary to perform a barium enema following the sigmoidoscopy so that the patient need undergo but one preparation for both examinations. When the sigmoidoscopy has been performed by a competent individual, in the absence of untoward symptoms, it seems reasonably safe to follow with a diagnostic enema.

Frequently one encounters difficulty in passing the sigmoidoscope into the pelvic colon of highly neurotic and tense individuals. In these circumstances, the examination should be postponed or foregone unless regarded as absolutely essential; no forceful attempt to enter the sigmoid should be made. In instances of ulcerative colitis it is not always essential to enter the sigmoid; only in cases of suspected carcinoma must the examination be complete.

### DIAGNOSIS

It is of utmost importance to make the diagnosis of perforation of the colon promptly. This, however, not always is possible; in many instances the examiner does not know when he has perforated the bowel wall; he is only warned of the accident by the patient's reactions. In certain instances the diagnosis can be made on objective evidence. Lockhart-Mummery (8) quotes the case of a physician who, upon removing the obturator, and looking through the sigmoidoscope, found his eye focused on a viscus which upon closer scrutiny proved to be the gall bladder. This is an unusual experience, yet others have similarly seen appendices epiploicae, the glistening surface of the peritoneum, or have noted peristalsis of the small intestines through the sigmoidoscope. Occasionally the rent itself has been seen or the rush of air upon respiration has been heard, giving evidence of the presence of a perforation. Bleeding is usually not observed and cannot be depended upon as a significant sign. A very valuable diagnostic sign is afforded by a flat X-ray plate of the abdomen in suspected cases. Air will be seen under one or both domes of the diaphragm in practically every instance. This examination should not be omitted in a case suspected of perforation during sigmoidoscopy.

The diagnosis on the basis of subjective symptoms is variable, the symptoms being of two types. Most patients complain immediately of sudden agonizing abdominal pain of such severity as to require repeated doses of morphine. Pain in these cases is soon followed by symptoms of peripheral circulatory failure, pallor, cyanosis, rapid, thready pulse and other familiar

symptoms of shock. This striking and dramatic sequence fortunately occurs in most cases of perforation and leaves no doubt that peritoneal shock had occurred. A smaller group of patients will manifest no discomfort at the time of the examination and will often leave the physician's office entirely unaware of any unusual circumstance, only to be seized with severe abdominal pain 12 to 24 hours later. Upon examining the patient at this time the signs and symptoms of peritonitis will usually be well marked. Under expectant treatment it is extremely rare that any patient who has suffered a perforation of the colon will escape peritonitis either general or local, and eventually all give the classic symptoms of this complication.

### TREATMENT AND END-RESULTS

Upon the recognition that a perforation has occurred during a sigmoidoscopic or other intra-rectal manipulation, there should be no delay in transferring the patient to the operating room. The type of operation will depend upon the discretion of the surgeon at the table. In cases in which there has been no delay, simple closure of the perforation has been successful. The procedure in "delayed" cases complicated by an active peritonitis cannot be bound by generalization and each case must be treated according to its own indications.

Records were obtained of 58 cases of perforation of the large intestine in the course of sigmoidoscopy or other intra-rectal manipulations. Of this number, 30 were reported in sufficient detail to enable derivation of certain facts regarding prognosis. Of these 30 cases, 24 were operated upon, laparotomy with closure of the perforation being done in each case. The mortality for this group of operated cases was 50%. Against this the mortality of the six unoperated cases was 66.6%. In 18 of the 24 operated cases the time interval between the examination and the operation was reported. Of this number 13 were operated upon within 7 hours of the accident; 7 lived and 6 died, making a mortality of 47%. The 5 remaining cases were operated upon between 7 hours and 72 hours after the perforation; the mortality in this group was 100%.

### SUMMARY

1. Perforation of the sigmoid as a result of diagnostic and therapeutic manipulation is not infrequent. 25 reported perforations in the experience of 28 physicians reveals it not as a rare occurrence.
2. Immediate recognition of the accident is mandatory in order to save life.
3. At best, with immediate operation, only 50% can be saved.
4. The trauma is not necessarily dependent upon a pathological process in the colon.
5. The accident does not necessarily imply faulty instrumental technic.

### DISCUSSION:

DR. CHARLES GORDON HEYD (New York City):

It is fortunate that from time to time we have an appraisal of certain commonplace diagnostic methods. I am always impressed in going to the scientific session to see complicated or simple instruments being sold to inadequately trained men, under high pressure salesmanship.

Many individuals will pass a sigmoidoscope who certainly wouldn't attempt to pass a bronchoscope or laryngoscope, and there is a tendency with our armamentarium of diagnostic procedures for men inadequately trained to attempt diagnostic maneuvers that are inherently associated with some danger.

I think a distinction must be made in sigmoidoscopy in the normal or alleged normal colon and one that is the site of the disease. By analogy it is difficult to perforate a normal uterus, and it is easy, extremely easy, to perforate a pathological uterus, and again here is a great clinical demarcation that the perforation of the normal rectum or sigmoid will be associated with almost an immediate agonizing pain, whereas the perforation through a diseased sigmoid or upper rectum may not be associated with an immediate agonizing pain.

At four o'clock in the morning a patient at Post-Graduate Hospital had a sudden agonizing pain. The previous day he had been examined by some six or seven individuals. Here again a warning should be uttered against the diagnostic exploitation of individuals. There is always some trauma in introducing the finger, and certainly in introducing an instrument. The patient was given some morphine, and here you have one of the ironies of medical accident. After a primary misadventure, there is a sequential list of further accidents.

The house doctor, not appreciative of the possible danger, ordered a colonic irrigation, and three quarts of a solution was given and about a pint returned, and still that didn't occasion very much inquiry; but at two o'clock in the afternoon, upon doing a laparotomy, the remaining two and a half quarts were found free in the abdominal cavity.

After a perforation occurs, the circumstances are set in motion for a peritonitis, and while it may be somewhat irrelevant to take up some of the surgical phases, I should like to bring to your attention certain recent contributions on the physiological mechanism of perforations and peritonitis, and particularly to suggest that you read W. Sampson Handley's paper on "The Treatment of Diffuse Peritonitis." (*British Journal of Surgery*, 12:47, 1925).

When a bowel is perforated, either grossly by instrumentation, or minutely by a pathological process, there is first a transudate which rapidly becomes an exudate. From these initiatory pathological changes there follow in rapid sequence: (a) an increase in the severity of the pathological reaction, (b) further attempts to arrest the spread of the infectious process by walling off, and (c) a breaking through of the barriers of the local peritonitis and the development of a progressive spreading, diffuse peritonitis.

Handley is of the opinion that intestinal obstruction is the outstanding feature in the death producing mechanism. In his paper he illustrates what he terms "ileus duplex," and demonstrates that intestinal obstruction occurs first as involving the terminal ileum and secondly as involving the sigmoid or intestinal colon. Dr. Handley advocates, therefore, as the treatment of this condition: (1) an anastomosis between the highest jejunal loop and the transverse colon as a means of overcoming the small bowel obstruction, and (2) a cecostomy to drain the large bowel. In our limited experience with this operation it has been most successful.

DR. JOHN L. KANTOR (New York City): It was stated that a knowledge of the anatomy was necessary to safeguard one against accidents in these cases. I don't think a knowledge of anatomy is of any great importance. If you think back to the days before we had electrically lighted instruments, you will recall being taught something like this: You introduce this proctoscope blindly, go two paces to the left, one to the right, three to the front, and so forth. As a matter of fact, you were actually guided by the patient's screams in your introduction, and not by anatomic knowledge.

What one really needs is one's eyes and a certain amount of judgment and experience. A proctoscope should be introduced under the guidance of the eye. As soon as the sphincter is passed, the need for the obturator is over. It is withdrawn and one uses the light and looks.

I think air inflation is used rather frequently and I wish to point out that air inflation is not desirable in the introduction of proctoscopes. What one needs is air, but that is provided for by the proper posture as was taught by Sims in pelvic examinations.

Next, to find the lumen ahead of the introducing instrument, it is wise to make use of long applicators, longer than the instrument, 12-inch applicators for 10-inch instruments. We provide these wooden applicators with cotton tips, and push ahead very gently to find the lumen.

Dr. Soper, of this Association, pointed out the relaxing value of magnesium sulphate. The applicator is soaked in a 25 per cent solution of magnesium sulphate and allowed to sink in and find its own way into the lumen.

Next comes the question of kinks. A kink is probably due to congenital bands or to adhesions. To my mind, it is very risky to try to go beyond a kink that cannot be readily passed. When such a kink is encountered, one had better call it a day and stop.

Now, the indications for proctoscopy are twofold. We look for either ulcerations or for cancer. If we are looking for ulcerations, we have usually seen enough when the first patch of diseased mucosa is reached. There is no advantage in going further.

In cancer suspects one would like to go the whole length, and heretofore it was important to do so. The old X-ray method left one in a fog, but now we have the oblique position of Stewart and the double contrast enema. These eliminate the need for taking undue risks with the proctoscope.

DR. BURRILL B. CROHN (closing the discussion): Scientific work requires an unbiased viewpoint and an impartial reporting of the findings and procedures in a given situation. Facts must be faced, not dodged. Frankness in difficult situations is always instructive and must eventually lead to the avoidance of the conditions which tend to lead to accidents.

Fifteen years ago, while performing a sigmoidoscopy upon a normal individual with a normal sigmoid and a cooperative patient, I was amazed to see the glistening peritoneal coat of the small intestine; I had been using no undue force, and was aided only by air inflation. The realization of what had happened prompted immediate operation, with fortunate complete recovery by the patient. For twelve years succeeding this mishap, several sigmoidoscopies a day were a regular routine.

Three years ago, in again a normal cooperative patient, some trauma must have resulted sufficient to give rise to a localized peritonitis. In this instance the patient left the clinic without complaining; only some weeks later did I hear of the result of an exploratory laparotomy.

Dr. Heyd mentions the subject of enemas following traumatic perforations. Any type of enema after perforation will materially increase the danger to the patient. There are however, instances where enemas have been given without fatal results, to-wit; I had the privilege of examining the following case:

Six or eight years ago a workman, while leaning over his bench, was approached by his associates in the shop and a pneumatic air hose was inserted into his rectum. He was examined by the company doctor at the time, who assured him nothing had happened to him and he was perfectly all right. He was given castor oil and was sent home and told to take an enema. Several enemas were given in twenty-four hours, and the man not improving,

he was taken to the Post-Graduate Hospital and was operated upon. He made an uneventful recovery.

In another case recently the fulguration of a polyp resulted in localized peritonitis under the diaphragm. The patient made an uneventful recovery.

The cases we have collected, twenty-five by questionnaire from the members of the American Gastro-Enterological Association advise us of the fact that perforations do occur and must be immediately dealt with. The seven-hour deadline seems to be very important. The 100% mortality after the seven hours seems very significant.

There is one more point I should like to make and that is that two of the largest clinics in the country reported they have no perforations. Whether perforation by a sigmoidoscopy is always avoidable I am not quite sure, but with extreme caution and care and being appraised of the dangers of the procedure, we may, in the future, possibly avoid all further perforations.

## Annual Abstracts of Protologic Literature

(May, 1934-May, 1935)\* By CLEMENT L. MARTIN, M.D., Chicago, Illinois

### ANATOMY

The investigations of various men doing post-graduate work in proctology at the University of Pennsylvania have given the following results: Confirmation of the presence of the "recto-sigmoid" one of the three arteries arising from the superior hemorrhoidal trunk, described by Pope in 1929; the demonstration by "duco" injections of lymphatic connections crossing the pectinate line; a posterior intersphincteric triangular space between the diverging fibers of the external sphincter (Brick's space) was demonstrated; the position of the branches from the inferior hemorrhoidal artery entering the posterior anal quadrant, described by Heller, was found to be approximately as defined by him. As to the sinuses reported by Hellwig, Tucker and Pope "they were partially demonstrated in a few specimens during routine examination in 1930, 1931, 1932, but credit should be given to these western workers since ours was incomplete and unpublished. At no time however were squamous cells of the stratified variety noted in our specimens, nor did we prophesy as to the importance of these ducts." In another study no longitudinal muscle fibers were found in the middle valve of Houston.

Through their examination of 161 patients, the recto-sigmoid junction, that vague and variable landmark, is located more definitely; they conclude, that although not exactly fixed it may be taken as being 6.6 inches from the anal margin, 5.4 inches from the ano-rectal line, 3.4 inches from the inferior valve, 2.2 inches from the middle and 1.4 from the inferior valve.

Milligan and Morgan describe the external sphincter ani as a trilaminar muscle consisting of a subcutaneous, superficial and deep portion. They describe the internal sphincter ani as a tubular muscle encircling almost the whole length of the anal canal. The inner surface of this ring is covered with mucous membrane, they state.

### AGRANULOCYTOSIS

This disease remains a matter of discussion. As to whether it is a definite disease entity, Jackson and Parker

state that discarding the extreme leukopenia secondary to sepsis, aleukemic leukemia, aplastic anemia, pancytopenia and leukopenias of certain metastatic bone tumors, arsenic, gold, and benzol poisoning, there remains what for lack of a better term may be called agranulocytosis, agranulocytic angina or idiopathic malignant neutropenia. . . . It is probably a disease entity.

Extreme leukopenia and neutropenia alone do not constitute valid criteria for the establishment of a single disease. Acute leukemia in the aleukemic phase may easily be mistaken for agranulocytosis, and agranulocytosis may shade into pancytopenia.

Cause: Amidopyrine is chiefly indicted. Madison and Squier, who first reported the drug as a cause, emphasize its important place in the disease, on the basis of further evidence. Although Kracke and Parker state "acetanilid can be ruled out as an etiological drug since there is no report of any case of granulopenia following the use of that drug alone," such cases were subsequently reported by the preceding authors. Dinitrophenol is reported by Dameshek and Gargill as another causative drug, and the barbiturates by Hertz. Fitz-Hugh lists 31 preparations containing amidopyrine, among them Allonal, Amytal Compound, Cibalgine, Neonol Compound, Neurodyne, Peralga and Pyramidon. The exact chemical structure of the responsible agent remains undetermined, suspected are the benzene ring, both the (NH) and (NH<sub>2</sub>) radicals and (NO<sub>2</sub>).

Jackson and Parker believe that overwhelming infections are the result rather than the cause of the disease. That allergy is of major importance has yet to be shown. Endocrine disturbances are questionable. Madison and Squier believe that those "who have developed allergic or anaphylactic hypersensitivity to amidopyrine" have the disease.

Amidopyrine and related drugs are of etiological importance in some cases but in other instances there is no such explanation.

Fisher presents two cases of agranulocytic angina in his article, one of which had barbiturates and amidopyrine, the other did not. He considers the latter "therefore belongs to that group of cases in which no etiologic factor can be determined."

Lotze studied cases of acute and chronic arthritis treated with amidopyrine to determine unfavorable secondary effects. In 5 cases the drug caused decreased diuresis.

*Editor's Note*—\*The annual compilations of important advances in Proctology arranged for the members of the American Proctological Society and published by that society for the convenience of its roster. To the Executive group of the society, as well as to the society's official Supervisor of Abstracts, Dr. Clement L. Martin, the Journal and its readers are indebted for the courtesy of here printing the abstracts. This annual survey of this special field of diagnosis and surgery appears elsewhere only in the Official Transactions of the American Proctological Society.

This change was reversible. One fatal case had marked amidopyrine intoxication and central nervous system manifestations. Predisposing factors he thinks were largely responsible for the effect in this case. His experience inclines him to continue the use of the drug in arthritis.

*Treatment:* As the exact etiology and pathology are still *sub judice*, diagnosis and therapy remain no more certain. As usual in such conditions general nursing care and hygienic measures are important. To stimulate bone marrow to produce granulocytes (to prevent maturation arrest of white blood cells at the stem stage), *Krackle* used 5-10 drops of turpentine as intramuscular injections,

*Henry Jackson* favors injections of pentonucleotide intravenously and intramuscularly. *Wm. P. Murphy* uses liver extract with good effect, *Dameshek* and *Gargill*, adenine sulphate.

Although the general condition of the patient, the oral lesion and blood picture are the striking aspects of this disease, as well as the almost invariably fatal termination, the subject has been again reported in a review of proctologic literature because of the anal or rectal ulceration which occurs in the occasional case. Blood studies in the unusual anal ulcer are advisable as well as caution in the use of certain post-operative analgesics.

## SECTION VIII—Editorial

*NOTE: The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Gastroenterological Association is in no way responsible for editorial expressions.*

### THE GREAT VALUE OF SOME PHYSIOLOGICAL OBSERVATIONS ON MAN

THERE are many occasions when a surgeon operating under local or regional anesthesia can make observations of tremendous value to clinicians, and particularly to gastro-enterologists. Any internist with a large material is seeing every month patients with abdominal pain that has not been relieved by one or more operations on appendix, gall bladder, pelvic organs, or stomach. Sometimes, then, the question arises, can anything be accomplished by interrupting the pathways of pain? Can they be cut or would it be possible in the case of mixed nerves to apply alcohol which can block sensory impulses without causing too much injury to efferent fibers?

One great difficulty in the way of attempting this sort of thing has been that, after all these centuries of anatomic research, neither the anatomist nor the physiologist nor the neurosurgeon always knows exactly where to cut. Doubtless much knowledge will come, but it may be that always there will be some doubt and difficulty because the pathways in man are somewhat different from those in nearly related animals, and worse yet, the pathways in one man are likely to be somewhat different from those in another. Even more perplexing is the fact that when the normally used pathway is interrupted in a highly sensitive person, new paths sometimes will form in order that the patient can go on with his torture.

With these thoughts in mind, it is particularly stimulating to find notes like those published recently by *Adson* (Proceedings of the Staff Meetings of the Mayo Clinic, 10:623-624, 1935) who, while operating on an intelligent man under spinal anesthesia, laid bare the splanchnic nerves and the celiac ganglion. It is well known that in dogs, the splanchnic nerves are exceedingly sensitive to injury, and it is thought that most sensations of pain coming from the upper abdomen reach the brain along these two big pathways. In the patient operated on by *Adson*, the mere sponging of the splanchnic nerves with a small cotton tampon produced excruciating, lancinating pains in the posterior axillary line, radiating from a point below the angle of the scapula upward to a point corresponding with the upper level of this bone. Stimulation of the lesser and minor splanchnics caused pain in the lower

part of this area, while stimulation of the major splanchnic nerves caused pain more in the upper part. Compression of the celiac ganglion produced pain radiating to the region of the right shoulder, while compression of nerve fibers peripheral to the ganglion caused aching pain in the right lower part of the abdomen. All these pains were blocked by injections of the splanchnic nerves with procaine.

It may well be that, in some cases of intractable duodenal ulcer, more relief will eventually be given by splanchnicotomy than by gastro-enterostomy or pyloroplasty. Fortunately for gastro-enterology, a number of neurosurgeons are now following the lead of *George Brown* and *Adson* and in many cases are cutting splanchnic nerves in order to relieve hypertension. It may be that, in this group of patients, can already be found one or more who, in addition to the hypertension, had pain in the upper abdomen. In that case, what we who are interested in painful intestines want to know is: was there relief from the pain?

It would be very helpful if readers who have made observations like those of *Adson* would send in short notes for publication in this Journal.

Walter C. Alvarez.

### THE ETIOLOGY OF PEPTIC ULCER; A REVIEW OF ONE THEORY

WE have just read with some interest an article by *Samuel C. Robinson, M.D.*, in the August, 1935, number of this Journal, bearing the title: "On the etiology of peptic ulcer—An analysis of 70 cases."

We are frank at the outset in stating that we are disappointed in the Author's conclusions, which, being made to rest upon the so-called "neurogenic" theory do not satisfy the demands of an enquiring mind.

We are heartily in agreement with his view, however, that many so-called factors of etiology that have heretofore been brought forward have nothing whatever to do with the origin of peptic ulcer.

Let us review this article in some detail, as the subject well warrants an impartial discussion of the observations that have been made—whether they be enlightening or confusing.

The Author is quite sound in his reasoning that peptic ulcer does not occur in the lower animals and

shows keen judgment in quoting Mann's opinion that "Chronic peptic ulcers have never been consistently produced experimentally in the gastric mucosa by any method." This premise, we believe, is of genuine importance and one upon which we can stand firmly and safely.

We believe that the lower animals do not develop peptic ulcer because their habits of living are natural, and just in so far as these habits are maintained, do they remain free from many a disease to which man is heir by reason of his being "civilized," as we say.

Peptic ulcer occurs very rarely in the Negro and in the lesser pigmented races, claims the Author. This is equally true of pernicious anemia, leukemia, coronary disease and diabetes mellitus—just to mention a few other diseases.\* So why should we think of this rarity of incidence as showing "a unique selectivity in the annals of disease"—to quote from the Author? If he must theorize as to the Negro in his apparent exemption from many diseases prevalent among the white race, let him recall how little is known regarding immunity to disease, natural and acquired, not only as to races, but also among families and related individuals.

For the white race, "a highly competitive and more complex civilization has made existence more precarious, and those who are on the firing line of this life-struggle, such as salesmen, specialists in all fields, particularly medicine, executives, etc., are more prone to this disease." So states the Author in laying the foundation for the neurogenic theory, but why doesn't he let his 70 cases bear him out in this contention, and why hasn't he a high percentage of his ulcer-patients arising among say those who drive the mighty steeds of the 20th century between Chicago and New York?\*\*\*

We believe that if Dr. Robinson had had any really significant figures to produce in his argument, he would have published them.

As to the question of "the ulcer build" we do not feel at all impressed by the finding that the victim of peptic ulcer belongs to the "long and lanky type." Isn't it just as logical and true to state that he is long and lanky because he has an ulcer? There probably comes to him an ability to handle his foods in such a way that he does not store body-fat and as a consequence he remains "linear" rather than becomes "lateral." There are probably many abnormal conditions within the body which may lead to the long and lanky type of individual, but ulcer is only one of many such pathological states. And to bring the personality of our ulcer victim into the picture does not elucidate the problem at all, but we believe merely shows the reaction of his temperament to the presence of his ulcer, just as any other disease of chronicity stamps itself upon the mentality of its subject in its own peculiar way. It is in this manner that all chronic disease leaves its impress upon the plastic tissues of the "mind."

\* Not quite so true as was suspected formerly, now that Negroes are being carefully studied by competent clinicians in modern hospitals. Ed.

\*\*\* Robinson includes no patients of the last named, but records of various institutions indicate that railroad, engine drivers are by no means free from peptic ulcer; how much bearing their occupation has upon the production of their ulcers, one can but conjecture. Ed.

We next proceed to consider the so-called ulcer-bearing area of stomach and duodenum as the *locus minoris resistentiae*. That the Author brings forth any evidence or proof why the peptic ulcer should develop within this limited area we cannot convince ourselves.

Dr. Robinson states that "the lesser curvature of the stomach which is the site of over 98% of all gastric ulcers receives most of the innervation to this viscus, etc." "This is the portion of the stomach that will receive the blunt of psychic trauma with the resultant hypermotility, hypersecretion, hyperchlorhydria, hypertonicity and vascular spasm." Except for the threat of an impending disaster as voiced in these high-sounding words we fail to discover a pathological basis for the development of ulcer in an area so richly supplied with nerves and blood-vessels. So long as ignorance continues to hide under terms as obscure as "psychic trauma," progress in medical investigation will continue to languish.

The Author's assumption of thrombosis for the true etiological basis of the incipient and chronic ulcer we accept as being well founded, but to attribute this thrombosis only to vascular spasm is not altogether satisfying in view of what we find by way of changes within the walls of these blood-vessels. As far back as 1883 Hauser, by his careful work upon the blood-vessels in and near peptic ulcers concluded that: "The hemorrhagic infarct is followed by a chronic ulcer, only when the disturbance in circulation follows local disease of the blood-vessels. The degree of vascular disease, therefore, determines the more or less chronic character of the ulcer."

Whence these vascular changes?

Shall we continue to accept as a Heavenly pronouncement the thread-bare theme of "over-work, stress, strain and worry"?

Shall we be influenced too far towards a "neurogenic" theory in our conception of peptic ulcer by the finding of a perforated ulcer in association with brain-tumor? Have we not seen perforating ulcers associated with chronic cholecystitis or other diseases of long standing? Why not blame the one on the other? Or, why not say in equal fairness of mind that what caused the ulcer likewise was responsible for the origin of the brain-tumor, etc.?

Are we venturing too far afield to look for a solution of the problem in the study of the relation of foods and poisons to certain degenerative changes in the vascular system?

The 16th Hektoen Lecture of the Frank Billings Foundation, by Timothy Leary, M.D., recently has been read with absorbing interest and the subject-matter contained therein doubtless will bear much fruit in our future conception and study of disease in the broadest sense.

It may lead us back to some fundamental considerations which apparently have slipped our minds. For instance: that a man is as well and as sane and as young as his arteries are free from disease, and that the degree of arterial disease is just, and justly, the expression of the distance he gets from the proper choice and use of that which entereth into the man.

Maurice B. Bonta, Los Angeles, Calif.

## SECTION IX—Book Reviews

(This section is open to contributions from any medical reader, whether or not a member of the Editorial Council).

*The Management of Colitis.* Dr. J. Arnold Bargen. National Medical Book Company, New York, 1935. 233 pages, price \$3.00.

THIS volume gives a comprehensive view of the whole problem of colon disease both organic and functional. Starting from a basis of anatomic and physiological principles, the normal function is first considered, then the etiology, pathology, diagnosis, complications, and treatment of the following conditions: Chronic ulcerative colitis, amoebic colitis, tuberculous colitis, mucous colitis or irritable colon, and finally a group of conditions to be distinguished from colitis.

The most extensive discussion is of ulcerative colitis in which field the Author has contributed so much. An enormous experience covering some 1500 cases at the Mayo Clinic permits him to speak with authority. Details of the bacteriological findings and the cultural methods in isolating the diplococcus, which Bargen regards as more or less specific in the etiology of the disease, are given in detail. He does not accept the idea that bacillary dysentery plays any primary or important part in the etiology of chronic ulcerative colitis. Whether or not one accepts the specificity of the "Bargen diplococcus" as the cause of the disease, one must have a great deal of respect for the results the Author has been able to obtain at the Mayo Clinic in a large series of cases.

Complications of ulcerative colitis are fully discussed with their relative frequency on a statistical basis given in detail. Considering the large amount of ulcerating surface, complications are relatively infrequent. Only about 15% of all patients have any complications although those who are so afflicted often show numerous complications. Perirectal abscess is one of the earliest and most frequent lesions to accompany the disease. Stricture of the rectum or colon was originally second in frequency but has been much reduced by modern treatment. Other septic complications such as endocarditis, (1%), arthritis, (4%), erythema nodosum, and uveitis occasionally occur. Abscess of the liver is extraordinarily rare as is also pyelitis despite the fact that we often attribute pyelitis to infection from even the normal colon. Carcinoma occurs in approximately 2½% of the cases most commonly associated with polyposis which is found in at least 9% of cases. Skin sloughs and lesions of the type of *pyoderma gangrenosa* are associated with ulcerative colitis more than with any other one condition.

Treatment has been well standardized by the Author and includes general measures in regard to diet, vitamins, rest, drugs, blood transfusions as well as specific therapy. The specific serum is obtained by immunizing horses against many strains of the diplo-strep-

tococcus. In the more severe cases this serum is given intravenously; routinely it is given by deep intramuscular injection after desensitization by intracutaneous injections. The vaccine is used in the more chronic cases. Irrigations are in general condemned although on special occasions very bland or mild antiseptics are used. Removal of foci of infection is stressed.

In the occasional case in which all medical measures have failed or in the presence of an acute emergency, such as uncontrollable hemorrhage (1% of cases), surgical treatment is considered. Ileostomy is the treatment of choice and may be a life saving measure under certain circumstances. It may however have to be a permanent fistula and this should be considered by the patient before operation. Subsequent anastomosis is difficult and may be impractical after a period of months on account of stricture formation or persistent ulceration. Even in the most favorable cases the disease may relapse after an apparent cure. The practical management of the ileostomy is considered in detail and the Huffer bag is regarded as the most suitable device for the purpose.

Excellent illustrations supplement the descriptive matter. In this connection, also case histories and personal experience of patients with permanent ileostomies are of special interest. The psychological adjustment of the patient to the artificial anus is discussed. Occasionally colectomy may be advisable and should be done about six to eight weeks after ileostomy.

Some experimental work is described including kymographic records obtained by balloons in the isolated colon in animals and in patients with ileostomy or colostomy. The cecum is the most motile portion of the colon, having three distinct types of movement. The distal colon, normally quiescent, is most easily activated by the stimulus of food in the stomach, the so-called gastro-colic reflex.

Amoebic and tuberculous colitis are also considered quite fully including the differential features clinically and radiologically. The final diagnosis rests upon bacteriological and microscopic findings. Practical methods for finding and identifying the amoebic cysts are given.

Finally, the Author has a lengthy discussion of so-called "mucous colitis," listing its many synonyms and also the various forms and conditions of irritable colon. Among the prominent causes of this colonic dysfunction he lists overwork, overeating, insufficient rest, nervous fatigue, nervous tension, exposure, local irritation caused by laxative, and colonic irrigations, foods and the bacteria that are normally present. In treatment, the principle of blandness in food and medication is approved in general and as in ulcerative colitis, colon irrigations are mainly mentioned for con-

demnation. Neurogenic and psychic factors are stressed at length. In the diagnosis of these disorders, food allergy and the colon complications of such systemic diseases as sprue, pellagra, anemia, exophthalmic goiter, uremia, etc., are discussed.

Altogether the book presents a very useful compila-

tion of the present day knowledge of the vexed problem of colon disease from the standpoint of differential diagnosis and the practical management of patients especially with the intractable forms of ulcerative colitis.

V. C. Rowland, Cleveland.

## SECTION X—After “Hours”

### Some Social and Medical Impressions of Moscow

By

CHAS. GORDON HEYD, B.A., M.D., F.A.C.S.  
NEW YORK, NEW YORK

SOVIET Russia represents a country of approximately 160,000,000 people. It occupies nearly one-seventh of the surface of the globe, and its nationals comprise various strains of some two hundred races, expressing themselves in something over sixty different languages. Any evaluation of the social and medical status of Soviet Russia must be made upon a knowledge of its pre-revolutionary status. Russia was a country pre-eminently agricultural, definitely deficient in industrial development, burdened by an autocracy of complete domination, with a spiritual background of superstition and mystery, and made up to a large extent of a dull, illiterate, slave-driven proletariat. Such was the background of Russia before the Revolution.

Any preconceived ideas that a first visitor may have had of Russia were rapidly changed upon arriving in Moscow. There was no evidence of starvation, and rarely a beggar. (Fig. 1). The people one met and passed upon the street apparently were happy, and although laughter and smiles were not common, one had no reason to believe that an urban population that on one day (Sunday) attended a football game to the extent of 70,000, had an attendance of 30,000 at the Jockey Club, and 100,000 at the “Park of Culture and Recreation,” representing in all some 200,000 people, was lacking in wholesome recreation and pleasure.

The personal impression of police surveillance, however, remained true, and the casual use of a kodak was only possible by express permission and with very evident restrictions. One did not see shelterless children nor homeless waifs, although everywhere at all hours of the day and night immense crowds of people seemed to be moving to and fro, apparently aimlessly. The entire population of the city of Moscow seemed to be dressed always the same, and almost always in the same way. There was practically no differentia-

tion between one woman and another, nor between one man and another. The use of rouge, lip stick, and hair adornments was restricted, according to my observation to the female employees in the three hotels set apart for the foreign tourist (August, 1935).

Perhaps the most constantly recurring impression that one received was that the Soviets were working like fury to develop a classless society and that all of their present activities were predicated upon some not too distant Utopian state of the future. Time and time again the traveler is lectured by his guides and informed, somewhat in the manner of the recitation of a ritual, of what the Soviets have accomplished, what they propose to accomplish, and how politically backward is the remainder of the world.

In the development of this so-called completely socialized state there occurred towards the end of the late World War a fateful juncture of four great forces. According to Chamberlain, these four great forces which made for the success of the Russian Revolution were: (1) the complete disintegration of the Russian Army, (2) the seizure of the land by the peasants, (3) the revolt of the workers in the industrial centers of Leningrad and later of Moscow, and (4) a separatist movement aroused by the enthusiasm for individualistic nationalism. The culmination of these forces provided the background for the surrender of Russia to the Germans, and gave Lenin the opportunity of applying his genius for revolutionary technic to the theories of Karl Marx, and of operating them by force for the alleged benefit of the 160,000,000 people living in Russia. Lenin and his co-workers proposed to liquidate all social and economic ills. In their opinion, accomplishment of this project necessitated (1) complete destruction of Czarism and its attendant evils, (2) destruction of capitalism and private ownership of property, and (3) destruction of the prevailing religion. The immediate effect of these three destructive influences was an almost complete annihilation of the intelligentsia—members of the professions,

\*Abstract of a Lecture before the Medical Society of the County of New York, January, 1934.  
Submitted October 24, 1935.

Fig. 1. Typical group of children as observed in the streets of Moscow.

lawyers, merchants, engineers and other technically trained citizens of the Czarist regime.

Since the historic Revolution, which began in March, 1917, and culminated definitely in the fall of that year, the postrevolutionary history of Russia embraces five distinct periods—The Revolutionary Period; 1917 to 1921: The War of Communism; 1921 to 1928: The New Economic Policy; 1928 to 1933: The First Five Year Plan; 1933 to date: The Second Five Year Plan.

All information obtained in Moscow by an American who does not speak or understand Russian fluently is entirely by the aid of and through interpreters. Apparently all the interpreters have memorized the particular speeches for each occasion, and fairly breathe revolutionary propaganda. They have the stock set of stories that all returning travellers tell, and particularly the one attributed to Stalin that there may be any number of political parties in Russia provided one is in power and all the others in jail. There is a common denominator for all the interpreters. Every feature that is objectionable in a capitalistic country is declared to be a social evil—illiteracy, poverty, prostitution, venereal disease, political enemies, churches, starvation—these are all social ills and can be "liquidated by the dictatorship of a proletariat." Time without number the word "liquidate" is used: to liquidate illiteracy, to liquidate the political enemies. In like manner "research" is used with the most extensive applications. Again, "scientific" is applied regardless of its original sense, so that in every interpretation the words "liquidate," "research," and "scientific" would appear repeatedly.

The spiritual level of character of any civilization can be determined by a consideration of two social factors: the rate of infant mortality, and the place occupied by women in the social scheme. Lenin wished to destroy every Czarist law which placed women in subordinate or humiliating positions, but that there ever was a nationalization of women or children is utter nonsense. Under Soviet legislation marriage is permitted solely upon the free will of the parties concerned, and marriages are either registered or non-registered. About seventy per cent of the marriages are registered, and divorce may be obtained at the desire of either party without previous notice, and without both parties being present. Yet the divorce rate in Moscow is, in 1933, less than in Chicago, and the divorce rate for the whole of Russia is one divorce to four marriages, while it is stated to be one to five in the United States.

Under the Soviet law there is no such thing as an illegitimate child, and in no country to my knowledge is the legal responsibility for children so onerous or so obligatory as in Russia. Either one or both parents are responsible for the financial maintenance of the children until they are sixteen years of age. Seventy-two per cent of the women between the ages of eighteen and fifty are workers, and have all the rights of men, there being no distinction in so far as working is concerned between the sexes.

The Soviet ideology is based upon the principle that women shall not be penalized because biologically they must be mothers, and every pregnant woman must cease working eight weeks before the birth of her

Fig. 2. Institute for Women and Children, Moscow: former home of Isadora Duncan, Dancer.

child and remain away from work for eight weeks after birth, representing in all sixteen weeks during which she receives her full pay as a laborer from the State Insurance Fund and from the factory. When she returns to work, she can only be employed on the first shift, from eight a. m. to three p. m., and doing light work. Practically one hundred per cent of the births in Moscow take place in medical institutions or hospitals. For the first three years of the child's life, the mother, if a worker, may avail herself of the so-called creches, or nurseries. The babies are graded by months into four age groups, aged respectively two to nine, nine to fourteen, fourteen to twenty-four, and twenty-four to thirty-six months. The Soviet authorities believe that the nurseries give the women the opportunity of taking part in the building up of the social structure. Special nurseries are for the casual traveler, the "show places" of Moscow (Fig. 2). However, like so many things one sees in Moscow, there is a tremendous discrepancy between the resources of the nurseries and their availability. Less than ten per cent of the children born in Moscow are able to receive the benefits of State-run nurseries.

Soviet philosophy believes that the fight against prostitution should not be against the prostitute, and the individual is neither penalized nor persecuted. The problem has been taken entirely out of the hands of the police and placed in charge of the social agents of the State on the assumption that prostitution is basically, economically, and socially an abnormality, the same as poverty, alcoholism, illiteracy, and crime, and that a new attitude of mind is more essential than laws.

Fig. 4. The Abortion Clinic.

Fig. 3. One of the three Prophylactoria.

In the days before the Revolution there existed in Russia a so-called "yellow ticket." A woman engaging in prostitution voluntarily or otherwise registered with the police. She was given a yellow ticket, really a yellow folder containing her photograph and other personality and identity data. From that time forth she was forever a registered prostitute. It was told to me that there were thirty thousand registered prostitutes in Moscow before the Revolution. At the time of my visit the social agencies could only definitely allocate between four and five hundred women in the ranks of the professionals. If these facts are to be taken as literally true, the success that has attended this social war against prostitution might well invite the serious consideration of all capitalistic countries.

Shortly after the Bolsheviks came into power, they established what are known as prophylactoria (Fig. 3), where by request and probably command, these unfortunate individuals became "guests" of the government. About eighty per cent had one or both major venereal diseases, and practically all were in varying degrees of ill health. These women were given a complete health examination and their specific diseases treated. Necessary dental work was done. They lived from one to three years in a prophylactorium and after their health was somewhat restored to normal, they were placed to work on knitting machines, or given similar labor in a division of the prophylactorium. They made neckties, scarfs, handkerchiefs, shawls, and the like, and received the prevailing rate of wage as obtained in similar occupations, one-third of their remuneration being collected by the government to defray the cost of maintenance, one-third being taken up by contribu-

tions to trade unions and by State taxes, and the remaining third becoming the property outright of the worker. It was represented to me that there was very little if any restraint upon these women, that the occasional few who escaped or ran away always returned. When they were cured and discharged the women were already in possession of sufficient technical skill to earn a living. Most of them married and became good citizens, with few relapses.

It was stated to me on many occasions that the laxity of the marriage laws and the standard of the State administered abortion clinics were large factors in the suggested improvement in prostitution. For the medical man the abortion clinic, or abortorium, (Fig. 4), is the most striking of the presentations in Moscow. There is in every one of the main political subdivisions of Moscow an official abortion clinic, and any woman who is registered or non-registered in marriage, or any woman without the marriage status, can have an abortion performed at her own request up to the ten week gestation period, after which time she must carry through with her pregnancy. In August, 1933, there were 1,155 beds for abortion in the fifteen geographical subdivisions of Moscow. Twenty-one per cent of the women applying for abortion did not have registered marriages. The abortion service is the only medical service that in some measure is paid for out of the individual earnings of the patient. This fact is not without a relative economic importance. I was informed (with no way of verifying the facts) that in one district approximately 400,000 rubles were collected for the abortion service during the year 1932,

Fig. 6. The District Court.

Fig. 5. "Zags," the Marriage Bureau.

that the disbursements by the government for salaries and overhead were 185,000 rubles, making an operative income of 215,000 rubles. Since the establishment of the abortion clinics the proportion of abortions has increased enormously, and in Moscow they were sixty-one per cent in excess of the normal births.

The Soviet ideology has as a background the principle of equal responsibility to its citizens, irrespective as to sex. The sexual relations in Moscow are more largely physiological than psychological. In all of the major districts there are contraceptive clinics. Sex information is frankly spread by every known device of propaganda—pamphlets, letters, books, exhibits, charts, lectures, etc. So far as one can observe there is no censorship on sexual information. There are texts and charts for the illiterate. Along the walls of the marriage Bureau, or Zags, Fig. 5, there hung any number of signs, two of which translated read as follows: "Don't forget before registering your marriage to consult a woman doctor on sex hygiene, contraception, and the future child"; "Any woman who wants to prevent conception should not depend on the man."

In regard to civil crime as opposed to political crime, one observes that the word "punishment" is everywhere replaced by the term "measures of social defense," and the maximum sentence for non-political crimes is ten years, the majority running for two to three years, and sentences of less than one year being usually remitted. There are no punitive measures for the correction of criminality in children under the age of fourteen, these children being placed under the pro-

Fig. 7. One of the few clinics; the so-called Railroad Clinic.

tection of the Institute for the Protection of Mothers and Children.

The courts (Fig. 6) are usually held in zones or districts presided over by three judges, the senior being appointed by the administration, and the other two by the labor union of the district. It is written into the criminal code that sentences must not cause the criminal needless suffering. There is a complete absence of lawyers. The system is one of class justice, and a worker, or a revolutionnaire, or the children of workers, receive special consideration as opposed to any of the former bourgeois class.

The Soviet philosophy in regard to disease and illness is very simple. It is held that illness is not primarily a personal responsibility, but as every citizen is an economic unit it becomes the duty of the State to restore the sick to well being, and to prevent illness. Medical practice, both curative and preventive, is one hundred per cent State medicine. In 1913, there were thirteen thousand physicians in the whole of Russia, and it was estimated in 1933 that there would be eighty-two thousand. Seventy-five per cent of the students in the medical school are women, and the social origin of the medical students is as follows: workers, 24.7%; peasants, 33.7%; hired farm laborers, 1.3%; employees, 40.3%. The percentage of workers and peasants in the medical schools is increasing each year. Eighty-five per cent of the students in the medical schools are members of a trade union. It is unquestionable that preference for admission to the universities and professional schools is undoubtedly given to the culturally lower strata of the population, and the univer-

sities are filled with students who are primarily ill fitted for higher education. The absolute State medicine imposed upon the entire country accepts the principle that one doctor is as good as another, a proposition that is manifestly false. In each zone is a point of medical consultation, and to this point comes the request for the visiting doctor. The physician makes the visit or sees the patient, and if a specialist is desired, the required specialist is called in. The patient may be treated at home, but is usually sent to a hospital or clinic (Fig. 7). The entire medical service is free, with the exception of the abortion service, and there is no such thing as personal choice of physician. Medical education is entirely under the control of the Commissaire of Health, and entrance to the medical school may be obtained in any one of the following ways: (1) the non-worker must have had from three to eight years of kindergarten and inferior school, and from eight to seventeen years of elementary and high school; (2) the worker in a factory may enter the medical school by attending a special workers' high school or Rabfac from three to five years, the last year of which he does not work at his trade, but receives a stipend from the government; (3) an individual may enter the medical school who has had a previous training as a nurse, a doctor's assistant, or as a graduate medical technician with three years of work in a medical institution. The result is a tremendous levelling process in education, with an almost ninety per cent preference for workers or children of workers. The universities are subject to an upsurging of students who are greatly handicapped by the absence of inherited or environmental educational advantages.

In the medical schools four types of medical instruction are given, and the medical student elects to enter one of the following: (1) The Faculty for Curing and Prevention of Disease—a five-year course with training for an internist, therapist, or surgeon; (2) The Faculty for Gynecology, Obstetrics, and Pediatrics—a five-year course; (3) The Faculty for Sanitation, Food Industry, Factory, and Sanitaria Practice—a course of four and a half years; and (4) The Faculty for Physiotherapy, and Mechano-Therapy—a five-year course.

The result of this medical educational system is to turn out an incompletely educated doctor, and to commit the medical student to the necessity of becoming a specialist, even while he is in attendance at the medical school. The system produces an extreme division in specialism. There is no uniform, all 'round medical curriculum. It recruits its members for class education. Basically there is a huge upswelling from below of incompletely educated students, and a tremendous accentuation of women in medicine. The system tends to reduce medicine to a trade in which medical practice is carried on as if it were a commodity, and it levels the economic status of the physician to a bare sustenance standard of living.

Yet at the same time the practice of medicine does offer in Soviet Russia one free day by law for every six days of work, and allows the individual to become a research worker or a hospital worker. For the first three years after leaving the medical school, however, the physician's time is entirely at the disposition of the Commissaire of Health. At the expiration of this three year period the doctor may take three years of study in one of a number of courses that will lead to

personal preferment and advancement along the road to a professorship. The success of an individual arriving at a professorship in medicine is largely dependent upon his energy and ability, his publications and research activities, together with the demonstration of his political regularity.

It is utterly impossible to apply the conditions of medical practice in Soviet Russia to such a highly industrialized country as the United States. Before the depression, fifty per cent of the physicians in the United States had a net income of \$3,500 a year or less; twenty-five per cent had incomes of \$2,500 or less; and eighteen per cent had an income of less than \$1,800 a year. If these amounts were translated into theoretical gold rubles, it would be respectively 7,000, 5,000, and 3,600 rubles, or a monthly income of 600, 420, and 300 rubles. The monthly stipend of physicians in Russia varies from a low average of 180 to 220 rubles up to a maximum of 900 rubles a month for the so-called "big professor." It is true that owing to the paucity of doctors, many of them work a double shift and of course double their earning capacity. The Russian physician, however, participates in so many indirect forms of income by reason of his being able to buy at the closed cooperative stores, and to participate in the general rental percentage of three per cent of the individual's income for rent, that his real income is probably in excess of the theoretical ruble value. It is my impression, however, that the physician earning \$2,500 a year in American money in the United States today is enjoying a higher standard of living than almost any of the doctors in Soviet Russia.

Newsholme and Kingsbury, in discussing the same subject, come to the conclusion that it is doubtful if the earnings of many Russian doctors have a purchasing power lower than \$1,500. The ordinary physician in Russia has considerable spending power, a condition that is shared with the laborer in that many of the fees charged for living are determined largely upon the individual's monthly income, such as one per cent for income tax, two per cent for trade unions and social insurance, and three per cent for rent. Bread, butter, cheese, eggs, meat, coffee, tea, and sugar are still high in Soviet Russia. While the quantity of these commodities may vary as well as the quality, there has been very little tendency in the closed cooperatives for the prices to be raised. The only millionaires, so to speak, in Soviet Russia, are the playwrights, authors, movie directors, and composers who on a royalty basis can receive an annual income as high in some cases as 100,000 rubles.

One must not forget that in the completely socialized medical set-up in Russia one of the most active agents making for its success is the complete police power of the government. Since private practice is non-existent, since there is no choice of physician and all medical practice is free, the sick individual must go to a point of medical consultation or a clinic. The effect of all these factors on venereal disease has been as remarkable as it has been successful. There are venereal dispensaries in all districts. The registration is one hundred per cent complete. There is no social stigma attached to the individual by being afflicted with a venereal disease. Every fresh case is traced, and the contacts are controlled. Before the Revolution there were in Moscow one hundred and sixty-seven fresh cases per ten thousand of the population, and this was

at a time when there was very incomplete venereal registration. In 1927 there were proportionately fifty-seven and three-quarters per ten thousand, and in 1931 thirty-one per ten thousand. Congenital lues in Moscow has fallen from six per cent in 1923 to one per cent in 1930.

Today every man and woman in Russia twenty years of age began his career under a new social order, without any previous knowledge of religion; every individual over thirty owes his present social and economic position, as well as the continuation of that position to the present regime; while for those over forty, who lost all previous standing, position, and income, a new regime is substituted for a former type of living that remains to them only in memory.

The philosophy of the Revolution was a destruction of Czarism, of capitalism, and of religion. Lenin is given credit for the original Marxian quotation that "religion is opium for the people." Out of nine hundred and eighty churches in Moscow that existed before the Revolution only fifty-six remain. It is only fair, however, to say that many of these were destroyed under the exigencies of traffic demands, and not primarily for atheistic reasons. Some of the churches have been converted into anti-religious museums, where the historical pageant of religious development is ridiculed by parallel exhibits supposed to be a pictorial presentation of the Darwinian theory.

History will record the rise of the Bolsheviks to power in Russia as an epoch in human affairs. Yet this tremendous revolution in world affairs is not without its antecedent example. On September 20th, 1792, France declared herself a Republic, and there was fought the Battle of Valmy, which according to Creasey was one of the decisive battles of the world. It is rather significant that, whereas the terror of the French Revolution started from the attempted invasion of France, the terror in Russia started at the cessation of any attempts at invasion of Russia proper.

Lincoln Steffens in 1919 made the statement regarding Soviet Russia, "I have seen the future and it works." It is alleged that Karl Marx stated that his chief diversion in life was to subject everything to doubt, and Lord Balfour ironically alluded to Chicherin that the Soviet formula was "an excellent means of making rich men poor, but a dubious means of making poor men rich." Perhaps the most far seeing statement in regard to the present social plan in Russia is that of Friedman ("Russia in Transition," p. 406): "In life as in a railroad journey, it is important not only to arrive at one's destination, but to enjoy the trip." The same Author further states that the argument put forth by some Soviet sympathizers that there are many defects in the capitalistic system is quite beside the point. It is admitted that there are defects in the capitalistic system, but these do not justify the Soviet organization, for they are suffering from still greater evils. "The Soviet system is designed for the masses. Capitalistic society is designed to raise individual talents to superior levels. The Soviet society is designed to prevent the inferior from falling to greater depths."

One day as my visit to Moscow was drawing to a close, I had a long chat with one of the original Revolutionnaires. This gentleman, whom we will call "X," has lived some years in America, and is familiar with American history and American ideology. I said to

him, "X, the Soviet government has taken over all of the economic details of a capitalistic state, namely, the differential wage scheme, the income tax, the sales tax, and so forth. Is not this a trend toward state controlled capitalism?"

"No," he replied, "this is a socialistic state on the way to communism." "What then is the ultimate condition of the people under communism?" He replied, "We will all fare the same, be the same, at all times, at all places. To each shall be given according to his needs. Competition will be eliminated, and by planned economy and planned distribution everybody will enjoy as full a measure of happiness as possible." I said, "X, this is heaven you are describing." Whereupon he turned and indignantly said, "There is no such

thing as heaven; there is such a condition as communism."

In conclusion, upon the variance of human nature and the unexplained biological mutation of personality will come the disruptive factors, for not everybody can be at one and the same time always the same and always happy.

## The Fifteenth International Physiological Congress, Leningrad and Moscow, August 8-18, 1935

By

A. C. IVY, M.D.\*  
CHICAGO, ILLINOIS

THE memorable feature of previous international congresses has been the scientific program and the pleasure and profit of meeting and discussing matters of mutual interest with foreign colleagues in the international atmosphere of Science. The Fifteenth "International Physiological Congress" not only was memorable in this regard but also in that the large majority of delegates was visiting a country concerning which they had read much and of which they knew nothing by first-hand experience. You may imagine the surprise of some of us, who had carried dried fruit, chocolate, etc., into Russia, when confronted at the opening informal reception (August 8, at 20 o'clock,—8:00 P. M.), held in the magnificent marble hall of the Ethnographical Museum, by the most luxurious and extravagant display of food and refreshments that most of us ever had seen. This surprise was only an introduction to the many surprises, opposites, paradoxes and apparent inconsistencies with which we were to meet, all of which may be explained by the engrafting of new social developments on the old culture of the tsaristic regime.

The Congress was formally opened the next morning by Professor Pavlov in the Uritsky Palace, which was originally built for Potemkin, a favorite of Catherine the Great, later the meeting place for the Duma and the Provisional Government of 1917, and now of the local Leningrad Soviet. The Palace recently had been renovated and the beautiful and famous Round Hall was decorated with palms and flowers. (\*Footnote 1).

\*Northwestern University Faculty of Medicine.

Submitted October 5, 1935.

\*Footnote 1. Before entering the building our attention was attracted by a group of workers, because we observed that the women were working and the men sitting near-by smoking. Among other items of interest, we ascertained that this group of workers had been working night and day to complete their work prior to the Congress, and, on completing it ahead of schedule, had been given a large bonus in rubles.

Academician Professor Pavlov called the Congress to order and gave the opening address, which, in spite of his eighty-six years of age, was delivered with his characteristic physical vigor and perspicacity. After greeting the members of the Congress, he paid tribute to Sechenov (1829-1915), who was the first Russian to deliver his lectures, not from texts, but from data gathered through his own experiments and demonstrations. Professor Pavlov, pointing out the international aspect of Science, made a plea for peace. He said: "I can well understand the greatness of a war for liberty. At the same time, it cannot be denied that war is essentially a beastly method of solving life's difficulties, a method unworthy of the human mind with its immeasurable resources."

The members of the Congress were then welcomed on behalf of the Soviet Government by I. A. Akulov and, on behalf of the Leningrad Soviet, by I. S. Kadatski (Mayor). Professor Karpinski welcomed the Congress on behalf of the Russian Academy of Sciences. The governmental representatives emphasized that physiology was the foundation of the health of the workers, of medicine and animal husbandry and that Science was of, and for, the people.

The keynote of these addresses was the high regard for and the great attention given Science by the workers and the Government. There can be no doubt of this. But, why is there such a dearth of foreign scientific literature in Russia? And, why are not more of the younger Russian scientists "permitted" to study abroad?

The scientific address of the opening plenary session was delivered by Professor W. B. Cannon (United States). By way of introduction to his technical discussion of, "Some Implications of the Evidence for Chemical Transmission of Nerve Impulses," Professor

A photograph of Pavlov taken August 8, 1935.

Cannon paid just tribute to Professor Pavlov and briefly discussed international politics as related to Science. (\*Footnote 2). Among other things, he said: "During the past few years how profoundly and unexpectedly the world has changed! Nationalism has become violently intensified until it is tainted with bitter feeling." "Creative investigators of high international reputation have been degraded and subjected to privations." "The scientific triumphs of the past have not been achieved by workers of any single nation; not by representatives of any single racial group." "No other example could illustrate more strikingly the international character of scientific endeavor" than the technical subject Professor Cannon discussed, namely, the "knowledge of the mode of action of autonomic nerves on their effector organs."

Two other plenary sessions were held, one in Leningrad and the other in Moscow. The session in Leningrad was addressed by Professor J. Barcroft (England), the title of his address being, "The Velocities of Certain Physiological Processes," and by Professor L. Orbelli (Russia), the title of his address being, "Pain and its Physiological Effects." The plenary session in Moscow was addressed by Professor L. Lapicque (France), the title of his address being, "Recent Progress in Our Knowledge of Nervous Mechanisms," and by Professor A. Ukhtomsky (Russia), his title being, "Physiological Liability and the Act of Inhibition." The usual boredom of having to sit and listen to an address in a foreign language was avoided at

these plenary sessions. Head phones were available, so that one could make connection with a very competent translator and follow the speaker in anyone of the five official languages of the Congress. This was an innovation in so far as the delegates were concerned, but a necessity for governmental meetings in a country like Russia where so many different languages and dialects are spoken.

All the meetings of the various sections were held in Leningrad. Five sections met simultaneously, some forty sessions being held. About 485 papers were presented. More than 1,200 members and associate members were registered, many of whom were faithful attendants at the scientific meetings. At some of the plenary sessions and entertainments the attendance was 1,500. More than 200 Americans (not all physiologists, of course) were in attendance; there were about 500 Russians.

The arrangements made for the meetings were excellent, when the number in attendance is considered. The special excursions provided by Intourist (the Travel Agency of U. S. S. R.) were superlative. Boats and trains were met in many instances by brass bands. Private cars (Lincolns and Fords) were provided for transfer between hotels and meeting places and, not infrequently, for sight-seeing excursions. The traffic police "knew we were there" and immediately changed traffic to give "right-of-way." Passes were issued which gave free *entré* to busses, street cars, parks, theaters, museums, etc., but purchases could be made only in "Torgsin stores." The evening excursion to Peterhof, the country place and palace originally designed by Peter the Great and completed by Catherine, with its forest, gardens and fountains, illuminated by lights of various colors, was an experience never to be forgotten. The same may be said of the most extravagant banquet tendered by the Organizing Committee and the Leningrad Soviet in "Dietskoye Selo," Catherine's Summer Palace. Set in a scene of great splendor and lasting for four hours, it was followed by an unusual display of fireworks. Also, a splendid concert was given in the State Theater of Drama by many of the prominent Russian artists. In fact, the entertainment was so exceptional that the International

The entrance to a district medical and dental dispensary in Leningrad. Here we saw X-ray apparatus "made in Russia." A dental school was housed in these buildings. All the dental students we saw were women.

\*Footnote 2. International politics has been a prominent item of discussion at every physiological congress held since the World War. Physiologists, like most people, believe in Peace.

A group of children at a rural communal nursery, with their two nurses. We saw no evidence of "fly consciousness" in Russia.

Committee of Physiologists advised that in the future the entertainment should be so simplified as to be covered approximately by membership fees. (\*Footnote 3).

On the evening of the eighth day, the Congress was moved *en masse* to Moscow where the third plenary session, referred to above, was held in the great hall of the Conservatory of Music, at the conclusion of which the Congress officially was closed. However, that evening a reception and banquet were tendered by V. M. Molotov, Chairman of the Council of the Peoples' Commissars of U. S. S. R., in the Grand Kremlin Palace. This was followed by another concert.

From every aspect, with the possible exception of the dining room services of the hotels, and of the complaints of a few members who contacted insects or had to occupy a sleeping compartment with the sexes mixed, the Fifteenth International Physiological Congress may be viewed as a transcendental success.

\*Footnote 3. It should be mentioned for those who have not visited Russia recently, that the largest palaces in the City are being used as museums and the country places as vacation resorts for the workers. We saw large groups of children and workers being conducted on parties through the museums. The palaces had been recently renovated and had apparently not been molested by the revolutionists.

Livada at Yalta. Formerly the Czar's large summer palace; now, the Rest Home for the Workers at Stalin's Tractor Works.

From the viewpoint of a physiologist, it was a great privilege to visit Pavlov's laboratories in which he and his students have done so much classical work. It was also a privilege to witness the high esteem tendered him by his scientific colleagues and by government officials.

It would appear that Pavlov was the initial stimulus responsible for the remarkable development of physiology, and possibly biology, which has occurred in Russia during the past fifteen years. It is claimed that in Russia there are now 380 institutes working in the field of physiology. In 1917 the Russian Physiological Congress had fifty members. Five hundred Russian physiologists attended the recent Congress.

Part of this mushroom growth undoubtedly has been due to the attention directed by the government to animal husbandry and to the increased production of physicians.

The increase in the number of institutes and research workers has led to a marked increase in the number of articles published. As one listened to, or

Evidence that "the king can do no wrong" even in Russia.

read the abstracts of, the papers presented by the younger Russian biologists, or read the completed works of the institutes, he was impressed by the imagination and enthusiasm of their Authors. On the other hand, it may be said, in the spirit of scientific friendliness, that one too frequently is surprised by the lack of breadth of training, adequate "controls" and critical thought. Many felt that due to the rapid growth there was a deficiency in critical judgment and a need for rigorous criticism and a higher standard of scientific accuracy. When, as a small group, some of us visited a dispensary or some similar institution, we were met not by a single official but by three or more officials, giving us the distinct impression that the "chief" official was apprehensive lest he might be reported for telling us something that he did not say. Taking these and similar impressions into consideration, one wonders whether in such an environment rigorous and stern criticism, marked differences in viewpoint and true scientific freedom are not suppressed. Yet, having met numerous Russian physiologists, having noted the changes already made by the Soviet Government in their system and being assured that further changes will come when practically expedient, I view the future

A view of two buildings in the Metschnikoff Hospital group just outside Leningrad.

of physiological science in Russia optimistically. (\*Footnote 4).

Some of us visited hospitals, dispensaries, nurseries, and prophylactoria, (\*Footnote 5), in an attempt to obtain an insight of the Russian system of medical practice. We learned that, on paper at least, they have a "perfect" system of socialized medicine. In so far as I could ascertain the facts, their system is most analogous to the Swedish system. One finds individual differences of opinion among physicians and patients in regard to how they like the system. Foreign tourists also react differently to the system of state capitalism in Russia, some entering Russia "pink" and returning "red" and others "white."

If one attempts to maintain an emotional balance and evaluate one's responses according to one's past conditioning and that of the Russians, (*i.e.* objectively, which is very difficult) he sees many things that are good and other things that are bad. Thus, when such a person is asked, "how do you like," or, "what do you think of Russia" (after 10 days of it—much too long for many people!), he may reply: "A very interesting experiment is being conducted in Russia. It is to be hoped that it will not be interfered with by external forces and that the Russian experimenters will not interfere with governmental and social experiments going on elsewhere."

The Russian experiment is in progress, and one cannot pass judgment, except on the basis of theory,

\*Footnote 4. Various sorts of devices, prizes, bonuses, badges, etc., are used to stimulate individual effort among scientists, officials and workers.

\*Footnote 5. A "prophylactorium" is an institution for the "cure" of prostitutes, or, as the Russian officials say, for their "reconditioning." Hard labor is one of the "cures." The following amusing conversation occurred during one of these visits. Noting that the majority of women rave the appearance of being "feeble-minded," we inquired for the percentage of cures. The reply was, "100 per cent." We manifested incredulity, and inquired how many of the women came back. The reply was that a number of them was brought back, but they were "crossed-off," because they had not been cured in the first place.

on an experiment in progress. One may say that a certain part of the technique of the experimenter is good or bad, but the critic who does not know all the details expedient for particular situations may be wrong. In another generation or two, the experiment should be about concluded. Then, and then only, may one pass judgment on its success. At least the prominent Russian experimenters are sincerely idealistic, though they claim to be materialistic, and are not becoming privately rich through graft. The experimenters, however, are well paid and have a high standard of living; this can hardly be said of the mass of workers at present, when their standard of living is compared with that of the mass of American workers.

In other words, from the viewpoint of an experimentalist, the Russians are conducting an interesting experiment, but it is preferable in this experiment to play the rôle of a prominent official, scientist or engineer. The result of the experiment may prove that communism or that state capitalism (not a "dictatorship of the proletariat," which is most repulsive to a thoroughbred American, though it may be expedient in present-day Russia) is not a Utopian dream, but is a practical social procedure.

The Memorial to the Unknown Dog, located in the yard of Pavlov's Institute.

DUFF, G. L.

*Experimental Cholesterol Arteriosclerosis and its Relation to Human Arteriosclerosis. Arch. of Pathology, 20-1, p. 81, July-Aug., 1935.*

The author gives a detailed and logical review of the literature and the experimental data concerning experimental cholesterol arteriosclerosis, and from a study of the known factors of human arteriosclerosis he attempts to analyze its relationship to the latter. In a brief review such as this it is possible to set forth only some of the more important points of the problem.

The experimental reproduction of human arteriosclerosis in animals has not as yet proved possible. Intimal changes from cholesterol feedings in rabbits is the nearest approach to it. It is not known whether the lipoids play the major role in human arteriosclerosis or not. They may represent either cause or effect. Aside from a few positive experiments in guinea pigs similar lesions have never been produced in other experimental animals than the rabbit. The lesions in experimental animals appear first in the aorta, but only after the liver, spleen, bone marrow and supra-renal glands have become loaded with lipoids. Early lesions in the media have been described by Bailey and by Duff as areas of focal necrosis which later become infiltrated with lipoids. The so-called "foam cells," macrophages, seemingly mononuclear phagocytes, make their appearance only after the destruction of the internal elastic lamina. The initial precipitation of cholesterol takes place within the ground substance of the walls, particularly of the intima. A high cholesterolemia of some degree is apparently necessary for the development of experimental arteriosclerosis in the rabbit, although an excessive degree is not necessary. A blood cholesterol in rabbits of 2584 mg. per c.c. of blood has been recorded. The usual degree of hypercholesterolemia, however, need not be great. Hypercholesterolemia has frequently been noted without the production of experimental lesions, making it necessary to assume the presence of other factors in the etiology of such lesions. There is some suggestive evidence of an effect from high protein diets, but no definite proof. There is no evidence of a relationship between hypertension and the production of these lesions.

As regards the influence of the endocrine systems, one fact seems to stand out as of importance. Thyroidectomy seems to hasten arteriosclerotic changes;

the feeding of thyroid extract seems to retard them. Potassium iodide retards arteriosclerotic changes, but thyroidectomy abolishes this protection. Local injury to the arteries seems to be of definite importance—trauma, cauterization, epinephrine, nicotine, viosterol and infection all apparently intensify the deposit of lipoids in the injured areas.

The author concludes that some form of injury to the vessel wall is the essential factor which operates in conjunction with hypercholesterolemia in the production of experimental cholesterol arteriosclerosis in the rabbit.

The imbibition theory of causation as suggested by Virchow and supported later by Aschoff, Anitschkow, and others, postulates that the lipoids do not arise from degeneration of the arterial wall but that they infiltrate it from the blood stream. The wall is assumed to be normal in structure before the entrance of lipid substances. The subsequent proliferation in the intima is due to the precipitated cholesterol and its esters. Rosenthal adds to this theory the supposition that the elastic recoil of the internal elastic membrane expresses the lipoids and tends to prevent their deposition, thus explaining the absence of arteriosclerosis in the muscular arteries as compared to its prevalence in the larger vessels in which this membrane is more poorly developed. The author holds this conception of Rosenthal's as impossible. In the presence of hypercholesterolemia and an associated hyperlipemia, the author necessitates the presence of local precipitating conditions which, operating together with the former, permit the deposit of cholesterol and the histologic changes following in its wake. His reasons for this postulation are: hypercholesterolemia does not produce experimental cholesterol arteriosclerosis of itself; injuries to the vessel walls localize and initiate the deposition of cholesterol; experimental cholesterol arteriosclerosis is a patchy process, not a diffuse one; local injuries in the media are known to precede cholesterol deposition in certain instances; the vaso vasorum are known to play a great or greater a role in the distribution and deposition of dyes, as trypan blue, and, by analogy, the precipitation of cholesterol might follow the same channels. Beyond this point the development of experimental cholesterol arteriosclerosis is not capable of accurate analysis.

The author then considers in detail the known factors of human arteriosclerosis and attempts to correlate the data concerning experimental chole-

sterol arteriosclerosis with them. The three main factors recognized in the etiology of experimental cholesterol arteriosclerosis, namely, cholesterol in the diet, hypercholesterolemia, and injury to the arteries, are considered as regards their possible significance in the etiology of human arteriosclerosis. The following assertions in brief are made: the result of cholesterol feeding in rabbits does not constitute a valid reason for believing that an excess of cholesterol in the diet plays any role in the etiology of arteriosclerosis in man. Hypercholesterolemia is not found with any regularity in association with human arteriosclerosis; it cannot of itself be regarded as a cause of human arteriosclerosis. The initial stage in the development of human arteriosclerosis consists of local changes in the walls of the arteries themselves, changes which are responsible for the subsequent precipitation of lipoids in the affected areas. Thus far the cause of injury to the arteries is unknown.

Noble Wiley Jones, Portland.

RANKIN, FRED W.

*Cancer of the Colon. Notes on its Surgical Treatment. S. G. and O., Vol. LIX, No. 3, pp. 410-414, Sept., 1934.*

The Author discusses the surgical treatment of cancer of the colon as divided into three phases; namely, the one of preliminary preparation, operative, and convalescent periods. During the period of preliminary preparation the treatment may be epitomized by saying that decompression, hydration, vaccination, and rehabilitation are the measures to be carried out. It is advantageous to attempt to decompress chronically obstructed colons by the employment of mild purgatives and irrigation over a period of from three to six days. Recently blood transfusions have been used routinely by the Author during this period. The routine use of an intraperitoneal vaccine of streptococci and colon bacilli has been found to be very advantageous.

Cases showing liver metastases, or with masses fixed to the parietes or to adjacent viscera, are usually inoperable. Certain cases with easily resectable growths, and with small hepatic metastases, should be resected because of the greater comfort it affords the patient. In the Author's experience about 50 per cent. of the cases of cancer of the colon are operable.

The Author believes that graded operative procedures are more advantageous than one stage operations. Cancers of the ascending colon are best

treated by a preliminary end-to-side ileo-colostomy and exploration, followed later by extirpation of the growth and the ascending colon. For growths situated beyond the middle of the transverse colon, and down as far as the junction of the middle and lower thirds of the sigmoid, the Author employs the obstructive type of operation only after complete pre-operative decompression of the bowel. In thin, elderly individuals possessing a carcinoma in a mobile segment of the large bowel, and yet physically unable to stand any extensive operative procedure, the Author employs the Mikulicz operation.

Where neither an obstructive resection, or some type of resection and anastomosis can be done because of insufficient decompression, the Author employs either a caecostomy, or colostomy, as a drainage measure. Caecostomy, after the method of Hendon, employing a Pezzar catheter, is the most satisfactory method.

Primary resection and anastomosis of the left colon, with or without complementary decompression, is rarely indicated in the Author's experience. The dangers of primary anastomosis are great, while the results of graded procedures are relatively safe, and are entirely satisfactory. In the Author's experience the hospital mortality from graded procedures is from five to ten per cent.

N. M. Percy, Chicago.

RIVERS, A. B., STEVENS, G. A., AND KIRKLIN, B. R.

*Diverticula of the Stomach. S. G. and O., Vol. 60, No. 1, pp. 106-113, Jan., 1935.*

The Authors present ten cases of diverticulum of the stomach, and suggest a simple classification of that condition.

1. True diverticula. Those in which the pouch includes all of the coats of the gastric wall without definite evidence that organic disease was the causative factor.

2. Acquired true diverticula. Those in which all the coats of the gastric wall are present although there may be some thinning, and there is evidence that some disease was instrumental in producing the pouching.

(a) Pulsion type of diverticula result from intra gastric pressure which is probably localized.

(b) Traction type of diverticula are incidental to extragastric adhesions.

3. False diverticula or diverticular formations. In these there is a break in the gastric wall resulting from disease.

The etiology of true diverticula is unknown. It seems that the weight of evidence favors a congenital basis for that group of diverticula. Acquired true diverticula usually result from the pull of adhesions to the gall bladder, spleen, pancreas or other adjacent viscera. Acquired false diverticula re-

sult from weakness of the stomach wall produced by inflammation, ulceration, or by neoplasm.

Of the cases presented 10 were removed at operation, while 4 were secured during routine post mortem examinations. The ages of the individuals (cases) ranged from 25 to 59 years; the average age was 42 years. Six of the patients were males; 8 were females. Six of the diverticula were found adjacent to the pylorus, 6 at the cardia, and 2 were some distance from the pylorus on the posterior wall. The diverticula varied from 1 to 7.5 centimeters in diameter. In two cases peptic ulcers were found adjacent to the diverticula; in one an adenomyoma in the diverticulum, and in another a sarcoma in the wall of the diverticulum. In one case a diverticulum was found in the duodenum also; in another multiple diverticula of the colon was found. In 10 of the cases the symptoms of which the patients complained could not be attributed to the diverticulum. The diagnosis of gastric diverticulum cannot be made without roentgenograms; roentgenologic diagnosis is difficult.

The treatment of diverticula of the stomach is, in the main, surgical. The particular surgical procedure in a given case will be determined by the size and location of the pouch, the presence or absence of associated pathology, and the symptoms which it might have produced.

Fourteen cases are reported in detail. Nine figures and a bibliography accompany the article.

KOSTER, HARRY, M.D., AND KASMAN, LEWIS T., M.D.

*Acute Pancreatitis. Arch. Surg., Vol. 29, No. 6, pp. 1014-1024, Dec., 1934.*

This article is a general discussion of this disease and a report of 22 cases treated by the Author.

In this series of 22 cases, 5 cases were correctly diagnosed preoperatively and the disease was suspected in three others. The age incidence varied from 17 to 78 years of age, 63.64 per cent of the group were less than 35. The average age incidence was 35.27 years. 36.36 per cent were men and 63.64 were women.

A history of biliary tract disease was present in 63.64 per cent of the cases.

The duration of the present illness in this series varied from 1 day to 2 weeks. In 40 per cent of the cases, it was 24 hours or less in 63 per cent of the cases, there was a sudden onset of pain in the epigastrium or right upper quadrant or both, followed by vomiting. In the remainder of this group, the onset was less precipitous but similar. Shock and cyanosis were present in 31

per cent. Transient glycosuria was present in 2 cases.

Those cases not diagnosed as acute pancreatitis suggested a variety of conditions, acute cholecystitis (63 per cent), perforated gastric ulcers (14 per cent), acute obstruction of the common bile duct (22 per cent).

At operation, the pancreas showed the typical inflammatory changes in all cases, fatty necrosis of the omentum and the typical sero-sanguinous exudate was observed in 63 per cent of the cases. In 50 per cent a greenish discoloration of the fat in the gastro-hepatic omentum, characteristic of this disease was noted. In only 18 per cent of the cases, was the pancreas the only organ in which there was apparent involvement. Cholecystitis with concomitant cholelithiasis was present in 54 per cent of the cases. Cholecystitis alone was present in 18 per cent, and common duct stones alone were found in 9 per cent of the cases.

The prevalent opinion that acute pancreatitis is usually secondary to an involvement of the biliary tract as the result of which there may occur an intrapancreatic activation of trypsinogen and a subsequent autodigestion of the gland seems to be borne out by this group of cases.

The diagnosis of acute pancreatitis is not difficult when an onset is presented of knifelike pain in the epigastrium associated with prostration and cyanosis. This pain is usually similar to that of a perforated gastric ulcer and a careful past history is, therefore, very important. In cases where the onset is less precipitous, where symptoms are present suggesting an exacerbation of inflammation of the biliary tract, acute pancreatitis should be suspected. This is particularly important when the patient is a male, because acute pancreatitis is as frequent in males as in females in contradiction to the higher incidence of disease of the biliary tract in the latter.

The mortality in several series of cases reported since 1910 is given. This varies from 68 per cent to the Author's series which is reported in the present article as 22.7 per cent. Early operation is the most important single factor in further reducing this operative mortality.

The surgical treatment of acute hemorrhagic pancreatic inflammation should include the following steps: Drainage of the biliary tract, removal of the gall bladder, if it is diseased or contains stones, removal of calculi if present from the common duct, being certain that no stones are left in the region of the head of the pancreas, splitting of the capsule of the pancreas for the relief of edema and drainage of the lesser peritoneal sac and pancreas.

N. W. Swinton, Boston.

## SECTION XII—"The Clinic"

### A Case of Noma (Cancrum Oris) Complicating Non-Specific Ulcerative Colitis

By

JOSEPH S. DIAMOND, M.D.\*  
NEW YORK, NEW YORK

THE extreme rarity of noma in adults, especially in association with non-specific ulcerative colitis, prompts me to report this case. With the exception of instances of noma occurring as complications of dysentery in infants and children and the diarrheas of undernourished and marasmic babies, a careful search of both the recent and older literature fails to reveal any report of the association of noma with ulcerative colitis in adults. In a series of 695 cases of ulcerative colitis collected at the Mayo Clinic over a period of five and one-half years (January 1, 1923, to July 1, 1928) and reported by Bargen (1), there were a total of 278 complications, which varied in nature from local intestinal conditions to arthritis, cutaneous disorders, endocarditis, etc. No mention of the occurrence of noma is made, however. In Logan's (2) series of 117 cases, and in Lynch and Felsen's (3) forty-one cases no mention is made of any oral complications. In Jones' (4) report of seven cases of ulcerative colitis with peripheral complications, two cases are mentioned with ulcerative stomatitis and three cases with ulcer of the cornea, which he attributed to dietary deficiencies and which cleared up with restoration of adequate nutrition. No Vincent's organisms were found in the mouth lesions. Mackie (5) cites the occurrence of glossitis and stomatitis among other nutritional disturbances in ulcerative colitis, and ascribes these to a deficiency state. Glossitis was the most common manifestation in his series. Small aphthous ulcers were found in only

four out of seventy-five cases of ulcerative colitis. He also reports an extension and spreading skin gangrene of the flank, in one case, which occurred suddenly following ileostomy, and which could not be attributed to any known cause. Aerobic and anaerobic cultures were negative. Mackie believes that the factor of deficiency in his series is a secondary manifestation of ulcerative colitis rather than the primary cause of the disease.

#### REPORT OF CASE

Mr. A. G., age 28, married, white, salesman, born in the United States, was referred to the Sydenham Hospital on April 2, 1933, by Dr. I. Margulies. The patient gave the following history: One month before admission, he began to have loose stools which contained some blood. Two weeks after the onset, the diarrhea grew worse, the patient having as many as ten movements a day, accompanied by cramp-like pains in the lower abdomen. There was a slight elevation of temperature (101 degrees) with occasional vomiting. Appetite was diminished. The patient lost weight and became weak. He remained in bed for two weeks and then entered the hospital.

Upon admission, the patient appeared well developed although somewhat pale and dehydrated. Pulse was rapid (120) and small; abdomen somewhat distended and tenderness in both flanks. Proctoscopic examination revealed the presence of bleeding ulcers of varying sizes, extending from the upper part of the rectum upwards into the sigmoid. Blood picture: hemoglobin 65%; red blood cells 4,340,000; white blood cells 21,400. Differential count: 75% polymorphonuclear neutrophils with 18% segmented and 57% band forms, 11% lymphocytes, 12% monocytes, and 2% eosinophiles, with a few myelocytes and metamyelocytes, and occasional Türk cells. Some leucocytes showed vacuoli-

zation. The urine was negative. Feces were foul smelling, loose, dark brown in color and mixed with blood. Blood agglutination for typhoid, paratyphoid A and B was negative. The Felix-Weil reaction was negative. Wassermann and Kahn tests were negative. Bacteriological study of the feces showed colon bacilli, streptococcus fecalis, diplococci, atypical dysentery bacilli of Flexner. Stool was negative for amoeba, parasites, and monilia.

Glucose and saline infusions were given and the patient was placed on a balanced, low-residue diet. Daily rectal irrigations with non-irritating fluids such as physiological saline and chamomile tea, and mild antiseptics such as neutral acriflavine (1:5,000) were used at different times. Kaolin, bismuth and opiates were administered per os to control the frequency of the movements. Due to the inability to obtain a pure strain from the base of an ulcer, a mixed vaccine was prepared consisting of streptococci, diplococci and colon bacilli and was administered in increasing doses.

During the first five days the temperature fluctuated between 100 degrees and 102.5 degrees (F). Pulse continued rapid and small and persisted at 120 and over. On the fifth day the temperature rose to 104. The patient appeared very toxic, and became disoriented, elated and restless. The picture resembled a mild manic psychosis. Paraldehyde was given and the condition cleared up within a few hours. Blood cultures made at this time were negative after seventy-two hours. A blood transfusion was given with slight general improvement.

Bowel movements seemed somewhat controlled; nutrition was maintained; but the pulse rate remained unaltered and the temperature persisted ranging from 99 to 103.4 degrees. The white blood count remained elevated reaching as high as 25,000-28,000, always with a persistently high percentage of band forms (as high as 60%). On April 13,

\*Attending Gastroenterologist Sydenham Hospital, New York, New York.  
Submitted August 27, 1935.

the patient again showed slight disorientation and had incontinence of feces. This cleared up in a very short time.

On April 14, the patient complained of pain in the teeth of the left upper jaw. Examination revealed a small grayish-white ulceration about two to three millimeters in diameter. This ulcerative process increased in size daily. Radiography showed normal second and third molar teeth. Within four days, the ulceration quickly spread from the gingiva over the inner side of the left cheek over an area of about three centimeters in diameter. The lesion began to assume a dark-grayish appearance and developed a strong fetid odor. A smear from the wound, made at this time (April 18), revealed the presence of fusiform bacilli and spirochetes; culture revealed streptococci and staphylococci. Noma was promptly suspected. The leucocyte count began to drop daily, falling to 16,000, 10,000, and on April 17, was 8,500, with 13% polymorphonuclears and 46% band forms. The possibility of an agranulocystic picture was considered. On subsequent examinations, however, the leucocyte count was found to be rising and fluctuated between 12,000 and slightly over 20,000. Local applications of a suspension of neosalvarsan in glycerin were made several times a day. The mouth was also irrigated with solutions of sodium perborate. A blood transfusion was again given. The condition of the mouth was not influenced by the salvarsan and the ulceration continued to spread.

On April 19, the patient suddenly developed a marked parotitis on the left side, with pain and tenderness. About two days later, the right parotid gland became similarly swollen. A sense of deep fluctuation was felt in both glands and incision and drainage were considered, but within the next few days the swelling of the glands receded spontaneously and both glands returned to normal.

On April 22, the patient had several copious intestinal hemorrhages, the first one during the night, about 400 c.c. and again later, about 500 c.c. of bright red blood. The pulse rose to 150-160. Transfusion was promptly given, along with thromboplastin and calcium gluconate. The hemorrhages ceased and the patient rallied. The pulse rate decreased to its previous value for several hours. On April 24, he was again incoherent and fingering the bedclothes. The blood showed a bleeding time of eight and one-half minutes; clotting time was three minutes; and blood platelets were 200,000.

On April 25, the gangrenous ulceration in the mouth suddenly spread to the hard palate, covering more than half and reaching as far back as the soft palate, spreading simultaneously over the entire inner part of the left cheek, and causing a marked indura-

Fig. 1. Noma showing gangrene involving roof of mouth and induration and edema of lip and left cheek (just before perforation).

tion of the cheek and edema of the upper lip (Fig. 1). A sharp line of demarcation was seen at the margin of the ulcerating process. The odor was very foul, penetrating throughout the room. Alimentation became somewhat difficult, but the patient was cooperative and made every effort to consume the liquid and soft foods given to him.

At this time ultra-violet radiation was instituted, and local treatment to the gangrenous portion of the mouth made with the Kromayer lamp. No improvement was noted. The gangrene spread, involving the entire palate and inside of the cheek. An attempt was made to stay the process by removal of the necrotic tissue. The sloughs were removed daily to encourage drainage and expose healthy tissue wherever possible.

Another blood culture was negative after seventy-two hours. Cultures from the mouth were positive for non-hemolytic streptococci and staphylococcus citreus. *B. Fusiformis* and spirilla, at this time, were no longer found on the surface of the gangrenous tissue, but could be found in the deeper strata after removal of the slough.

The hemoglobin dropped to 55% and the red blood count to 3,890,000. Blood transfusion was again given on the 28th of April.

On May 30 and May 1, the patient was again irrational and had incontinence of urine and feces. The mouth was irrigated with a 1:5000 solution of potassium permanganate and an "Enzymol" plug was introduced. The red cell count fell to less than three million and the hemoglobin to less than 55%. Another transfusion was given on the 4th of May. There was very marked edema of the lips and upper eyelids. The patient also developed a moderate degree of exophthalmos of the left eye. The center of the left cheek became dark. On May 5, a radical operation was undertaken to remove the slough with the high frequency cautery, cutting into the bordering healthy

tissue. Following another transfusion the entire soft structure of the left upper maxillary region was also removed exposing the bone. The hard palate also was exposed. The slough of the soft structure of the left cheek and buccal mucosa was excised. The center of the left cheek was about to perforate.

On May 6, the cheek had perforated and the patient was failing rapidly. He became stuporous and incontinent and in spite of stimulation, intravenous glucose, etc., he died on the following day, May 7.

## DISCUSSION

In the early part of the Seventeenth century Bathus (6) described for the first time the symptom complex of noma, although the word "noma" has been employed since the time of Hippocrates to denote destructive and perforating lesions. Van der Voerde (6), in the latter part of the Seventeenth century, applied the term to this clinical picture. Other names that have been employed are "cancrum oris," "cancer acuticus," etc., and due to its high mortality, which reaches from seventy to eighty per cent, it has also been called "malum mortum."

## ETIOLOGY

The causation of noma has been attributed to many factors. The nutritional element, both general and local, was considered the sole cause by the older writers. Martin (7), in 1796, and others such as Marshall Hall (7) and Karl Weil (8) (1916) stressed the association of malnutrition and noma from their observation that noma, as a complication of the exanthemata, is more frequent among undernourished and debilitated children. Henoch (9) called the disease "cachexia pauperium"

## Avoid the Vicious Circle of Alkali Neutralization

WITH

# TRI-CALSATE

• Unlike the alkaline antacids (sodium bicarbonate, magnesium oxide, etc.) TRI-CALSATE does not stimulate the secretion of gastric HCL.

• Neither does TRI-CALSATE alkalize the stomach contents for it is a *buffered neutral antacid*.

• Yet, TRI-CALSATE is a powerful neutralizer of gastric HCL, palatable and non-irritating.

• That's why extensive clinical experience proves the definite superiority of TRI-CALSATE in the treatment of the gastric hyperacidity syndrome.

Available on prescription or direct in 4 oz. and pound bottles.

and attributed it likewise to the poor living conditions, poor nutrition, and uncleanness, and unhealthy dwellings. It was more commonly encountered in the older institutions where nutrition and hygiene were in

virus was the underlying cause. Bouday (15), however, seems to have definitely established the bacterial origin of the process. He demonstrated *B. fusiformis* and spirilla in the peripheral healthy

Fig. 2. (After Bouday) Showing pure strain of spirilla and fusiform bacilli extending into healthy tissue. No other form of microorganisms are seen.

a primitive state, from which it has also received the name "hospital gangrene."

Woronichin (10) held the lesion to be a trophoneurosis which he confirmed by experiments in which the extirpation of the infraorbital nerve of a dog was followed by the appearance of gradually increasing ulceration on the corresponding lip. These, however, were regarded by Waurick (11) and Krassin (12) as decubitus ulcers following trauma to the anesthetized lip. Ziem (12) regards it as an anemic necrosis, following thrombosis of the blood vessels of the mouth. The histological studies fail, however, to reveal thrombi in the larger vessels.

Since the discovery of Plaut (13) and Vincent (14), in 1894 and 1899, of spindle-shaped bacilli and spirilla in inflammatory process of gangrenous character in the mouth and throat, the bacterial causation of noma has assumed primary importance. For a time questions were raised (Baumgarten 6) whether these microorganisms, including streptococci and staphylococci, etc., were not secondary invaders multiplying in necrotic tissue. Others, such as Heinemann (11) and Strada (11) maintained that a filtrable

tissue surrounding the lesion (Fig. 2) removed during the life of the patient. In fact he was able to prognosticate the outcome from the degree of invasion of the healthy tissue, the fewer the bacteria, the better the outlook. Furthermore, he found these two specific microorganisms in the healthy zone to the exclusion of any others, while in the adjacent necrotic tissue, streptococci, staphylococci, thick rods, and other organisms were present. All these findings have been confirmed by Kalina (6) and a large number of investigators such as Bertheim, Grawitz, Elder, Guizetti (16), and others who substantiated the findings pertaining to the symbiosis of the *B. fusiformis* and spirilla in ulcerous and gangrenous stomatitis. That these bacteria are not harmless saprophytes harbored in the mouth, has been demonstrated by Vincent who has proven that they are the causative agents for the inflammatory changes of Vincent's angina, and that in debilitated children with poor nutrition, in chronic diseases, the organisms become more virulent and produce profound gangrenous changes.

It is claimed by Perthes (16), Krahn (16) and Bouday (15) that

# Gastric Hyperacidity

In the relief of gastric hyperacidity, *speed* is essential—Cal-Bis-Ma provides it. The neutralizing effect should be *prolonged* so as to prevent secondary acid rise—again Cal-Bis-Ma takes care of that. The irritated gastric mucosa should be soothed and protected from further irritation—that, too, is an important mission of Cal-Bis-Ma. Send for a trial supply and descriptive literature.

# CAL-BIS-MA

WILLIAM R. WARNER & CO., INC.  
113 WEST 18TH STREET • NEW YORK CITY

Cal-Bis-Ma (powder) is supplied in tins (with removable label) containing  $1\frac{3}{4}$  and 4 ounces and one pound. *Tablets*, in bottles of 110.

the spirillum is the initiator of the necrosis and forces its way into the healthy tissue, as though paving the way for the *B. fusiformis*. This mass invasion of the normal tissue by the spirilla is the first step in the gangrenous process, and complete necrosis can only occur if the *B. fusiformis* find their way into the tissue along with the spirilla. In our own observation, in the case reported, when the gangrene was fully developed the *B. fusiformis* and spirilla could no longer be found on

the surface. Only after the removal of the gangrenous slough could these microorganisms be demonstrated in smears taken from the underlying exposed tissue. Vincent's observations were that where the *B. fusiformis* were found alone, the process was milder without any deep ulceration. These form a crust on the surface which simulates a diphtheritic membrane, and in these pseudomembranes one finds exclusively *B. fusiformis*. The *B. fusiformis* causes inflammation and irritation. The

brownish-green gangrene is due to numerous and various bacilli and cocci which grow on the tissue surface. While the same bacteria are found in Vincent's angina, without the necrotic process present in noma, the histological pictures are identical, differing only in degree, the difference being due to the increased virulence of the organisms and the lowered resistance of the tissue, as in the severe infections where the blood and the blood-forming organs are also attacked.

#### PATHOLOGY

Rona (17) describes three characteristic zones. The first zone is the superficial gangrenous portion which is recognized as a thick diphtheritic membrane. It consists of homogeneous cells without nuclei which, with fibrin and red cells are converted into hyaline-like poorly staining mass. Zone two is beneath the superficial crust and consists of an infiltration with groups of polymorphonuclear leucocytes and growing connective tissue cells. This does not extend very deeply as the infiltrated tissue early undergoes coagulation necrosis. A fibrin boundary can often be seen between the two zones. The walls of the blood vessels in the vicinity of the inflammatory process show very early the appearance of coagulation necrosis. Zone three is the healthy zone. The transition from diseased to healthy tissue is abrupt. The process presents a sudden death of tissue without noteworthy reaction of neighboring tissue.

Bouday (15) also found a sharp line of demarcation between the healthy and necrotic tissue. At the periphery, the tissue still stained fairly well and the fat connective tissue and muscle cells were still recognizable; while in the brownish-green, gangrenous area, the tissue was disorganized, no definite cellular structure being discernible, the spaces were filled with clumps of pigment. The blood vessels were thrombosed. In the peripheral healthy zone, there was neither hyperemia nor thrombosis of the vessels. However, the *B. fusiformis* and spirilla, as previously mentioned, were seen forcing their way into the adjacent tissue, while in the necrotic zone, there were masses of fusiform and strand-like organisms which strained with fuchsin, and in the superficial brownish-green gangrenous tissue, many cocci and clumps of small

## For "INTESTINAL TOXEMIA"

## KARICIN

*The combined adsorptive-detoxifying effects of kaolin and ricinoleate aid in*  
Detoxifying intestinal bacterial toxins

Checking fermentation

Reducing flatus

Soothing irritated mucosa

Establishing normal bowel action

An average tablespoonful of Karicin contains:

|                            |          |
|----------------------------|----------|
| Pure Colloidal Kaolin      | 53 grs.  |
| Ricinoleate                | 6 grs.   |
| High Viscosity Mineral Oil | 1¼ drams |

The new flavor insures a new palatability  
—the same detoxifying properties.

# The NORMAL STIMULATION TO COLON PERISTALSIS ....*Distention*

*The ideal therapeutic agent for correcting constipation by physiologic distention should satisfy these requirements:*

1. It must be non-irritating to the sensitive gastro-intestinal tract.
2. It must supply bland bulk to a spasmodic colon to overcome cramping.
3. It must lubricate the bowel, to facilitate passage of the gastro-intestinal content.
4. It should not interfere with digestion and, preferably should not be digestible, itself.
5. It should have a viscous tenacity, in order to unite the fragmented stools during the diarrheal stage.
6. It should not leak from the anus when taken in quantities sufficient to afford the desired therapeutic effects.

## MUCILOSE

*Complies Fully with All These Requirements*

This hemicellulose is obtained from the *Plantago loeflingii*. Supplies bland, non-irritating bulk. Mucilose does not leak — does not impair digestion.

*Effective . . . Easy to Take . . . Economical*

Mucilose offers a non-irritating stimulant to the spastic colon, by physiologic distention.

thick bacilli were found. Bouday claims that the absence of *B. fusiformis* and spirilla in vital tissue is a good prognostic sign.

### TREATMENT

The treatment of noma is still very unsatisfactory as can be seen from the high rate of mortality. Many forms of therapy have been advocated each one claiming some measure of success.

The most important is early surgical excision which is best carried out

today with the electro-cautery, extending the incision into the surrounding healthy tissue. Curettage of the slough is also recommended. Golianitzky (18) also advocates incision and drainage of the ducts of the salivary glands (parotid and submaxillary), producing external fistulae, since he believes the lesion is spread by the infected salivary secretion.

Petruschy (19) claims to have been successful in a few instances

with the use of anti-diphtheria serum, where the Loeffler's bacilli have been found in abundant numbers in the ash-gray superficial membrane.

In view of the presence of the spirilla, the use of salvarsan has been advocated both locally and intravenously. Romeo (11) reports the cure of four cases with this treatment. Plaut (11) cured one case. Various forms of radiation therapy have also been employed, such as the red lamp, and X-ray. Locally all forms of mouth antiseptics and deodorants are to be used. Metaphen, potassium permanganate, hydrogen peroxide, perborates, zinc chloride, copper sulphate, etc., and iodoform applied in pledgets have been recommended and also various dyes such as methylene blue, gentian violet, and acriflavine.

In the case reported, removal of the slough was begun early and complete surgical excision with the electro-cautery was done about two weeks after the onset of the process.

The application of a suspension of neosalvarsan in glycerin was employed as a first measure, when the lesion was still small. In spite of its free and early use, the lesion continued to spread.

Radiation therapy was also employed in the form of ultra-violet light, locally, by daily use of the Kromayer lamp. There was also application of the quartz light over the body. No visible impression was made by these procedures. All types of mouth antiseptics were used.

The general condition of the patient must be taken into account. In this instance, the markedly debilitated state from the persistent diarrhea, intestinal hemorrhages, marked toxemia with high and irregular temperature, and high leucocyte count with the large percentage of immature forms, interfered with the success of the treatment in spite of five blood transfusions.

### CONCLUSIONS

1. A rare case of noma in an adult, complicating non-specific ulcerative colitis, is here described, possibly the first one of its kind to be reported.

2. The Bacillus fusiformis and the spirillum were found very early on the surface of the lesion, but with the development of the gangrene, could be recovered only from the depths of the lesion, after removal

## DR. TWISS' DUODENAL TUBE

Designed by Dr. John Russell Twiss, New York City

**A** RADICALLY new tube with bucket and terminal swivel weight that guides tube and bucket easily through pylorus into duodenum without kinking or curling.

The use of slightly larger and more resilient tubing tends to prevent looping in stomach.

The small diameter of solid terminal tip makes engagement in pylorus easier and the smaller size tubing attached is drawn after it by peristaltic action on the terminal ball. Thus the small size bucket which is attached by the means of swivel connection between terminal ball and bucket permits torsion of terminal ball without affecting duodenal tube and bucket or causing it to loop in the stomach.

Construction of slots in bucket allow free flow of fluid. Concavity prevents adherence to visceral walls. Terminal

ball and bucket are attached to rubber tubing by silk thread, but without use of knots.

The rubber tube has the standard one, two and three ring marking, but in addition the tube is calibrated in inches from the two-ring marking to a point four inches beyond the three-ring mark. This calibration is advantageous where drainage is to be repeated, because the three-ring mark represents only the distance where bile may be obtained in the average patient. Since there is a variation of length required, the correct length may be recorded for reference.

of the slough. This substantiates Vincent, Bouday and Kalina with regard to the relationship of these organisms to noma as causative agents, and the manner of their spread through the tissue.

3. The marked general toxemia accompanying this fulminant type of ulcerative colitis must be considered as the predisposing factor.

## ABSTRACTS

RICHTER, H. M., M.D., F.A.C.S.

*Gastric Resection for Peptic Ulcer: Technique. S. G. and O., Vol. 59, No. 3, pp. 337-343, Sept., 1934.*

The purpose of this paper is to present the Author's conception of the objective to be obtained in radical subtotal resections of the stomach and to give a short description of the most important points in technique.

Neutralization and reduction of gastric acidity are incidentally obtained following adequate subtotal resection of the stomach and are not the prime objective of resection. The object of gastric resection for benign ulcer is the removal of the ulcer bearing segment of the stomach, which is the lesser curvature and distal half or more of the stomach, and first portion of the duodenum. The poor results following surgery for benign gastric ulcers have been due largely to technical errors and also to a non-realization of the objective to be obtained. He believes that if a resection is to be done at all, it should be a radical resection.

The usual preoperative preparation of these patients is discussed. The regulating of a proper water balance is emphasized. Transfusions are given when indicated, especially in cases which have been hemorrhaging and gastric lavage is freely used where there has been obstruction and dilatation of the stomach. In discussing acute perforations of gastric ulcer, the Author points out that if the patient is operated upon at an early period following the perforation, a radical resection may be done without excessive danger to the patient.

Important points only in the technique as described will be mentioned. The Author follows the Hoffmeister and Finsterer method in doing

# *The Doctor Chooses*

*And every month more and more physicians are choosing Meyenberg Evaporated Goat Milk for their Food Allergy, Tuberculosis and difficult pediatric cases.*

## **BECAUSE**

Goat milk protein is non-allergic and forms a fine, easily digested curd, and

## **BECAUSE**

The fat in goat milk is in fine globules of easily saponified oleates, and

## **BECAUSE**

The minerals of goat milk are in splendid proportion and quantitatively high, and

## **BECAUSE**

Meyenberg Evaporated Goat Milk is easily available, economical and bacteria-free.

If, so far, you have not chosen Meyenberg Evaporated Goat Milk, Doctor, send for the generous clinical size and descriptive literature.

a subtotal removal of the lesser curvature of the stomach, spur formation by partial closure of the end of the stomach and vertical position of the stoma in the standing position of the patient. The jejunum is anastomosed to the stomach near its origin, forming a short loop. The Author believes that the long loop gastro-jejunal anastomoses predispose to gastro-jejunal ulcers. A well defined spur is formed at the lesser curvature border of the cut end of the stomach and the attachment of the jejunum is placed so as to reinforce this spur. At the junction of the greater curvature of the stomach with the jejunum, a spur is definitely avoided. These steps prevent retrograde filling of the duodenum with stomach contents.

*Tuberculous Abscesses of the Brain Secondary to Tuberculosis of the Cecum. S. G. and O., Vol. 60, No. 2, pp. 229-235, Feb. 1, 1935.*

Not infrequently the central nervous system is invaded by tuberculosis which usually manifests itself there in the miliary form, or, less frequently, as single or multiple tuberculomata. The pathology of tuberculous abscess of the brain differs from that of tuberculous abscesses elsewhere in that it does not involve the various stages of granu-

lomatous changes to be expected from an organism of this nature. There is probably a primary period of localized encephalitis, a secondary period of softening, and a final period of capsule formation in the development of a true abscess.

In a review of the literature many cases of tuberculous involvement of the brain secondary to involvement of the cranial bones, or meninges, were found.

The Author reports in minute detail one case of true tuberculous abscesses of the brain associated with tuberculosis of the cecum.

Six figures and a bibliography accompany the article.

N. M. Percy, Chicago.

## ERROR

In the December Journal on page 598, an unfortunate omission was made in not stating the Journal in which Prof. William Boyd's article on Polycythemia appeared. The correct reference was as follows: American Journal of the Medical Sciences, v. 187, pp. 589-594, May, 1934.

# Viable Bacteria Reduced To Zero (Or Near Zero)

In 15 series of samples of the defecate from a number of human subjects. The subjects were not injured by the medication, as determined by thorough clinical and laboratory examinations immediately after cessation of medication and for a number of months subsequent thereto.

The medications employed were two saponaceous glycerites of Alpha Naphthol designated:

## ALPHA NAPH CO AND JELLY OF ALPHA NAPH CO

The Alpha Naph Co was taken in water and orange juice. The "Jelly" was administered in enteric coated capsules opening in the intestinal tract.

A resume of the reports, and adequate supplies for clinical test, will be gladly sent to any physician interested, with our compliments.

## SECTION I—*Clinical Medicine: Diseases of Digestion*

### The Incidence and Biological Characteristics of the Hemolytic *Bacillus Coli* in the Intestinal Tract of Patients with Chronic Ulcerative Colitis\*

By

EDITH E. NICHOLLS, M.D.†  
NEW YORK, NEW YORK

IN 1934 an investigation was carried out by the Author relating to the incidence and biological characteristics of the hemolytic *Bacillus coli* in the stools of healthy individuals. Results of this study showed that the hemolytic *Bacillus coli* was a normal inhabitant of the intestinal tract and that if several stool specimens from the same person were examined, it was invariably found in at least one of them.

The presence of this organism in healthy individuals, however, has no bearing on the role that this same organism may play in pathological conditions of the intestinal tract. Throughout the literature there are equivocal statements concerning the significance of the hemolytic *Bacillus coli* in ulcerative colitis and other intestinal disorders. Many investigators have treated patients with vaccine, Dorst and Morris 1930 (1), Mateer and Baltz 1932 (2), Niles and Torrey 1934 (3), and serums, Vincent 1930 (4), Schwartzman and Winkelstein 1934 (5), made from this organism, but no convincing experimental data has been produced to demonstrate that the hemolytic *Bacillus coli* is of etiological importance in diseases of the gastrointestinal tract.

Schmidt, in 1909 (6), Dudgeon, Wordley and Bawtree 1921 (7), and Mateer and Baltz 1932 (2) studied the incidence of the hemolytic *Bacillus coli* in the stools of patients with "diarrhea" and colitis and found that it is approximately the same as in those of normal people. On the other hand, Meyer and Lowenberg 1924 (8), Dudgeon 1926 (9), and Niles and Torrey 1934 (3) found the percentage markedly higher in the group of patients with disorders of the gastrointestinal tract.

#### THE PRESENT STUDY

The present report is based on a study of the *Bacillus coli* recovered from fecal material removed from ulcers in the colons of patients suffering from chronic ulcerative colitis. The specimens were obtained from patients in the gastrointestinal clinic of the New York Hospital, through the courtesy of Dr. Thomas T. Mackie. In all of these cases there was a definite diagnosis of chronic ulcerative colitis based on the history and clinical findings. Forty-two patients were studied.

\*From the New York Hospital, and the Department of Medicine, Cornell University Medical College, New York City.  
†With the technical assistance of Herman P. Saltz, B.S.  
Submitted August 30, 1935.

24 males and 18 females. The youngest patient was 13 years of age, the oldest, 57, and the average age was 34.7 years. The duration of the ulcerative colitis varied from 3 months to 18 years, with an average of 3.9 years. In a high percentage of cases, several proctoscopic smears from the same patient were examined. Altogether, 135 specimens were analyzed.

#### TECHNIC

The culture was obtained by passing a long, sterile swab through the proctoscope and rubbing it over the surface of one of the ulcers. The swab was then placed in a tall, sterile test tube and was sent to the laboratory. As soon as it was received it was passed over the surface of an Endo's plate and the plate was incubated for twenty-four hours. In approximately 10 per cent of the samples there was such a small amount of material on the swab that very little or no growth was obtained on the Endo's plate. Therefore, in order to avoid losing a culture, one c.c. of sterile broth was put into the test tube containing the swab, after the Endo's plate had been streaked, and the tube was allowed to remain in the room overnight. If no growth, or only a few colonies, appeared on the Endo's medium, another plate was streaked and in this way a good growth was always obtained.

One hundred colonies were then transferred to a blood agar plate and the percentage of hemolytic *Bacillus coli* was obtained by the method described in a previous publication by the Author in 1934 (10).

#### RESULTS OF PROCTOSCOPIC SMEARS

One hundred and thirty-five proctoscopic smears from 42 patients with chronic ulcerative colitis were cultured and the hemolytic form of the *Bacillus coli* was found in 84, or 62.2 per cent of the samples (Table I). In 45, or 53.6 per cent of the 84 cultures the hemolytic *Bacillus coli* was present in large numbers (50 to 100 per cent). If we consider only the first swab specimen from each patient, hemolytic *Bacillus coli* organisms were present in 26, or 61.9 per cent of the 42 cases.

From 28 of the patients, repeated swab cultures were obtained, the number varying from 2 to 10 from a single patient. Specimens were taken at intervals ranging from one week to several months, and 13 patients were studied over a period of one to two years. In 22, or 78.6 per cent of the 28 patients, hemolytic

*Bacillus coli* was present in at least one of the specimens studied. In the 6 negative cases, 4 patients had 2 cultures only and 2 had 4 cultures.

In Table II are recorded the results of the examination of specimens from 15 patients from whom 4 or

TABLE I

*Relation of Positive Results of the Hemolytic Bacillus coli to the Number of Proctoscopic Smears Examined*

|                                  | Number of individuals | Positive for hemolytic B. coli |          | Negative for hemolytic B. coli |          |
|----------------------------------|-----------------------|--------------------------------|----------|--------------------------------|----------|
|                                  |                       | Number                         | Per cent | Number                         | Per cent |
| First or one specimen submitted  | 42                    | 26                             | 61.9     | 16                             | 38.1     |
| Two or more specimens submitted  | 28                    | 22                             | 78.6     | 6                              | 21.4     |
| Four or more specimens submitted | 15                    | 15                             | 100.0    | 0                              | 0        |

Total number of specimens submitted was 135, of which 84, or 62.2 per cent, were positive for hemolytic *Bacillus coli*.

more proctoscopic smears had been made. In 6 of the cases, all of the cultures studied contained hemolytic *Bacillus coli*, while in the other 9 cases, from 14.3 to 80 per cent of the smears showed the nonhemolytic type. In the case of no individual was the hemolytic organism absent from every culture examined, although there was a wide variation in the quantity of the hemolytic type present in the consecutive samples. As a representative example, the consecutive specimens from the patient B.G. ran as follows: 89, 100, 0, 23, 40, 0, and 48 per cent positive for the hemolytic *Bacillus coli*.

The hemolytic *Bacillus coli* colonies showed a variation in the size of the hemolytic zone on blood agar similar to that originally described by Schmidt (6). Seventy-two per cent of the strains fell into his "group one," 19 per cent into "group two," and 2 per cent into "group three." However, an organism was recovered from 7 per cent of the 96 hemolytic strains that had a much larger zone of hemolysis than the "group one" of Schmidt. In 11 cases two types of hemolytic colonies appeared in the same culture.

## CULTURAL AND BIOLOGICAL CHARACTERISTICS OF THE *BACILLUS COLI* STRAINS

Various tests were carried out on the strains of the hemolytic and nonhemolytic *Bacillus coli* for their identification. These tests were performed as soon as

possible after isolation of the strains. All of the organisms grew well in litmus milk, with the production of acid and clot. On Russell's medium they gave the characteristic appearance with acid and gas in the butt and acid in the slant. None of the strains liquefied gelatin at 22 degrees Centigrade.

The Voges-Proskauer and methyl-red tests were carried out on the strains according to the method described by Clark and Lubs (11), and the technic followed was that outlined by Levine (12). All of the strains were Voges-Proskauer negative and methyl-

\*C: hemolysis of all the red cells. I: hemolysis of nearly all of the red cells. M: distinct coloration of the whole medium. T: slight tingeing of the medium above the red cells. 24 hours: packed red blood cells added at time of inoculation and incubated 24 hours. 1 hour: packed red blood cells added after 24 hours of incubation and incubated an additional hour. 0.85 and 0.5: strengths of sodium chloride in peptone water medium.

red positive, which results conform to the usual reaction for *Bacillus coli*.

**Sugar fermentations.** Tests were carried out to determine the action of the *Bacillus coli* strains recovered from swab cultures on the various sugars. The mediums were prepared and the tests were carried out as described in the previous article (10). The sugars studied in that investigation were again employed and, in addition, salicin, dulcitol, and indol.

All of the strains examined fermented lactose, maltose, glucose, and mannite with the production of acid and gas. All of the strains produced indol in peptone solution. Twenty-seven of the 93 nonhemolytic organisms and 25 of the 68 hemolytic strains formed acid and gas in saccharose. Of the hemolytic strains, 44 fermented salicin, and 36, dulcitol. Of the nonhemolytic organisms, 54 acted upon salicin and 51, dulcitol. A

more detailed classification of the organisms according to their sugar reactions will be found in a subsequent article.

*Hemolysis tests.* The method described by Dudgeon, Wordley and Bawtree (7) was the one employed

TABLE IV

*Comparative Virulence for White Mice of 64 Hemolytic and 71 Nonhemolytic Strains of Bacillus coli*

| Minimum lethal doses c.c. | Hemolytic Bacillus coli Number | Bacillus coli Per Cent | Nonhemolytic Bacillus coli Number | Bacillus coli Per Cent |
|---------------------------|--------------------------------|------------------------|-----------------------------------|------------------------|
| 0.5                       | 1                              | 1.6                    | 5*                                | 7.0                    |
| 0.3                       | 4                              | 6.2                    | 15                                | 21.1                   |
| 0.1                       | 14                             | 21.8                   | 25                                | 35.2                   |
| 0.05                      | 24                             | 37.5                   | 19                                | 26.8                   |
| 0.01                      | 12                             | 18.8                   | 3                                 | 4.3                    |
| 0.005                     | 9                              | 14.1                   | 4                                 | 5.6                    |

\*The M.L.D. for one nonhemolytic strain was 0.8 c.c. and is included in this group.

in the examination of the various strains of the *Bacillus coli* for their capacity to produce hemolysis of red blood cells. Human blood was used and the test was performed twice, with a week's interval between each analysis.

Altogether, 32 strains of the *Bacillus coli* showing hemolysis of the red cells on rabbit blood agar were tested. A representative number of strains from each of the three groups was selected and the results of the study are shown in Table III. The organisms possessing active hemolyzing properties showed very little difference in the degree of hemolysis present in the 0.85 per cent and the 0.5 per cent sodium chloride mediums. In the tubes to which human red blood cells had been added before incubation, the degree of hemolysis was more marked than in those to which cells were added the following day.

All of the strains belonging to "group one," that is, those showing a large zone of hemolysis on rabbit blood agar, manifested complete hemolysis of the red cells when incubated with the blood for twenty-four hours. When they were incubated for one hour, there was a wide variation from complete hemolysis to only a trace. The "group two" strains showed only a moderate amount of hemolysis and the "group three" strains showed only a trace of hemolysis.

*Virulence tests.* It was a matter of interest to determine the comparative virulence of the hemolytic and the nonhemolytic strains of the *Bacillus coli*. White mice of approximately twenty to twenty-five grams were used for the test, and the method employed was similar to the one previously outlined (10).

The test for virulence was carried out on 64 hemolytic and 71 nonhemolytic strains of the *Bacillus coli*. In Table IV is shown, under the various dilutions of the cultures, the minimal lethal dose for the different strains. It may be seen that 70.4 per cent of the hemolytic strains and 36.7 per cent of the nonhemolytic were virulent for white mice in doses of 0.05 or less. Thus, the hemolytic organisms were somewhat more virulent for white mice than the nonhemolytic.

*Agglutination reactions.* In order to determine whether there was any biological relationship between the hemolytic and the nonhemolytic strains of the *Bacillus coli* recovered from proctoscopic smears and those recovered from the stools of healthy individuals, agglutination tests were carried out with the serums

from four rabbits immunized against two hemolytic and two nonhemolytic strains of *Bacillus coli*, previously recovered from stool cultures of normal people. The four immune serums were tested for agglutinins against 40 strains of the *Bacillus coli*, 19 of which were hemolytic and 21 nonhemolytic.

The agglutination tests were carried out according to the method previously described (10). The *Bacillus coli* strains were divided into two main groups, the hemolytic and the nonhemolytic. These, in turn, were separated into two subgroups, the communior and communis, depending upon their reaction to saccharose.

Agglutination tests were carried out with the four immune serums, NH-8 cs.; NH-21 cr.; H-46 cs.; and H-62 cr. against 16 nonhemolytic communis strains, 5 nonhemolytic communior, 13 hemolytic communis, and 6 hemolytic communior.

From Table V it may be seen that the strains showed no tendency to fall into biological groups. Thus, of

\*NH indicates nonhemolytic; H, hemolytic; cs., communis; cr., communior.

the 16 strains in the nonhemolytic communis group, about 50 per cent were agglutinated by NH-8 cs. of the same group. Most of these same strains were agglutinated, as well, by serums NH-21 cr., H-46 cs., and H-62 cr. of the other three groups. Three strains

were agglutinated by two serums only, and five strains failed to be agglutinated by any of the serums.

The strains in the other three groups showed a marked tendency for agglutination similar to that described above for the nonhemolytic communis organisms. There seemed to be no type specificity. With a few exceptions, the strains were either agglutinated by all four serums, or failed to be agglutinated by any of them.

#### A COMPARISON OF THE INCIDENCE AND BIOLOGICAL CHARACTERISTICS OF THE HEMOLYTIC *BACILLUS COLI* RECOVERED FROM THE INTESTINAL TRACTS OF HEALTHY INDIVIDUALS AND OF PATIENTS WITH CHRONIC ULCERATIVE COLITIS

One hundred and thirty-five proctoscopic smears from 42 patients with chronic ulcerative colitis were cultured for the presence of the hemolytic *Bacillus coli* and this organism was found to be present in 84, or 62.2 per cent, of the specimens. The results obtained from the study of single and repeated specimens from the same patient were of particular interest. In the 42 first or single samples cultured the incidence of the hemolytic *Bacillus coli* was 61.9 per cent. In the 28 cases where two or more specimens from the same person were studied the figure rose to 78.6 per cent, and in the 15 instances where 4 or more cultures were examined hemolytic *Bacillus coli* was recovered from 100 per cent of the patients.

In 1934 an investigation was carried out by the Author concerning the incidence and biological characteristics of the hemolytic *Bacillus coli* in the stools of healthy individuals (10). In the study, one hundred and sixty-nine specimens of stools from 73 persons were cultured and the hemolytic *Bacillus coli* was found to be present in 114, or 67.4 per cent of the samples. In the 73 first or single specimens studied the incidence was 36.2 per cent. In the 25 cases where two or more specimens from the same individual were studied the figure was 88 per cent, and in 12 instances where 4 or more cultures were examined hemolytic *Bacillus coli* was found in 100 per cent of the subjects.

If one compares the frequency of occurrence of the hemolytic type of the *Bacillus coli* recovered from patients with chronic ulcerative colitis and from healthy individuals, the results are found to be surprisingly similar in each group. In each study the percentage of patients showing the presence of the hemolytic *Bacillus coli* increased with the number of specimens per patient examined, and where four or more samples were studied the hemolytic type was found to be present in every subject. From these figures it seems reasonable to conclude that the hemolytic *Bacillus coli* is a normal inhabitant of the intestinal tract of patients with chronic ulcerative colitis as well as of healthy people and that the incidence is no higher in the colitis patients than in the normal subjects.

All of the hemolytic and nonhemolytic strains of the *Bacillus coli* recovered from the colitis patients conformed to the same cultural reactions as those from the healthy individuals. There were no unusual forms of the *Bacillus coli* recovered from the colitis cases as compared with the strains recovered from normal stools.

The majority of the hemolytic strains tested showed active hemolyzing properties for the red cells of human blood when incubated for twenty-four hours. Seven strains which showed only a small zone of hemolysis on rabbit blood agar had only moderate or slight hemolyzing properties for human red blood cells. These results were practically identical with those obtained from the study pertaining to the healthy individuals.

The virulence of the strains of the *Bacillus coli* recovered was an interesting feature in the study, and especially as seen in the hemolytic type. In the study of the stools for normal people the hemolytic organisms were found to be somewhat more virulent for white mice than the nonhemolytic, but the difference was not sufficiently striking to be significant. In the present investigation, the hemolytic strains were definitely more virulent than the nonhemolytic. If, however, one compares the hemolytic and nonhemolytic strains of the two studies, this difference is found to be due to a decrease in the virulence of the nonhemolytic strains rather than to an increase in that of the hemolytic. Of the hemolytic strains, 70.4 per cent of those recovered from colitis patients were able to kill the mouse in doses of 0.05 c.c., or less, while as many as 65 per cent of those from healthy individuals showed the same virulence. Of the nonhemolytic strains from the colitis patients, 36.7 per cent of the strains and of those from normal intestinal tracts 50 per cent required 0.05 c.c., or less, of the culture to kill the mouse.

It was considered of some importance to determine whether any immunological relationship existed between the strains of *Bacillus coli* obtained from patients with chronic ulcerative colitis and those from healthy individuals. A representative number of strains from each of the four groups, namely, the hemolytic communior, hemolytic communis, nonhemolytic communior and nonhemolytic communis, was selected and agglutination tests were carried out with 4 immune rabbit serums, one from each group, which had previously been used for agglutination tests with the strains from normal stools. A high percentage of the strains of each group were agglutinated, at least in some degree, by the immune serum of their own group and also by those of the other three groups. Thus, as was found in the previous study, a biological analogy seemed to exist, not only within the membership of each group, but also between the strains of all four groups, regardless of type. In addition, a definite relationship was found to exist between the strains of *Bacillus coli* obtained from proctoscopic smears from patients with chronic ulcerative colitis and the strains obtained from stool specimens from healthy individuals.

#### CONCLUSIONS

1. The hemolytic type of the *Bacillus coli* may be recovered from the intestinal tract of patients with chronic ulcerative colitis in a high percentage of cases. If four or more specimens from a single individual are examined, it is shown to be present in one hundred per cent of the cases. The results are similar to those obtained from a study of stool cultures from healthy individuals.

2. The hemolytic strains of the *Bacillus coli* recovered from proctoscopic smears were found to be

somewhat more virulent for white mice than the non-hemolytic. However, the virulence of the hemolytic type was approximately the same as for those recovered from the stools of healthy persons, while the non-hemolytic showed a somewhat lower virulence.

3. The *Bacillus coli* recovered from the intestinal tract of patients with colitis appear to be heterologous strains having agglutinins more or less in common

with each other and with those isolated from the stools of healthy people.

4. From this study it may be concluded that in incidence and biological characteristics, hemolytic and nonhemolytic strains of *Bacillus coli* recovered from proctoscopic smears of patients with chronic ulcerative colitis, differ in no respect from those obtained from stool specimens of healthy individuals.

## The Takata-Ara Test of Liver Function

By

THOMAS B. MAGATH, M.D.\*  
ROCHESTER, MINNESOTA

**T**AKATA and Ara, in 1925, proposed a test based on a colloidal phenomenon manifested by the spinal fluid to differentiate between meningitis and syphilitic involvement of the central nervous system. This test has enjoyed apparently wide usage in Europe as a substitute for other colloidal tests on spinal fluid, but the reports do not support the contention that it has advantages over the gold or benzoin colloidal methods. The same year Takata extended the test to the blood serum of patients with pneumonia. By the test he proposed to differentiate lobar and lobular pneumonia but no further work has been reported.

These Japanese investigators thought the reaction was due to change in the relative amounts of albumin and globulin in the serum. Since the test involves the flocculation of a mercury oxy sol, and since this seemed to take place when relative excesses of globulin were present, so that the colloid was no longer protected, it was assumed that this phenomenon depended on a reversal or partial reversal of the ratio of albumin to globulin.

Jezler realized that such a protein shift was not peculiar to the blood of patients with pneumonia but often occurred in parenchymatous diseases of the liver. So he applied the test in a variety of such cases and pointed out that a major number of serums from patients with cirrhosis gave a positive test—in his series, in thirty-eight out of forty-two cases. He noted positive tests in other cases of hepatic disease and in some cases of nephritis, but in the twelve cases of parenchymatous jaundice studied by him and in seventeen cases of tumors of the liver he obtained only negative tests. He pointed out that the test could be

performed on ascitic fluid as well as on serum, and this has been verified.

Since the publication of the work of Jezler, others have studied the test with reference to its value in detecting disease of the liver. The impression is gained from the numerous papers published in Europe, and from the few now recorded in the American literature, that the test is thought to be fairly specific for cirrhosis, but that early in the disease the test is negative, and further, that the correlation between positive Takata-Ara tests and reversals of the albumin-globulin ratio is high.

Nevertheless, a careful reading and study of protocols leaves one in doubt as to the specificity of the test in cirrhosis. Thus Heath found the test to be positive in 60 per cent of cases of cirrhosis, although it was positive in nearly all advanced cases. He found that the reaction was positive in nine of thirty-one cases of hepatic injury and disease and in only 3 per cent of general medical cases in which damage to the liver was not diagnosed. Shindel and Barth found the test positive in 83.8 per cent of cases of cirrhosis but noted that massive involvement of the liver, especially with carcinoma, also gave positive tests. Rohrer believed the test was frequently positive in disease of the liver which was not cirrhosis and that negative tests did not exclude cirrhosis.

Van Ginkel noted that the test, while usually positive in cirrhosis, was also positive in advanced carcinoma and syphilis; on the other hand, however, Crane found it highly specific for cirrhosis and acute yellow atrophy, but negative for neoplasms, nephritis, and active pulmonary tuberculosis, although Pongor found 90 per cent of cases of this last gave positive tests.

Submitted August 19, 1935.

Ragins obtained 114 positive results in 276 cases. Of these only 50 per cent were cases of cirrhosis, the other half being a variety of hepatic diseases, tumors, infections, renal disease, cardiac disease, and so forth. Ninety-eight per cent of his patients with cirrhosis gave a positive test, but he remarked that for latent

hepatic damage the test is not entirely reliable. He was unable to correlate the protein content of the serum with the reaction.

#### METHOD

The method of performing the test has undergone some slight modification at the hands of various investigators, and at this Clinic it has been performed following the suggestions of Heath.

Into each of six small test tubes (100 by 13 mm.) is placed 1.0 c.c. of 0.9 per cent sodium chloride. To the first tube 1.0 c.c. of serum is added and the contents thoroughly mixed. One cubic centimeter is then removed and added to the second tube. After mixing, 1.0 c.c. is transferred from the second to the third tube, and so on until the sixth tube, from which 1.0 c.c. is discarded. The dilutions of serum thus range from 1:2 to 1:64. To each of the tubes 0.25 c.c. of 10 per cent sodium carbonate is added and the contents well shaken. Then 0.15 c.c. of mercuric chloride is added to each tube and the tubes are again shaken. The mixtures are allowed to stand at room temperature over night and readings are made at sixteen to twenty-four hours. The readings are divided into five groups: strongly positive, positive, weakly positive, suspicious, and negative. A strongly positive reaction is characterized by a maximal precipitate in any one tube or some precipitate in at least five tubes, the maximal precipitate on settling filling at least the lower third of the fluid column. A positive reaction occurs when there is a definite but not a maximal precipitate in any one tube or some precipitate in at least three tubes. A weakly positive reaction is present when there is a definite but minimal precipitate in any one or two tubes, and a suspicious reaction is present when there is a doubtful precipitate in any two tubes. The reaction is considered negative when there is no flocculent precipitate. A definite, pearly flocculent precipitate must be present to interpret a reaction as positive. Granular or flaky precipitates are disregarded.

The impression gained from performing the Takata-Ara test is that slight flocculations and precipitations occasionally occur and that these are difficult to interpret. The so-called "suspicious" positive reaction is especially difficult to read, and its significance is, therefore, extremely questionable. In the series here reported there were six reactions called suspiciously positive. In the tabulation these were considered negative; however, the liver was involved in four of the six cases, two being cases of carcinoma of the liver

and two of cirrhosis. From a technical standpoint it is impossible to identify the test accurately as positive unless a degree of precipitation is present sufficiently great to leave no doubt about the positiveness of the reaction.

#### RESULTS OF OBSERVATIONS

In order to test the value of the Takata-Ara reaction, a series of eighty-six consecutive cases in which the test was performed were studied (Table I). In each case a bromsulphalein test\* was also performed simultaneously. Qualitative and quantitative van den Bergh tests\*\* were done in eighty-three cases, and quantitative determinations of protein were made in sixty-two cases, all the tests being done on sixty-one patients. All these patients were carefully studied clinically, with special reference to the possibility of disease of the liver. The condition of the liver of twenty-seven patients was observed either at operation or at necropsy.

The diagnosis of cirrhosis was made on twenty-five patients, of whom sixteen gave a positive Takata-Ara test; however, sixteen other patients without cirrhosis also gave positive tests. Hepatic disease of some kind was diagnosed in fifty-three patients, the Takata-Ara test being positive in twenty-eight and negative in twenty-five instances. With four patients who apparently did not have involvement of the liver the Takata-Ara test was positive. Of nine patients with malignant conditions involving the liver, seven gave a positive Takata-Ara reaction. It was evident that the negative tests in cases of disease of the liver were for the most part obtained in cases of early lesions, or relatively small ones, and that, usually, obstructive lesions did not result in positive tests.

There was no evidence to suggest that changes in the total protein of the serum could be correlated with the Takata-Ara tests. In twelve cases in which there was a positive Takata-Ara test there was a reversal of the albumin-globulin ratio, while in nine there was a normal ratio; in two cases the ratio was reversed but the Takata-Ara test was negative. In only about half of the cases in which there was reversal of the albumin-globulin ratio was the liver involved, and in nine out of twenty-one cases of cirrhosis the ratios were reversed. Only one case, that of hypernephroma, had a reversed ratio and one in which involvement of the liver was not diagnosed. It should be noted that very few cases of disease of the kidney were included in the series. It is possible that the fibrinogen content of the serum has an influence on the Takata-Ara reaction and may account for Takata's results in cases of pneumonia.

The correlation between the Takata-Ara test and the bromsulphalein test was not high; only half the cases that showed dye retention gave a positive Takata-Ara test. There were four cases having a

\*The bromsulphalein test was performed by injecting, intravenously, 5 mg. of the dye per kilogram of body weight after the patient had abstained from food for twelve hours. Blood for a control was taken at the time of injection. One hour later a specimen was taken for testing. Serum was carefully obtained from the blood without laking. To the specimen taken after an hour was added a drop of 10 per cent sodium hydroxide and the color was compared by transverse comparison with standards, using a part of the hour serum in front of the color tube. As a further control to the reading, the control serum was used after adding a drop of alkali to it. It requires experience and constant attention to details in order to have consistent results. A retention up to 6 per cent of the dye is considered negative; from 6 to 12 per cent, grade 1; from 12 to 24 per cent, grade 2; from 24 to 40 per cent, grade 3; and 40 per cent or more, grade 4. The standard equivalent to 40 per cent contains 4 mg. of bromsulphalein per 100 c.c.

\*\*Performed in Laboratory of Clinical Chemistry.

positive Takata-Ara test and a negative dye test in which the liver was not involved. Direct van den Bergh reactions were present when twenty-two Takata-Ara tests were positive and when twenty were negative. In nine cases with positive Takata-Ara tests, the van den Bergh reaction was indirect. In four of these cases the liver was not involved. Of the ten patients in the series diagnosed as having syphilis, five had a positive Takata-Ara test; the liver was evidently involved in these five cases.

The relation of the van den Bergh reaction to the presence or absence of injury to the liver is of great importance. In this series the reaction was direct in thirty-nine of fifty-two cases in which the liver was involved and in two in which the liver was not involved according to clinical diagnosis. These two cases were one of hypernephroma, in which there was also retention of dye and a reversal in the albumin-globulin ratio, and one of hemolytic jaundice, a type of case in which the liver is sometimes involved but in which it is difficult to detect such involvement clinically.

The results of the dye test in this series are quite significant. In fifty-one cases in which the liver was involved by disease the test was positive. The test was also positive in three cases in which the liver was thought to be uninvolved. These were cases of arthritis, hypernephroma, and facial neuralgia. In these three cases the dye retained was just sufficient to report the test as grade 1 (6 per cent of dye retained). In two cases there was evidence to justify the clinical diagnosis of involvement of the liver, but the report of the dye test was negative. In these two cases—retention of dye, although recorded as grade 0, was actually 4 per cent, and this is the upper limit of percentages which can be designated grade 0. These two cases were of tertiary syphilis, with clinical manifestations of hepatitis but with no positive laboratory tests, and of recurrent cholangitis, respectively, tests being done during a remission. The importance of dye retentions of grade 1 (up to 12 per cent retention) is brought out by the fact that of sixteen cases in which retention of grade 1 was present, involvement of the liver was surely present in thirteen and probably was present in one other.

### COMMENT

From this series of cases and from a study of the results of others, it becomes clear that the Takata-Ara test on serum is a colloidal phenomenon which has as yet not been explained. It is, therefore, an empiric

test. It is evidently of no value in diagnosing types of pneumonia, and while it has been reported as useful in testing spinal fluids, it does not give positive reactions on serums in more than half of the cases of syphilis. The test is evidently not specific for either

injury to the liver or cirrhosis, but in the presence of hepatic disease a positive Takata-Ara test is more likely to indicate cirrhosis than other disease. About one-half of the patients with damage to the liver may be expected to yield a positive Takata-Ara test. If the

§Hypernephroma in one case, hemolytic icterus in the other.

injury is severe or of long standing, the incidence of positive reactions will increase. Early cirrhosis quite evidently does not produce changes which result in a positive Takata-Ara test. The degree of positiveness of the Takata-Ara test is not well correlated with the degree of liver disease, and it is evident that the subdivisions of the test are too fine for clinical use.

In 83 per cent of cases there is a correlation between the Takata-Ara test and a reversed albumin-globulin ratio, although some shifting from normal is observed in a higher percentage of cases (Table II). A reversed albumin-globulin ratio occurs about as frequently in cases of hepatic disease as does a positive Takata-Ara test.

If a direct van den Bergh reaction is used as a criterion of injury to the liver, it will be found to be reliable in about 80 per cent of cases. One may expect only about 1 per cent of cases to yield a direct test in the absence of clinical evidence of hepatic damage if careful ring tests are performed. Indirect van den Bergh reactions will occur until the damage to the liver is great enough to render the organ unable to excrete the changed bilirubin through the bile passages.

As compared with the bromsulphalein test, the Takata-Ara and van den Bergh tests and the albumin-globulin ratio are all far less sensitive in indicating hepatic injury (Table III). In this series almost every case (96 per cent) in which there was evident parenchymal hepatic injury or even moderate obstruction to the output of bilirubin, the dye test so indicated it. An important point is that in most instances dye retention of low grade indicated disease of the liver. A large share of the retentions of high grade occurred in cases of mechanical obstruction, and the test indicates in this series, as in others, that there is a failure of the liver to excrete the type of bilirubin commonly referred to as "direct reacting." Fundamentally, this is due to either physiologic or anatomic obstruction, and frequently the dye test indicates the obstruction long before the patient becomes jaundiced.

The desire of clinicians, however, is to have a test which will go farther than indicating a failure of the liver to excrete pigments properly, and it was hoped that the Takata-Ara test would aid in this regard. To a certain extent it does, in that mechanical obstruction

without much hepatic damage does not result in a positive Takata-Ara test. On the other hand, a considerable amount of parenchymatous hepatic damage must be present before the test becomes positive. That the test is not specific for cirrhosis is plainly evident, and if one can make use of the test at all in such diagnoses, it is just a matter of saying that, of the nonobstructive lesions of the liver, cirrhosis is among the most common, and hence that there is more chance that the lesion under such conditions is cirrhosis. Doubtless almost all advanced cases of cirrhosis will yield a positive Takata-Ara test. Evidently a moderate infiltration of cancer into the liver will cause changes which will result in a positive Takata-Ara test. There is no need of performing the test if the bromsulphalein test is negative, and perhaps rarely if the test is positive. Of patients with dye retention of grade 3 or 4, about half had positive Takata-Ara tests; the distribution of diagnoses did not seem to vary from those with negative Takata-Ara tests but it may indicate a more severe grade of hepatic damage when the Takata-Ara test is positive under such circumstances than when

the Takata-Ara test is negative. If this be true, then the Takata-Ara test is of more value in prognosis and in determining operative procedures than in diagnosis, for there is evidence that the test becomes less positive and even negative as the patient improves. It is questionable, however, whether it will prove more reliable than van den Bergh tests in this regard.

### SUMMARY AND CONCLUSIONS

The Takata-Ara test will be positive in slightly more than half of the cases in which there is parenchymatous hepatic damage when the injury has reached a moderately severe stage. The test is not specific for any one disease of the liver.

The test is correlated to a great extent with changes in the ratio of albumin to globulin, but the correlation is not an absolute one.

Although few false positive reactions are encountered, the test is not very sensitive.

The bromsulphalein test is highly specific in detecting that injury to the liver which results in its failure to excrete bilirubin properly.

## The Hippuric Acid Test for Hepatic Function; Its Relation to Other Tests in General Use

By

ALBERT M. SNELL, M.D.†

and

JOHN E. PLUNKETT, M.D.‡

ROCHESTER, MINNESOTA

THE majority of tests now in clinical use for the study of hepatic function are designed to test the excretory function of the liver or its properties with regard to the metabolism of carbohydrate, protein, and fat. The latter group of tests has been somewhat disappointing in clinical use, because of the enormous reserve function of the liver in respect to its metabolic activities, and its regenerative ability. Difficulties also arise because in many cases extraneous factors, which may interfere with the results of the test, cannot be completely eliminated. The galactose tolerance test, because of its simplicity and the relatively satisfactory results which have been obtained by its use, is one exception, but there is little to indicate that one can de-

termine hepatic damage quantitatively by its use. The dye type of test of excretory function gives more valuable information in regard to the degree of hepatic damage than any one test in general use; however, such cannot be used satisfactorily in the presence of jaundice, and in fact, do not give a true picture of the degree of hepatic dysfunction in this condition. In cases of jaundice the most satisfactory idea of the extent of the hepatic lesion is often attained from a study of the level of bilirubinemia and variations in it. It is obvious that this factor may depend on the rate of destruction of blood and the degree of obstruction to the biliary passages, so that information obtained from this source may not be absolutely reliable. For these reasons, it is obviously desirable to devise tests of certain other functions of the liver, in the hope that

Submitted August 2, 1935.

a clearer idea of its functional capacity may be obtained.

Among the more important and neglected functions of the liver are those which pertain to the detoxification of certain noxious substances. Priestley, Markowitz, and Mann have demonstrated the importance of the liver in these mechanisms, by various experimental procedures. The best known of these detoxifying functions is, as Quick (9) has pointed out, that which is concerned with a conjugation of benzoic acid and glycine to form hippuric acid. Bryan was one of the first to note that hepatic disease might affect the rate of synthesis of hippuric acid, but present interest in the study of this function is the result of the work of Quick (9, 10). It was at his suggestion that the test was applied to a study of our clinical material, and an attempt made to correlate the results with other functional tests and the condition of the liver, as noted at necropsy or operation.

The site of synthesis of hippuric acid has been the subject of much debate; this matter is considered in detail in Bryan's earlier paper; Bunge and Schmiedberg originally claimed that in the dog it was effected by the kidney and later experiments have corroborated this fact (8). Subsequent studies have shown that in the rabbit (3) and possibly in the human (7), the liver may be the principal site of formation of hippuric acid (3). Quick (7) has demonstrated that the rate of formation of hippuric acid depends to a large extent on the speed at which glycine can be furnished. In other words, the amount of hippuric acid formed does not depend so much on the amount of benzoic acid given as on the rate of formation of glycine. It has been generally supposed that the latter substance is formed by the liver and that in hepatic disease the glycine available for purposes of synthesis is reduced. It was on this basis that the hippuric acid test of hepatic function was advanced. Quick (9) has published the results of a series of cases studied by this means and his results seem to indicate the probable usefulness of the method in clinical practice.

#### METHODS

The methods used by us are those recommended by Quick (8) and for details the reader is referred to his original article. The test is performed by administering, by mouth, 6 gm. of sodium benzoate dissolved in a small amount of water; this may be given after a breakfast of coffee and toast, and should be followed by the administration of a half glass of water. The patient is instructed to void immediately after taking the drug, and hourly specimens of urine are collected for four hours thereafter. Hippuric acid is determined by a simple gravimetric method, the hippuric acid being precipitated by acidification with concentrated hydrochloric acid. If the volume of the individual specimen is large, it should be concentrated to about 50 c.c. by boiling. The specimen is allowed to stand until precipitation is complete and is then filtered; the filtrate is washed with cold distilled water and allowed to dry. The filtrate is then weighed and to the observed weight of hippuric acid is added a correction to allow for the quantity remaining dissolved in the urine. This is necessary since 100 c.c. of urine will hold 0.33 gm. of hippuric acid in solution. The results are best expressed in terms of benzoic acid, which can be determined by multiplying the amount of hippuric acid by the factor 0.68. We have used the total four-hour output as the figure indicating the completeness of the synthesis of hippuric acid.

Quick recommended separate determinations of hippuric acid in each of the four specimens obtained hourly, especially in cases in which any doubt exists in regard to gastric retention; if the accuracy of the collection of urine is in doubt, this also may be the safest procedure.

If more accurate determinations are required, the specimens of urine may be extracted with ether, hydrolyzed with hydrochloric acid, and the glycine thus liberated determined by titration with formol. For clinical purposes, the simple gravimetric method seems sufficiently accurate. The excretion of benzoic acid in normal subjects varies but is usually about 3 gm. under the conditions of the test. It has been pointed out that in actual practice the range of excretion is from 85 to 110 per cent of this amount (2.55 to 3.3 gm.). In eleven hospital patients, presumably without hepatic involvement, which we studied (duodenal ulcer, neurosis, arthritis, chronic cholecystitis, pernicious anemia), the results fell within this range in all but two cases. In one case in which there was functional vomiting, and in another case in which there was duodenal ulcer, figures 0.15 gm. below the lower limits of normal were noted. These were perhaps explainable on the basis of delayed absorption, dehydration, and malnutrition.

In view of the earlier experience of Bryan, who demonstrated that the elimination of hippuric acid was altered in various types of nephritis and other conditions associated with renal involvement, it was obvious that some attention had to be paid to the presence of disorders of the kidney in attempting to apply the test to studies of hepatic function. Snapper and Grünbaum noted that the elimination of hippuric acid was normal in all types of renal disease, provided there was no retention of urea in the blood; they also showed that if the concentration of urea in the blood was elevated, the rate of elimination of hippuric acid was greatly decreased. Bryan's studies gave somewhat similar results. For practical purposes, therefore, it is desirable to confine the use of the test to cases in which the amount of urea in the blood is within normal limits. Snapper and Grünbaum also contended that there was some relation between elimination of water and elimination of hippuric acid, and it is quite probable that erroneously low values for the elimination of hippuric acid may be obtained in cases in which the patients are dehydrated and secrete a small amount of urine.

#### MATERIAL

We have studied the excretion of hippuric acid of thirty-seven patients who had various types of hepatic disease and have attempted to make comparisons with the results of other hepatic functional tests, with the findings at operation and at necropsy, and with certain clinical factors, such as the general condition of the patient and the severity of postoperative reactions. The results in this small series seem to indicate that the test gives a reasonably satisfactory idea of the general state of the hepatic parenchyma, and, for general clinical purposes, is probably as reliable and satisfactory as any other type of hepatic functional test now in use. Ease of performance and relative specificity also recommend it.

#### PORTAL AND BILIARY CIRRHOSIS; SPLENIC ANEMIA

Twelve patients who had various types of cirrhosis were studied; the results in these cases are tabulated

in Tables I and II. In the three cases of definite portal cirrhosis, there was definite correlation of the hippuric acid test and the observed degree of retention of bromsulphalein. The bromsulphalein test is generally regarded as one of the most satisfactory clinical methods for the determination of hepatic function in cirrhosis, especially if jaundice is absent, as it was in these cases. The correlation of the hippuric acid test and the reversal of the albumin-globulin ratio is also of some interest, especially since it is now believed that this phenomenon is often associated with advanced hepatic damage (Myers and Keefer). The patient with the smallest elimination of hippuric acid had a definite reversal of the albumin-globulin ratio and a reduction in the amount of total protein in the blood serum. The other two patients, who were in considerably better general condition than the previously mentioned patient, had a normal albumin-globulin ratio, although the total amount of serum protein was reduced. In two cases in which there was a very chronic type of syphilitic cirrhosis, the patient with the lowest elimi-

nation of hippuric acid showed reversal of the albumin-globulin ratio.

In two cases of splenic anemia and cirrhosis, the hippuric acid test gave results which were nearly normal. The second patient had had splenectomy performed a year previously and had made a satisfactory recovery, in spite of the presence of marked cirrhosis, which was verified at operation. In this case the hippuric acid gave practically normal results. In the other case, in which there was definite jaundice and a reversal of the albumin-globulin ratio, the synthesis of hippuric acid was reduced, a point which seemed to agree with the acuity of the process and the probable degree of hepatic damage.

Three patients who had chronic diffuse hepatitis and jaundice of the type usually described as biliary cirrhosis were studied. In these cases, as will be noted from Table II, there was a fairly close correlation of the rate of synthesis of hippuric acid and the excretion of galactose. The hippuric acid test also checked fairly well with the general clinical condition of the three patients; the most marked reductions in synthe-

sis of hippuric acid were noted in the two cases in which the lesions were more chronic and extensive. A still more striking correlation was noted in the two

cases listed under the heading of chronic atrophy (Table II), which was the diagnosis at necropsy. The hippuric acid test, performed in each case shortly before the appearance of fatal hepatic insufficiency, was strongly positive; in each case, a positive galactose test, a marked serum bilirubinemia, and a reversal of the albumin-globulin ratio were also observed. In Case 11, the liver weighed 785 gm.; in Case 12, it weighed 1,553 gm. In both cases, extreme atrophy of the hepatic parenchyma was noted, and there were practically no regenerative changes. Careful examination of the kidneys in each instance failed to reveal any evidence of renal damage which could have affected the tests in question.

#### INTRAHEPATIC JAUNDICE

Six patients (Table III) who had intrahepatic jaundice were studied, the two most interesting being

14), who was in a convalescent stage, had an increased excretion of hippuric acid. The galactose test was still weakly positive, but the jaundice had practically disappeared. An increased rate of synthesis of hippuric acid has been noted by Quick in other cases during the convalescent stages of intrahepatic jaundice; this appears to correspond with the increased excretion of phenolsulphonethalein during recovery from acute nephritis.

Of the four cases of epidemic jaundice (Table III) which were studied, the synthesis of hippuric acid appeared to be normal in two, a fact which checked very well with the rapid improvement which was taking place in these cases at the time of observation. The strongly positive hippuric acid test in one case coincided with the severity of the illness and its long duration; in fact, it was at one time believed that the patient (Case 15) was suffering from subacute yellow atrophy. In the whole group of cases of intrahepatic jaundice, the hippuric acid test seemed to give a fair idea of the severity of the hepatic lesion. It will be noted that in three of the four cases, the amount of hippuric acid eliminated paralleled the degree of bilirubinemia observed. In Case 18, the bilirubinemia was rapidly decreasing and the liver was probably in the stage of regeneration.

#### HEPATITIS AND CHOLANGEITIS ASSOCIATED WITH CHOLECYSTIC DISEASE

Twenty cases of so-called surgical types of jaundice (Tables IV and V) were studied with particular care, since in this field any test which gave even an approximate indication of the degree of hepatic injury would be of considerable clinical value in determining surgical risk. Eight of the patients had cholecystic disease with or without stones, associated with hepatitis and cholangitis of various degrees. The diagnosis was verified surgically in each case, and since the common bile duct contained no stones in any case it was assumed that the jaundice was not of a def-

nitely obstructive type. In six of these cases the hippuric test was positive. In Case 19, which presented the greatest impairment of synthesis of hippuric acid, the patient was acutely ill; the value for the serum bilirubin was 11.3 mg. and the excretion of galactose was 4.7 gm. in five hours. An unusually extensive hepatitis was noted at operation; the postoperative course was very stormy, and the convalescence prolonged. In another case (Case 21) the galactose test was negative, although the patient was deeply jaundiced and acutely ill. At operation, all of the extrahepatic biliary passages showed evidence of marked infection, and the hepatic parenchyma was severely damaged. The second patient listed in Table IV (Case 20) had a postoperative cholangitis with biliary colic; the exact state of the liver had not been verified at operation when the hippuric acid test was performed. In the remaining five cases of this group, the elimination of hippuric acid was 2 gm. or more, and mild to moderate degrees of hepatitis were noted at operation.

Of the twelve cases of obstructive jaundice pre-

TABLE V

*Results of Laboratory Tests in Cases of Obstructive Jaundice*

| Cause of obstruction | Case | Benzole acid test, gm. | Serum bilirubin, mg. per 100 c.c. | Dye retention, grade | Galactose tolerance test, gm. | Remarks                                                                      |
|----------------------|------|------------------------|-----------------------------------|----------------------|-------------------------------|------------------------------------------------------------------------------|

|                      | 33   | 2.20                   | 3.1                               |                      | 0                             | Stricture of common bile duct                                                |
| Carcinoma            | 34   | 0.50                   | 12.8                              |                      | 0                             | Carcinoma of pancreas; marked cirrhosis.                                     |
|                      | 35   | 0.52                   | 22.1                              |                      |                               | Carcinoma of ampulla of Vater; marked cirrhosis.                             |
|                      | 36   | 2.45                   | 14.6                              |                      | 0                             | Carcinoma of pancreas; hepatitis and cholangitis.                            |
|                      | 37   | 2.65                   | 12.3                              |                      | 0                             | Carcinoma of pancreas; liver in fair condition.                              |
|                      | 38   | 2.90                   | 3.5                               | 2                    |                               | Carcinoma of pancreas (early).                                               |

sented in Table V, three deserve particular comment. In the first (Case 27), the excretion of hippuric acid was nil, except for the amount remaining in solution in the urine. This patient had had repeated attacks of

biliary colic and had been jaundiced continuously for more than a year. She was very anemic and in extremely poor condition. It will be noted that the galactose test was negative in this case, and it is believed that a much more accurate idea of the degree of hepatic damage present was obtained from the hippuric acid test. In all of the cases in which there was a stricture of the common bile duct and definite biliary cirrhosis, the hippuric acid test was positive; the lowest rates of synthesis were noted in the two cases in which the patients were in the poorest condition from the clinical standpoint. In both of these cases the rate of excretion of galactose was somewhat greater than normal. In two of the five cases in which carcinoma occluded the biliary passages (Cases 34 and 35), the hippuric acid test was strongly positive, and in each instance it was noted at operation that the degree of hepatic damage was extreme. In these cases, hepatic insufficiency and death ensued shortly after operation. A misleading result was obtained in the third case of the group (Case 36), in which the hippuric acid test gave an approximately normal result. The patient gave an antecedent history of chills and fever; marked hepatitis and suppurative cholangitis were noted at operation and later were verified at necropsy. After consideration of the postmortem findings, it seemed fair to assume that the hepatic damage present was the result of the infectious process and was not caused by the damage which had occurred directly as a result of biliary obstruction. Nevertheless, a positive hippuric acid test would have been expected, since the degree of hepatic destruction was considerable.

In the whole group of patients who had "surgical types" of jaundice, the rate of synthesis of hippuric acid could be correlated well with the observed degree of hepatic injury, the general clinical condition of the patient, and the degree of postoperative reaction. Vaccaro (12) has also studied the rate of synthesis in a similar series of cases and his conclusions were similar to ours. From a consideration of Tables IV and V, it will be noted that there was little if any correlation of the excretion of galactose and the synthesis of hippuric acid. However, general agreement between the degree of bilirubinemia and the rate of hippuric acid synthesis was noted. In the whole series of cases, it appeared that the hippuric acid test gave a reasonably good idea of the actual state of the liver and its ability to withstand surgical procedures. We believe that in cases in which the elimination of hippuric acid is 1.5 gm. or less, severe damage of the hepatic parenchyma can be assumed to exist, and that surgical procedures will entail a considerably increased risk. On the basis of the one case previously mentioned, it seems that a negative hippuric test probably does not entirely exclude a critically damaged liver. It should be noted that the test does not differentiate obstructive and intrahepatic jaundice; in fact, there are theoretical reasons to believe that no test will ever accomplish this differentiation with any great degree of accuracy. The peculiar merit of the test lies in the fact that it gives satisfactory results in jaundiced patients; where the dye tests cannot be used satisfactorily, and that in the

nonicteric patient, in which the galactose test is of little value, the hippuric acid test appears to give accurate information.

In the foregoing paragraphs, we have laid particular emphasis on the frequency with which the results of the hippuric acid test correspond with the results of other tests of hepatic function and also with the condition of the liver, as noted by the surgeon at operation. Cases in which no such correlation existed should also be mentioned. The relatively small elimination of hippuric acid in two cases in which the livers presumably were normal and the case of malignant obstruction of the biliary passages and suppurative cholangitis (Case 36) in which the elimination of hippuric acid was normal have been mentioned previously. Two other cases were encountered in which the test gave results which we believe to be misleading. In one case in which extensive metastatic carcinoma of the liver was verified at operation, there was a normal synthesis (3.3 gm.). In another case in which there was a pyogenic granuloma in the subdiaphragmatic space, two hippuric acid tests gave strongly positive results, the total urinary output (calculated as benzoic acid) in each case was approximately 1.2 gm. At necropsy, no hepatic lesion could be found which in any way explained this finding. In other words, there is probably a definite margin of both negative and positive error in the use of this test. We know of no hepatic functional test, however, of which this same statement cannot be made, and the statement does not imply a serious criticism of any test. As Mann has pointed out, some general reservations must be made in interpreting the results of tests of hepatic detoxification. It has not yet been conclusively demonstrated that the liver is the sole site of synthesis of hippuric acid in the human subject; neither has the test been studied in relation to the physiologic state of the liver at the time the test substance is administered. It would also appear desirable to have more information in regard to the rate of elimination of hippuric acid in the so-called toxic nephroses, which are not uncommonly present in association with hepatic injury. From a practical (and perhaps an empiric) standpoint, the test seems to give information of clinical value, in spite of some objections based on physiologic grounds.

#### SUMMARY AND CONCLUSIONS

In a series of thirty-eight patients who had various types of hepatic disease, the results of the hippuric acid test for hepatic function were studied in an attempt to correlate the results of such generally used procedures as the bromsulphalein test and those of the galactose test. The results seem to indicate that the rate of synthesis of hippuric acid is a reasonably accurate and satisfactory test for the determination of parenchymatous hepatic damage, particularly in the "surgical" types of jaundice. The errors noted are no greater than are those to which other hepatic functional tests are subject. From a physiologic standpoint, these results are of interest, since they add to the accumulated evidence which indicates that hepatic lesions have a definite influence on the rate of synthesis of hippuric acid in human beings.

## Phenolphthalein Studies\*

## I. Colloidal Phenolphthalein

By

BERNARD FANTUS, M.D.

and

J. M. DYNIEWICZ

CHICAGO, ILLINOIS

IT seems that a stable colloidal phenolphthalein preparation is not as yet available. Inasmuch as it may be reasonably assumed that such colloidal phenolphthalein would have a higher degree of solubility than the highly insoluble crystalline form, we have undertaken experiments to determine whether such a preparation might be developed.

The nearest approach to a colloidal phenolphthalein seems to have been secured by E. B. Putt (1) who obtained a patent upon the microcrystalline form (Brit. Pat. 352,924, April 4, 1930, and U. S. A. Pat. No. 1574934 and 1693666) with the claim that he had produced a "finely divided crystalline phenolphthalein obtained by pptg. an alk. solu. of phtn. with an acid in the presence of a colloid such as gum acacia or tragacanth or agar agar, sufficient to delay pptn. but insufficient to form a thick gel. on standing. HoAc may be used for the pptn."

There is no doubt that Putt secured a colloidal solution of phenolphthalein; but this does not remain colloidal for more than a very short time. He did not solve the problem of colloidal phenolphthalein in stable solid or liquid form.

The colloidal solution of phenolphthalein produced by precipitating the phenolphthalein by means of acetic acid in the presence of either 1% tragacanth or 1% agar or 1% acacia, as undertaken by Putt, does not remain colloidal for more than a very short time.

We have attempted to prepare colloidal phenolphthalein by passing a stream of carbon dioxide gas over a solution made by dissolving 1 gm. phenolphthalein in 50 c.c. N/10 NaOH and then made up to 100 c.c. with distilled water so as to represent a 1% solution of phenolphthalein. As this process yields a white milky fluid, containing microcrystalline phenol-

phthalein, which soon sediments the phenolphthalein in crystalline form, we added various "protective colloids," such as gelatin, bile, bile salts (sodium taurocholate, sodium glycocholate and "decholin" sodium), and saponin to the solution. Carbon dioxide gas was then passed over the surface of the liquid with constant agitation until the color was discharged. The result is an opalescent fluid that on standing gradually becomes a milky white and ultimately yields a white sediment of crystalline phenolphthalein: the time relations depending somewhat upon the proportion and nature of the protective colloid.

**Solubility of Colloidal Phenolphthalein.** The solubility of the colloidal phenolphthalein thus obtained, in comparison with the crystalline phenolphthalein, is shown in the subjoined table (Table I), as far as expression of color permits.

TABLE I

|                                    | pH— | 7.8 | 8.0  | 8.2 | 8.4  | 8.6 | 8.8  |

It is also shown by line 3 (Fig. 1). The lines 1 and 2 of Figure 1 were obtained by occasional agitation for one hour, filtration, and mixing the filtrate with an equal volume of N/10 NaOH V.S., to bring out the pink color to its maximum value, and then estimating the quantity in solution by means of a colorimeter. Line 1 represents solubility at room temperature (25° C.), line 2 at body temperature (38° to 40° C.). Line 3 was obtained in a manner somewhat different from

\*From the Laboratory of Pharmacology and Therapeutics of the College of Medicine, University of Illinois, and assisted by a grant from Phenolphthalein Research, Inc.  
Submitted November 2, 1935.  
(1) *Chem. Abst.*, 26:5315 (1932).

the one that was used in developing curves 1 and 2, because of the impossibility of filtering the colloidal solution. We therefore estimated the amount of dissolved phenolphthalein by a direct matching of color as compared with an alcoholic standard solution of

Fig. 1

phenolphthalein added to fluid of the same pH. The broken portion of line 3 indicates that below pH 8.0 there is practically no color. Diffusion experiments (the results of which are represented by the broken line) indicate that a considerably greater quantity goes into solution even below this point in pH value than is the case with crystalline phenolphthalein.

**Preparation of Colloidal Phenolphthalein.** We believe we have succeeded in producing a stable "colloidal" phenolphthalein in solid form by the following process:

|                  |            |
|------------------|------------|
| Citric acid      | 1.0 Gm.    |
| Phenolphthalein  | 2.15 Gm.   |
| Granular gelatin | 5.0 Gm.    |
| N 1 NaOH V.S.    | 10.75 c.c. |
| Distilled water  | 50.0 c.c.  |

The phenolphthalein is dissolved in the N 1 NaOH V.S. with the aid of heat and is filtered through paper. The gelatin is dissolved in the distilled water with the aid of gentle heat. The two solutions are mixed. A stream of CO<sub>2</sub> gas is passed with agitation over the

surface of the solution contained in a relatively large Erlenmeyer flask until the color is completely discharged. Finally, the citric acid is added, until a pH of 5.5 is obtained. The resulting mixture is spread in a thin sheet on glass plates and dried at room temperature.

An explanation of the reason for each of the ingredients and of the process as a whole might be desirable.

Phenolphthalein sodium is produced in the first step by dissolving the phenolphthalein in the sodium hydroxide solution. This results in a red liquid. Gelatin is used because it has been found to be the most potent "protective" colloid. The more distant the particles are from each other, in other words, the more dilute the solution, the finer the precipitate. Hence, carbonic acid, one of the feeblest of acids, is employed; and we get a better colloid if we merely pass the gas over the surface of the solution than when we permit it to bubble through. The exposure to CO<sub>2</sub> is continued with gentle agitation until the pink color is lost completely. We then know that the sodium salt has been decomposed. A yellowish opalescent fluid is the result. As, in spite of all these precautions, the particles coalesce when the preparation is kept in the liquid state, and larger aggregates form and a precipitate occurs, we proceeded to dry the product. To be able to do this, it was necessary to add a non-volatile acid, such as citric acid, as otherwise during the drying the CO<sub>2</sub> would be lost and the product return to the original pink color of the phenolphthalein sodium. The resulting scales contain about 25 per cent of phenolphthalein.

It is possible to make a product as strong in phenolphthalein as 33 per cent, but not much stronger.

**Physical characteristics:** The material occurs in glistening yellowish scales that should be quite transparent and no more than slightly opalescent, odorless, and have a rather persistently bitter taste.

#### TESTS FOR COLLOIDAL PHENOLPHTHALEIN

That we have produced a phenolphthalein of a much higher solubility rate than the ordinary form may be proved by the following tests:

1. The finely powdered material strikes a pink color immediately with a buffer solution of pH 8.2 at 40° C.
2. Sodium bicarbonate solution (pH 8.0) strikes no color with crystalline phenolphthalein, but is colored pink by colloidal phenolphthalein. This difference is better shown when the product is freshly prepared. The dry material needs to be dissolved in a little water with the aid of gentle heat (not above 40° C.).

It might be inserted here parenthetically that, when phenolphthalein is used as indicator, i.e., when one puts several drops of 1% alcoholic solution of phenolphthalein into sodium bicarbonate solution, a pink color is obtained. The reaction is dependent upon what we believe to be the colloidal condition; for this reaction could not be obtained unless the phenolphthalein test solution (in alcohol) is used. The rather large quantity of phenolphthalein required has been ascribed to mass action (cf. *Chem. Abstr.*, 18:2788, 1924); but it certainly must also be due to colloidal nature of the precipitate for no color change occurs when even a large excess of crystalline phenolphthalein is added to the bicarbonate solution, unless the solution is permitted to stand, when—on account of loss of CO<sub>2</sub>—a higher pH value and solution of the phenolphthalein result.

3. The difference between a solution of crystalline phenolphthalein and of colloidal phenolphthalein in sodium bicarbonate solution can also be brought out by instillation of such solutions into the human conjunctiva. We prepared a 2.12% solution of sodium bicarbonate, which is isotonic with the tears and has a pH of 8.0. We saturated this with crystalline phenolphthalein and another portion of such solution with colloidal phenolphthalein. It is im-

Fig. 2

possible to distinguish, after instillation in the conjunctiva, between crystalline phenolphthalein solution and the bicarbonate solution without phenolphthalein. The solution of the colloidal phenolphthalein, which is pink in contrast with the colorless solution of the crystalline form, causes a smarting sensation in the conjunctiva that lasts for a few minutes.

4. The taste of colloidal phenolphthalein is decidedly bitter, unless the mouth is quite acid, as it may be the first thing in the morning. There is practically no taste sensation produced by crystalline phenolphthalein.

5. The microscope shows very few of the characteristic crystals of phenolphthalein (Fig. 2) in a good preparation of colloidal phenolphthalein (Fig. 3).

*Quantitative estimation:* The scales should contain about 25 per cent of colloidal phenolphthalein and not less than 23 per cent or more than 25 per cent, which may be tested for as follows:

Place 0.010 Gm., accurately weighed, of the material to be tested in a 50 c.c. glass stoppered, graduated cylinder; add 50 c.c. of a buffer solution pH 8.2 at a temperature of 40° C.; and maintain this temperature until all is dissolved and the maximum color is reached. At the same time, heat another 50 c.c. of buffer solution and add an alcoholic standard solution of phenolphthalein (containing 0.5 Gm. in 100 c.c. of alcohol) until the color matches that produced by the material to be assayed, using a colorimeter for the final comparison.

From the amount of standard phenolphthalein solution used, the per cent of colloidal phenolphthalein may be determined.

When crystalline phenolphthalein is treated in the same way, it does not yield more than about 4 per cent of phenolphthalein to a solution at this pH.

#### SAPONIN STABILIZED COLLOIDOL PHENOLPHTHALEIN

There is one way we have been able to secure a relatively stable colloidal phenolphthalein in liquid form; and that is by means of saponin.

When one adds to a one per cent solution of phenolphthalein in 50 c.c. of N/10 sodium hydroxide solution, ½ per cent of saponin and passes a stream of carbon dioxide over the solution, a white milky fluid results, which, on standing in a refrigerator, deposits a sediment, leaving, however, a milky supernatant fluid. This supernatant

fluid, after prolonged standing (about two months), has been found to contain phenolphthalein, soluble in pH 8.2; and, assayed as above described, it was found to contain 41 per cent of the phenolphthalein still in colloidal form.

*Fate of Colloidal Phenolphthalein in Artificial Gastric Juice.* It becomes of interest to determine what happens to colloidal phenolphthalein when it passes through the stomach. We therefore incubated (at 38°-40° C.) colloidal phenolphthalein with artificial gastric juice prepared according to the following formula:

|               |            |
|---------------|------------|
| Pepsin        | 1.5 Gm.    |
| N/10 HCl V.S. | 100.0 c.c. |

This solution (with the colloidal phenolphthalein added) has a pH of 1.1, which might be considered a relatively high degree of gastric acidity and a rather severe test for the stability of our colloid in the stomach. We find that our bicarbonate solution test for phenolphthalein colloid can be obtained up to but not after half hour's incubation at the pH of 1.1. At a lower pH, however, the test can be secured for a much longer time,—up to two hours (Table II).

TABLE II

| Incubation (38°-40° C.) of colloidal phenolphthalein at pH: |       |       |        |
|-------------------------------------------------------------|-------|-------|--------|
|                                                             | 1.1   | 1.5   | 2.5    |
| Colloid absent after                                        | ½ hr. | 1 hr. | 2 hrs. |

*Purgative Value of Colloidal Phenolphthalein.* In view of the greater solubility of colloidal phenolphthalein, one might expect it to have a greater degree of purgative action. A fairly well controlled study in a small group (24 persons) showed that it does indeed possess greater potency than the U.S.P. phenolphthalein, but that it is probably not more than twice as active. There is a possibility that it may be more uniformly active than the crystalline form. This remains to be shown.

The disadvantage of colloidal phenolphthalein is its bitter taste, which would demand administration in capsule form.

#### Colloidal Phenolphthalein in Petrolatum Emulsions.

In view of the fact that there is a tendency to separation of phenolphthalein on prolonged standing in emulsions of liquid petrolatum containing phenolphthalein, it seemed of interest to determine whether col-

Fig. 3

loidal phenolphthalein could be incorporated in an emulsion and how long it would remain colloidal.

It should be noted here that when, in the making of this preparation, an alcoholic solution is added to the emulsion, a precipitate of colloidal quality is secured. This is shown by the fact that this solution strikes a pink color with buffer solution of pH 8.2. This reaction is lost, however, within two hours, which indicates that the phenolphthalein has lost its colloidal by that time. When we add the gelatin prepared colloidal phenolphthalein to the petrolatum emulsion, the color change is obtained with buffer solution of pH 8.2 for as long as two days, but no longer. It therefore probably presents no practical advantage and has the disadvantage of making the preparation more bitter.

## CONCLUSIONS

1. We have prepared stable colloidal phenolphthalein in solid form.
2. Colloidal phenolphthalein strikes a pink color with sodium bicarbonate solution (pH 8).
3. Colloidal phenolphthalein is considerably more soluble than is crystalline phenolphthalein at the hydrogen ion concentrations prevailing in the human body.
4. Colloidal phenolphthalein has a bitter taste.
5. Colloidal phenolphthalein may pass through the stomach, providing it is not detained in exposure to active gastric juice for an excessive length of time.
6. Colloidal phenolphthalein is somewhat more active in producing bowel evacuation than is the crystalline form.

## ABSTRACTS

W. A. MACKEY.

*Cholecystitis Without Stone. British Jour. Surg., Vol. 22, No. 86, Oct., 1934.*

A detailed investigation is reported of almost 300 operative cases with deductions worthy of merit as to clinical, radiological and pathological aspects. A serious attempt is made to evaluate prognosis. Emphasis is laid particularly on prognosis: is it more favorable in cholelithiasis or in gall bladder disease without stones? Great stress is attached upon evaluation of history, pathological examination and radiological findings.

Although operative mortality has been enormously reduced in recent years, the end results are still not entirely satisfactory. Great significance is ascribed to biliary colics whether functional or organic. It seems that more satisfactory results can be guaranteed from cholecystectomies due to such colics. Moreover this symptom alone is considered of greater importance than the pathological changes themselves.

The Author tried to divide his material into distinctive groups namely gall bladder disease with minimal lesions, chronic catarrhal cholecystitis, chronic fibrous cholecystitis, and cholesterosis of the gall bladder ("strawberry" gall bladder). This classification may fit well practical purposes, histological and roentgenological findings, however, can not be divided so sharply. There still are no decisive histological manifestations of a diseased gall bladder. Clinically only 30% of the cases were cured after cholecystectomies affiliated with stoneless gall bladder disease. About the same amount improved and more than 36% remained unimproved, with an operative mortality of about 3%. It is significant, however, that cases with definite history of biliary colics revealed a much higher percentage of cure following cholecystectomies. Prognostically, therefore cases with colics are easier to cure, although stones may not even be present. Therefore cases presenting biliary colics are an indication for surgery.

Other symptoms such as flatulent dyspepsia, food selection and constipation are only accidental findings, although valuable from practical standpoint. Undoubtedly such symptoms may have their origin outside of the gall bladder.

either in the pylorus or in the colon. Such cases do not respond to cholecystectomies.

An interesting chapter is devoted to the coincidence of appendectomies. It is surprising that appendices were more involved in those cases that have not improved sufficiently. Consequently the removal of the gall bladder was solely responsible for the improvement of the symptoms. Rather poor results were obtained in simple cholesterosis i.e., "Strawberry gall bladder," another point to prove that microscopical changes should not be over-estimated. In more advanced cases of gall bladder disease as chronic fibrous cholecystitis or cholesterosis with stone, the results were better.

Much has been written about pains following cholecystectomies. A disturbed coordination in the activity of the motor elements in the gall bladder, in the sphincter of the gall bladder neck and the sphincter of Oddi were supposed to be responsible for post operative colics and dyspepsias (German view-point). Others thought that accompanying hepatitis, pancreatitis or other functional derangements of the gastro-intestinal tract were to blame for the untoward results. Involvements of accompanying pancreatitis, diminution of HCl secretion and possible derangements of the bile-flow through the common ducts are not mentioned incident to the quite common complaints following surgical procedures on the bile ducts.

The roentgenological findings offer some help. They may be important in establishing a decision for operation. However only in 60% did surgery confirm with the roentgen findings. The only outstanding group was that showing deformed gall bladder shadows. This is practically always a sign of a pathological gall bladder revealing pericholecystitic adhesions. Diminution of intensity or impairment of the density are not sufficient evidences for gall bladder pathology and the same may be said about totally absent gall bladder shadows.

Gall bladder disease without stone is one the border-line between functional and organic disease. All the laboratory methods serve only as helpful hints. Prognosis must be weighed individually based on many of elements entering the complexity of these ailments.

## SECTION II—*Experimental Physiology*

### The Influence of Some Organic and Inorganic Acids on the Motility of the Small Intestine\*

By

N. M. GRAY, M.D., M.Sc.  
MONTREAL, CANADA

THAT the contents of the gastro-intestinal tract may influence its neuro-muscular apparatus not only mechanically but also chemically is generally acknowledged. These contents are normally composed of the constituents of the food-stuffs or the products of their disintegration, or the digestive juices themselves. They may influence the motility of the alimentary canal either positively or negatively, that is, they may either stimulate or inhibit intestinal movement. Thus they may rightly be called the "natural chemical stimuli" of the gastro-intestinal tract (Babkin, 1916, 1924, 1925, 1928 (a)).

In the present study only one group of "natural chemical stimuli" was investigated, their effect being tested on the motility of the small intestine of the cat. This group consisted of three acids, namely, hydrochloric acid, lactic acid and acetic acid. The reasons for choosing these particular acids were as follows. *Hydrochloric acid* is a normal product of the secretory activity of the gastric glands. After every meal it passes with the chyme into the duodenum and determines the slightly acid reaction of the duodenal and jejunal contents. The hydrochloric acid has moreover a twofold action on the motility of the small intestine, i.e. partly inhibitory and partly excitatory (Babkin, 1916). This property of hydrochloric acid may provide a clue to the understanding of the changes in the motility of the intestine during the normal course of digestion, for example, when rhythmic segmentation is replaced by a peristaltic wave or by temporary rest of the organ.

The investigation of the excitatory and inhibitory properties of hydrochloric acid may aid us also in understanding some pathological conditions. For instance, in patients with achylia gastrica there is often a tendency to diarrhea owing to the rapid passage of food masses from the stomach to the large intestine; this may be due to the absence of the inhibitory effect of the acid on the motility of the stomach and the faster evacuation of that organ (the "entero-gastric reflex" of Thomas and Morgan, 1931). Another cause of the more rapid transportation of the chyme along the small intestine in cases of achylia gastrica may be

the very weak acid reaction of the chyme, determined probably by organic acids only.

*Lactic acid* was chosen because milk is one of the most generally used food-stuffs. *Acetic acid* is also a very common constituent of foods, being present in vinegars, pickles, etc. However, there is an additional interest in investigating the effect of acetic acid on intestinal motility. According to Magnus (1925) acetylcholine is the substance which stimulates the myenteric plexus, which, in its turn, discharges motor impulses to the intestinal muscles. If this is so, it seems of interest to observe how a loop of intestine will react to a solution of acetic acid introduced into the lumen. If the acid is absorbed by the walls of the loop, might it not convert an inert choline into active acetylcholine? Also, how will physostigmine, which inhibits the effect of the esterase inactivating acetylcholine, change the reaction of the loop to the acid? No complete solution of these complicated problems has been attempted, but a number of definite facts has been accumulated with which to form a basis for later work.

#### EXPERIMENTAL PROCEDURE

As mentioned, the experimental animal employed was the cat. Anesthesia was obtained by intravenous injection of chloralose (0.05 gm. per kilo) and urethane (0.5 gm. per kilo). The vagus nerves were cut on both sides of the neck. The abdomen was opened and the adrenal veins ligated on each side of the adrenal glands, so that the latter were cut off from the general circulation. The splanchnic nerves were then cut on both sides.

The solutions of hydrochloric acid, acetic acid and lactic acid were introduced into the lumen of the gut, for which purpose two denervated loops of small intestine were used. Each loop measured about 10 cm. and in all the experiments at least 15 cm. of intact intestine were left between them. The loops were prepared after the method described by Babkin (1928(b)). At the cephalad end of each loop a straight glass cannula was inserted into the lumen and fixed by a ligature about the mucosa; at the ab-oral end a glass T-piece was similarly inserted and fixed.

When thus prepared, the cat was placed in a bath of Ringer-Locke solution and the lower part of the body submerged to such an extent that the loops were kept constantly 0.5 to 1 cm. below the surface of the solution. The bath was maintained at the cat's body temperature. One limb of the T-piece of each loop was then connected by thin rubber tubing to a Marey's tambour, the other limb being connected to a drain at the side of the tank. The vagi and splanchnic nerves were now sectioned and the

Fig. 1. Cat—wt. 3.0 kgm... Upper tracing—hydrochloric acid 0.00219M. Lower tracing—acetic acid 0.303M.

loops gently washed out with normal saline. After resting the loops for five or ten minutes the experiment would be commenced by filling each loop by means of a pipette with a constant volume of the solution to be tested. Handling of the loops was kept at a minimum.

In some of the experiments rhythmic stimulation of the vagus was carried out, this being obtained by means of an induction coil and a metronome. In these experiments not only was special attention paid to the dissection of the vagi in an effort to preserve their blood supply but the right and left nerves were tested and that producing the greater effect was employed for the experiment.

In all the experiments the solutions of the acids used were made isotonic with blood ( $\Delta .56$ ) by the addition, if necessary, of sodium chloride; their temperature was raised to that of the animal before they were introduced into the loop.

Sufficient experiments were done with the various acids, sometimes in the cephalad and sometimes in the caudad loop, to obviate any false conclusion being drawn as a result of some difference in the activity of the loop depending on its level in the gastro-intestinal tube.

In order to analyse the origin of the effect of the various acids two series of experiments were carried out, namely, Series A and B.

#### SERIES A

In this series the acids all had the same hydrogen ion concentration, equivalent to a pH of 2.5. The pH was checked in all the solutions by means of the hydrogen ion electrode. This particular pH was chosen as being within physiological bounds.

#### SERIES B

In this series only hydrochloric and acetic acids were used. The concentration of the hydrochloric acid was .04 molar, and that of the acetic acid .1 molar. In all the experiments rhythmic stimulation of the vagus was employed.

In both of the above series of experiments the effect of subminimal doses of physostigmine, given intravenously, was noted, and in some experiments this was combined with small doses of choline hydrochloride, also introduced intravenously.

### EXPERIMENTAL RESULTS

#### SERIES A

In these experiments the acids used were of the same pH but differed in molar concentration. The following table gives their pH, their molar concentration

and the corresponding titratable acidity expressed as a percentage of hydrochloric acid.

|                           | pH  | Molar concentration | Titratable acidity as HCl |
|---------------------------|-----|---------------------|---------------------------|
| Hydrochloric acid (.008%) | 2.5 | .00219              | .008%                     |
| Acetic acid (1.82%)       | 2.5 | .303                | 1.09%                     |
| Lactic acid (.36%)        | 2.5 | .04                 | .146%                     |

As the following graphs will show, acetic acid appeared to be a better stimulant of motor activity than either lactic acid or hydrochloric acid, while lactic acid proved to be superior to hydrochloric acid. Subminimal doses of physostigmine and choline emphasized the effect of the acids in the same order as that in which they acted alone. Of the many graphs obtained only representative examples are given illustrating the typical responses.

Fig. 1 is from an experiment in which the action of acetic acid and that of hydrochloric acid were compared. The greater effectiveness of acetic acid as a motor stimulant is well shown.

Fig. 2 is from a similar experiment, but here a small dose of physostigmine was administered; the result is a marked accentuation of the superiority of the acetic acid.

Fig. 3 shows two periods during an experiment in which lactic acid and hydrochloric acid were compared. It will be seen that the organic acid caused the greater activity even when, as in the second period, it was placed in the loop which previously held hydrochloric acid. This difference between lactic and hydrochloric acid was accentuated after a small dose of physostigmine.

In numerous experiments acetic acid constantly proved to be a somewhat more effective motor stimulant than lactic acid and this difference was emphasized by physostigmine and choline. Fig. 4 illustrates one such experiment where choline and physostigmine were employed.

#### SERIES B

In these experiments a comparison was made of the effect of hydrochloric acid and acetic acid respectively upon the activity of the intestinal loops, while the loops were undergoing rhythmic stimulation through the vagus. If the modern theory of O. Loewi concerning the chemical transmission of the nerve impulse be accepted, then it is possible that we were superimposing the effect of hydrochloric acid or of acetic acid on that of a local hormone—which might be acetylcholine. Lactic acid was not used. The hydrochloric acid used was .04M with a pH of 1.4, while the acetic acid was .1M with a pH of 2.87.

The results in this series differ somewhat from those in Series A. In some of these experiments the hydrochloric acid solution provoked as good or even slightly better contractions than the acetic acid solution but this was by no means constant. Furthermore the administration of physostigmine seemed to enhance the effect of the acetic acid more than that of the hydrochloric acid.

Fig. 5 is from an experiment in which both choline and physostigmine were employed. When the loops were first filled with the acids, the activity was about equal in both; if anything, the loop containing hydrochloric acid was a little more active, and it will be seen that the first dose of choline hydrochloride (2 mgm.) produced an approximately equal effect on the two loops. After six minutes the dose of choline was

Fig. 2. Cat—wt. 3.4 kgm. Upper tracing—hydrochloric acid 0.00219M. Lower tracing—acetic acid 0.303M. Physostigmine  $\frac{1}{8}$  mgm. (repeated). R. L. S. = Ringer-Locke Solution.

repeated with similar results. A minute or two later the loops were emptied, washed out and rested. Ten minutes afterwards they were filled with Ringer-Locke solution. Physostigmine was then given, with the result that the loop which had held the acetic acid showed strong spasmodic contractions, while the other loop continued in its previous state of activity, exhibiting chiefly a display of pulsating rings. The remainder of the gastro-intestinal tube showed no spasmodic contractions during this experiment.

It was also noted in these experiments that the effect of acetic acid was always more prolonged than that of hydrochloric acid. This might of course be due to the property which .04M hydrochloric acid possesses of producing an inhibitory phase. These experiments, however, are only preliminary and a more thorough investigation should be carried out. We consider them merely as possible evidence that the effect of neural

stimulation through the vagus may combine with that of chemical stimulation produced by certain "natural chemical stimuli."

### DISCUSSION

Since the three acid solutions used in *Series A* had an equal H ion concentration, the difference in motor effect produced by each acid could not have been determined in these experiments by a difference in the H ion concentration in the three solutions.

The difference between the three acids, in effectiveness as motor stimulants might be determined by one, or both, of two factors, *viz.*:—the concentration of the anion and the chemical nature of the anion, in the three solutions.

It was necessary in making the solutions isotonic with blood to add a small amount of sodium chloride, about the same for each, to the solutions of hydro-

Fig. 3. Cat—wt. 3.1 kgm. Upper tracing—lactic acid 0.04 M; then hydrochloric acid 0.00219M. Lower tracing—hydrochloric acid 0.00219M; then lactic acid 0.04M.

Fig. 4. Cat—wt. 3.4 kgm. Upper tracing—lactic acid 0.04M. Lower tracing—acetic acid 0.303M. Blood pressure tracing. Choline hydrochloride 2.0 mgm. Physostigmine  $\frac{1}{8}$  mgm.

chloric acid and lactic acid. The acetic acid solution at the concentration used was already isotonic with blood and no sodium chloride had to be added.

Thus the solutions of hydrochloric acid and lactic acid each contain the chlorine ion while the acetic acid solution does not. Since the amounts of sodium chloride added to the hydrochloric acid solution and the lactic acid solution were about equal it is obvious that the hydrochloric acid solution will have a much higher concentration of chlorine ions than the lactic acid solution. However, the lactic acid solution was very definitely a better motor excitant than the hydrochloric acid solution. It would seem therefore that the concentration of chlorine ions could not give rise to the results we obtained unless the chlorine ion has an inhibitory effect on intestinal motor activity and of this there is no evidence.

The other anions which played a part in the experiments were the acetate anion and the lactate anion.

Now since the acid solutions which contained these anions had equal concentrations of H ions it follows

that the concentration of these two anions in their respective acid solutions must have been equal and the difference in the effect of the acetic acid and lactic acid solutions could not have been due to a different concentration of their anions.

From the above analysis it does not seem probable that the concentration of the anions in the solutions played a very important role in the results obtained and the latter would appear to have been determined by the chemical nature of the anion.

The above statement is not meant to minimize the importance of other factors, such as the concentration of the ions, for it is realized that if different concentrations are used this chemical effect of the ion might not be apparent.

Babkin (1916) showed the importance of the concentration factor in the response of the gut to hydrochloric acid for example, and in some other experiments of our own with solutions of hydrochloric acid, acetic acid and lactic acid solutions of equal molar concentration (0.04M), equivalent to a titratable acidity of .15% hydrochloric acid, the hydrochloric acid proved to be a much more active stimulant than either of the organic acids. It is interesting to note that in these experiments with acids of equal molar concentration the acetic acid and lactic acid solutions were about equally effective although as a matter of fact the concentration of anions in the lactic acid solution was about four times that in the acetic acid solution.

The physostigmine and choline were employed in the present work in an effort to investigate further the manner in which the acids produced their effects.

In discussing the mechanism of the action of the acids on the motility of the small intestine we are merely putting forward some suggestions, since the experimental material does not permit of any more definite conclusions being drawn. Further work of a

Fig. 5. Cat—wt 3.2 kgm. In suction coil at 9 cm., on right varus. Upper tracing—hydrochloric acid 0.04M. Lower tracing—acetic acid 0.1M. Choline hydrochloride 2.0 mgm. (repeated). Physostigmine  $\frac{1}{16}$  mgm. (repeated).

specialized nature is needed in order the more fully to elucidate this important problem.

One explanation of the stronger effect of the acetic acid as compared with hydrochloric and lactic acid may be based on the physico-chemical properties of the organic and inorganic acids. Organic and inorganic acids, although having the same pH, penetrate through the cell membrane with different velocities, which may be due to the greater solubility of the organic acids in lipoids. In our experiments this fact may have determined the greater effect of the organic acids than of hydrochloric acid upon the neuro-muscular apparatus of the gut.

Another explanation, however, may be given, based on the modern conception of "local hormones" or the "chemical transmission of nerve impulses." As histological study of the distribution of the capillary blood vessel net and of the lymph vessels shows, it is quite possible that a solution absorbed from the intestine before it enters the general circulation may act on the nerves and muscle elements of the gut. Therefore, the acid solutions which we used in our experiments could have affected the neuro-muscular apparatus of the intestine and those chemical bodies, such as choline, which are considered necessary for originating the spontaneous motility of the alimentary canal as well as for transmitting the impulses from the pre-ganglionic to the post-ganglionic autonomic nerves.

In the light of recent investigations the earlier observations on the stimulating effect of salts of various fatty acids on isolated strips of small intestine become of increased interest. Rona and Neukirk (1912) showed that the salts of acetic and pyruvic acid were especially stimulant. LeHeux (1921) studied the effects of a series of sodium salts of formic, acetic, propionic and other acids and the effects of the corresponding esters of these acids formed with choline. There was a striking parallelism in the effects of the two series, and the effects of both were inhibited by atropine. He observed that washing of the gut strips inhibited the characteristic effects of the salts but that the addition of choline restored the activity of the strips. He concluded that probably there is present in the gut some enzyme capable of synthesizing choline and acids to form the ester, and that the stimulating activity of the acid depends on this reaction. Further work by Abderhalden and Paffrath (1925), Loewi and Navratil (1920) and Plattner and Hinter (1930) gives strong support to the idea of the presence of such an enzyme in the gut.

In connection with the above theory we believe that the following facts brought out by our work are of some significance:

(1) That physostigmine and choline greatly increased the effect of acetic acid in comparison with that of hydrochloric acid and lactic acid.

(2) That very often under the combined action of acetic acid and physostigmine spasmodic contractions were noted; this type of contraction may be regarded as representing the strongest activity of the gut.

To conclude, it must be emphasized once more that we merely suggest some explanations, fully realizing that the true mechanism of the action of acids on the intestine can only be disclosed by further investigation. However, even the facts reported in the present study, as well as the work of our predecessors, clearly indicate how important is the part which various natural chemical stimuli play in maintaining the normal motor activity of the gastro-intestinal tract.

It seems highly desirable to extend these studies in order that it may be possible to deal in a more rational way with many motor ailments of the gastro-intestinal tract.

### SUMMARY

The effect upon intestinal motility of isotonic solutions of hydrochloric acid, acetic acid or lactic acid, introduced into the lumen of the small intestine of the cat, was investigated. The action, upon the response provoked by the acid solutions, of subminimal doses of physostigmine and choline hydrochloride given intravenously was noted.

Two series of experiments were performed:

#### SERIES A

In this series the three acid solutions were of equal pH. It was found that:

(1) The acetic acid solution was the most effective motor stimulant.

(2) The lactic acid solution was more effective than the hydrochloric acid solution.

(3) Physostigmine and choline accentuated the above-noted differences in the motor response to the three acid solutions.

#### SERIES B

In this series only hydrochloric acid and acetic acid were used. The hydrochloric acid solution was more concentrated and the acetic acid solution less concentrated than in Series A. Rhythmic vagal stimulation was employed in each experiment. It was found that:

(1) The acetic acid solution was not much more effective as a motor stimulant than the hydrochloric acid solution.

(2) Physostigmine and choline enhanced the effect of the acetic acid solution more than it did that of the hydrochloric acid solution.

The Author wishes to thank Dr. B. P. Babkin for suggesting this problem and for his helpful advice and criticism during the progress of the work.

## SECTION III—Nutrition

### Blood Buffer Values in Mineral Deficiency\*

By

I. NEWTON KUGELMASS, M.D.

NEW YORK, NEW YORK

THAT rachitic infants have a relatively unstable acid-base mechanism has been a consistent clinical observation when compared with well nourished infants. To be sure, it is a consequence of infectious invasion but the extent of the disturbance is much too striking to be passed up as a concomitant of the rachitic state. The acid-base disturbance either manifests itself as an alkalosis of some form with or without latent or active tetany. These deviations from biologic neutrality are exceptional in the normal child thus indicating the relative buffer stability of all its tissues.

Furthermore it has been observed, in experimental studies with rachitic animals, that it takes less acid or alkali to disturb the acid-base equilibrium of the rachitic than it does of normal animals. Some workers have attempted to explain these differences in acid-base behavior by seeking for a non-existent lowered alkali reserve or a negligible diminution in blood pH. We have, therefore, approached the problem by determining the buffer capacity of the blood of rachitic infants in comparison with that of normal infants as a biochemical refinement for the interpretation of the acid-base behavior in the rachitic state. This study is an application of the physical chemistry of the buffer mechanisms in heterogeneous systems as developed by the Author (1) in 1924.

Buffer capacity of a solution represents the known equivalents of either acid or alkali necessary to be added to the solution or lost from it in order to alter it by one unit of pH. Clinically the buffer capacity of blood is more frequently altered by a loss of bases in diarrhea and acids in vomiting than by frank addition of either acid or base for therapy. The buffer capacity of such an ideal buffer system, as blood, constitutes therefore its degree of stabilization to alteration in that narrow range of acid-base equilibrium which is most favorable for normal life function. This buffer capacity is additive in that it constitutes the buffer values of the individual buffer systems which are contained in blood—the proteins, phosphates, carbonates, etc. Any depletion in any one of these blood components in disease necessarily diminishes the total buffer capacity of the blood although it may not become manifest as a change in pH or in vol. of  $\text{CO}_2$ . Buffer value is further differentiated from potential acidity

which is the amount of alkali necessary to neutralize the available acidity in a definite amount of solution.

The buffer value,  $B$ , of serum at a given pH may be determined practically by electrometric titration. Strong standard acid or alkali is added to the serum in increasing amounts and the pH determined after each addition. If the concentration of added acid or alkali be great enough to keep the maximum increase in volume of the buffer solution relatively small, the volume may be neglected as the pH changes of buffer solutions are but slightly affected by volume changes of such magnitudes. Addition of each cubic centimeter of 0.1N. NaOH to serum of original volume 5 c.c. produces an increase of  $\Delta B = \frac{1}{V}$ . The buffer value  $\frac{dB}{dpH}$  at any pH may be determined graphically by plotting on a coordination system pH as ordinates, equivalents of alkali to the right and equivalents of acid to the left, as abscissae. The buffer value is the slope of the line tangent to the curve at the pH required.

#### PROCEDURE

The hydrogen ion concentration of the alkaline titrations was determined electrometrically by a Leeds and Northrup direct reading potentiometer of low resistance with enclosed lamp and scale galvanometer; a Weston standard cell; saturated KCl calomel and hydrogen cells and platinized platinum electrodes. The measurements were standardized by 0.05N, KH phthalate solution. The hydrogen ion concentrations of the acid titrations were determined by the quinhydrone electrode consisting of a bright platinum wire immersed in a solution containing quinhydrone to the extent of about 0.005N. This is the simplest of electrodes, the potential established being a linear function of the hydrogen ion concentration up to pH 8. Foaming of the solution in the alkali range was prevented by drops of amyl alcohol.

Five cubic centimeters of serum from normal and rachitic infants respectively were introduced into the titration chamber, the pH determined electrometrically at equilibrium and the acid titration carried out by the addition of successively increasing amount of 0.1N, NaOH and the resulting pH similarly measured in each case. The pH values were plotted against the total concentration of standard acid and alkali added. These titrations included a wide pH range with a total volume maintained in each case of about 10 c.c. or about twice the initial serum content. This represents

\*From the Hecksher Institute, New York City.  
Submitted July 12, 1935.

the optimum limit for utilizing buffer values with some degree of accuracy because dilution necessarily decreases buffer capacity. The purpose of the problem is the comparative evaluation of normal and rachitic serum rather than absolute determination of their buffer values.

### RESULTS

Three striking buffer curves are obtained from these electrometric titrations of the relative buffer

capacities of serum of normal and rachitic infants in comparison with that of physiologic saline. The buffer value of a non-buffer system upon additions of strong acid or alkali is slight within the pH range biologically significant. If there were no buffering at all, each addition of acid or alkali would produce infinite change in pH. The graph (Fig. 1) shows that the buffer value of completely dissociated acid or alkali is slight indeed, too slight in fact to be evident on the scale represented.

Figure 1

Electrometric Titration Values of Serum

| Titer     | Equiv. | Normal Serum |       | "Rachitic" Serum |       |       | Saline |
|-----------|--------|--------------|-------|------------------|-------|-------|--------|
|           |        | I            | II    | I                | II    | III   |        |
| N/10 NaOH |        |              |       |                  |       |       |        |
| 0.5       | .005   | 8.05         | 8.12  | 8.10             | 8.35  | 8.30  | 6.6    |
| 1.0       | .010   | 8.72         | 8.60  | 9.30             | 9.42  | 9.40  | 11.8   |
| 2.0       | .020   | 9.20         | 9.32  | 10.10            | 10.25 | 10.22 | 12.4   |
| 2.8       | .028   | 10.10        | 9.85  | 11.00            | 10.90 | 11.10 | 13.0   |
| 4.2       | .042   | 10.50        | 10.55 | 11.50            | 11.60 | 11.65 | 13.0   |
| 6.0       | .060   | 11.20        | 11.28 | 12.00            | 11.95 | 11.95 | 13.4   |
|           |        | 11.90        | 12.02 | 12.50            | 12.55 |       | 13.5   |
| N/10 HCl  |        |              |       |                  |       |       |        |
| 0.7       | .007   | 7.20         | 7.45  | 6.50             | 6.65  | 6.62  | 2.8    |
| 1.0       | .010   | 6.35         | 6.20  | 5.60             | 5.62  | 5.70  | 2.6    |
| 1.5       | .018   | 5.30         | 5.25  | 4.45             | 4.50  | 4.52  | 2.5    |
| 3.0       | .030   | 4.00         | 4.10  | 3.62             | 3.65  | 3.70  | 2.2    |
| 4.0       | .040   | 3.52         | 3.40  | 2.80             | 2.95  | 2.92  | 2.0    |
| 6.5       | .065   | 2.55         | 2.70  | 2.12             | 2.25  | 2.28  | 1.6    |

But at both ends of the graph of this non-buffered solution the buffer value becomes quite significant. This stoichiometric behaviour between pH 3 and 11, representing the neutralization of acid and base, and the alkaline buffer effect beyond pH 11 and the acid buffer effects below pH 3, are demonstrable both chemically and mathematically. Further physico-chemical discussion is beyond the purpose of this paper. Its graphic inclusion has only been made for control comparison of the buffer behaviour of the sera of normal and rachitic infants.

The buffer value of normal serum on both acid and alkali sides of the pH axis shows a sloping more and more marked as one recedes from neutrality in both extremes. The degree of sloping at any pH represents the total buffer capacity of the serum at that pH. The contrast between the curve of the non-buffered solution which falls over the pH axis between 3 and 11 and that of normal serum is quite marked. Although blood is an unusually ideal buffer system it is not constant in its buffer action but rather varies with each pH region. In fact, it appears most strongly buffered on the acid side below about pH 5, that is, below the iso-electric points of serum albumin and globulin when in this acid region they begin to act as electro-positive chemical constituents. The mechanism of this interesting behaviour is beyond the purpose of the present paper. Another interesting observation deduced from the buffer curve of normal serum is that its buffer value in the alkali range is greater than that on the acid range. This explains, for example, why frank acidosis is much more prevalent than is alkalosis. It also reveals the protective mechanism available in the blood in the prevention of alkalosis, inasmuch as the pH range on the alkaline side compatible with life is much more limited than that on the acid side.

The buffer curve of the sera obtained from rachitic infants is very definitely between the normal buffer curve and the control curve of a non-buffered solution. The striking diminution in buffer capacity of rachitic serum offers a substantial basis for the instability of the acid-base mechanism in rachitic infants. This diminution in buffer capacity is evident on both acid and alkaline sides thus making the development of both acidosis and alkalosis a more prevalent concomi-

tant of rickets when precipitated by acute infectious disease. The relative course of the buffer curve in rickets is not unlike that of the normal curve except for the fact that the area lying between the rachitic curve and the non-buffered curve represents a buffer capacity considerably diminished in comparison with the larger area occupied by the normal buffer curve.

The *therapeutic consequence* that follows from these observations on the diminished buffer capacity in rickets is for the administration in the dietary of the base-forming foods, as milk, fruits, and vegetables in addition to the anti-rachitic specific, vitamin D. There has been so much emphasis placed on the vitamin side of rachitic therapy that the intrinsic mechanism of the healing has been more or less lost sight of in routine clinical procedure. Vitamin D specifically catalyzes the absorption and utilization of calcium and phosphate salts but can do no more as far as the rachitic processes are concerned. Without calcium and phosphate salts made available in the dietary, vitamin D alone cannot induce calcification. In addition to the body depletion in bone constituents, the other buffer salts are evidently likewise decreased in content and must be made up in the daily dietary by sufficient addition of base-forming salts (2).

### CONCLUSIONS

1. The buffer values of serum obtained from normal and rachitic infants have been determined electrometrically for the entire pH range.
2. The blood buffer curves of normal and rachitic infants plotted against that of a non-buffered solution show the marked diminution in the blood buffer capacity in rickets.
3. The buffer action of blood is not constant but is determined by the pH at which it reacts.
4. The buffer capacity of normal serum is greater on the alkaline side than it is on the acid side within the biological range of pH 5 to 8.5, beyond which the buffer values of serum become markedly accentuated.
5. The diminished buffer capacity of the serum of rachitic infants at all pH ranges explains the relative instability of the acid-base mechanism in rickets.

## Statement

In the October issue of this Journal appeared an article by the undersigned called "A Year's Exclusive Meat Diet and Seven Years Later," in which was reported the present health status of Mr. Vilhjalmur Stefansson, the subject of the article.

Mr. Carson Anderson, who with Stefansson subsisted on an exclusive meat diet for one year and whose case was intensively studied at the Russell Sage Foundation, has just finished a health audit in my office. It will be recalled that Mr. Anderson spent four years with Mr. Stefansson in the Arctic circle.

Mr. Anderson has been in excellent health since the experiment. He is now forty-five years of age and weighs one hundred seventy-four pounds. He looks in fine physical trim and has no neurocirculatory, gastro-

intestinal or genito-urinary symptoms. His hair, though never thick, is in the same condition it was six years ago. The teeth and gums have shown no striking change over what was found during hospitalization six years ago. His blood pressure is 135/85. Blood and urine normal in every particular. All special senses are unimpaired, vision is perfect without the use of glasses. Mr. Anderson's diet has consisted largely of bread and potatoes with more meat than the average person eats. He takes a small amount of fruit and green vegetables daily and not more than one glass of milk per week and very little butter and cream.

### A New Technique for the Continuous Control of Acidity in Peptic Ulcer by the Aluminum Hydroxide Drip

By

E. E. WOLDMAN, M.D.

and

V. C. ROWLAND, M.D.

CLEVELAND, OHIO

**D**URING the last five years, considerable experimental and clinical evidence has accumulated to indicate that the acid factor is really important as an immediate or exciting cause of peptic ulcer and of its persistence in chronic form. There is no doubt about the profound significance of a number of predisposing causes of clinical ulcer—the neurogenic, vascular, traumatic, infectious, toxic and possibly hormonal or other X factors. These predisposing conditions in different degrees in individual cases render the local tissues vulnerable to the attack of the acid gastric juice. The length of time the tissues are exposed to this action is also important. Nervous disturbances and spasm of the pylorus interfere with the normal regurgitating and neutralizing mechanism which seems to provide an important protection to the ulcer bearing area.

Mann's "Surgical Duodenal Drainage" operation which diverts the alkaline juices to the lower intestine and attaches the jejunum directly to the pylorus leads almost uniformly to ulceration just beyond the pylorus. That the acid factor is the important one from the experimental standpoint is well confirmed by the work of Elman and Hartman, Morton, Mathews and Dragstedt, Weiss and Hubster and other well known investigators in this field.

Clinically, there is evidence that a similar mechanism exists, however much it may be modified by other factors. It is suggestive to find peptic ulcer occasionally adjacent to a Meckel's diverticulum or wherever there is aberrant gastric mucosa. This has been demonstrated at the umbilicus with the secretion of free hydrochloric acid and pepsin and ulceration of the surrounding skin. (Aschner and Karelitz: *Ann. of Surg.*, 91:573, 1930). Thirty-three cases of chronic ulcer with pain, hemorrhage or perforation and characteristic histology of peptic ulcer have been described in the neck of a Meckel's diverticulum in the adjacent ileum.

As a final evidence of the importance of the acid factor in the etiology of human peptic ulcer, the following personal experience with duodenal suction siphonage may be cited.

A well nourished woman of 33 years with an essentially negative past history was admitted to the hospital with jaundice and a complaint of three weeks of gall bladder pain. She grew sicker and pain shifted to the left hypochondrium with slight rigidity. The temperature was 37.5 to 38.5. White blood count was 18,000, icteric index 16, urine showed sugar and blood sugar was 153. A diagnosis of pancreatitis was made and the suction siphonage regimen instituted. It was continued with short interruptions for over three weeks. The details of her course are irrelevant here, but the patient finally died of infectious complications, about five weeks after hospitalization.

Autopsy confirmed the pancreatitis and complications but the finding of special significance in connection with the prolonged aspiration of duodenal contents was the presence of three large acute duodenal ulcers histologically typical of acute peptic ulcer.

This case seems really to present a clinical duplication of the above experimental conditions. It indicates that in human beings as in dogs the prolonged action of acid gastric juice unneutralized by the duodenal contents may lead to ulcer. If this is true, the logical first step in treatment and the most direct attack upon the lesion is the continuous neutralization of the acid. At the same time physical and mental rest, appropriate diet and medication may be used.

The great difficulty of medical ant-acid treatment aside from the menace of alkalosis has been its intermittency especially its discontinuance during the long night period. By the continuous instillation of an adsorbent substance with the indwelling nasal Levin tube night and day a constant control may be attained and readily checked at any time by aspirating samples. Soluble alkali in milk as used by Winkelstein has several disadvantages. Aluminum hydroxide is an amphoteric adsorbent substance which is not absorbed from the gastro-intestinal tract in any appreciable amount. Victor Myers by blood analysis found from five to twelve hundredths of a milligram of aluminum to one hundred cubic centimeters of blood after the ingestion of 168 cubic centimeters of a heavy suspension of precipitated aluminum hydroxide. Such minute traces are sometimes found normally without medication. No irritation of the gastro-intestinal or urinary tract is observed and the  $\text{CO}_2$  combining power of the blood and Ph remain unchanged. Six hundred cubic

Fig. 1

centimeters of the concentrated suspension of aluminum hydroxide precipitate were used daily and apparently any reasonable amount may be used with impunity.

A seven per cent colloidal suspension of aluminum hydroxide will adsorb twenty times its volume of N 10 hydrochloric acid. A fresh, washed, flocculent

precipitate of the hydroxide made from a solution of aluminum chloride is very efficacious, but the dry powder or tablets break down to oxides or other inert substances which by direct titration have little or no effect as an ant-acid. Colloidal milling of the washed precipitate greatly enhances the adsorbent properties, apparently by increased surface tension. It requires as long as 40 minutes for the colloidal jell to exert its complete ant-acid effect. By this method, symptomatic relief is usually prompt and X-ray evidence is at hand to show that an extraordinarily rapid rate of healing of sizeable deformities of the lesser curvature may be attained.

The seven per cent suspension is too gelatinous to flow freely through a constricted tube and is also much more concentrated than necessary for the continuous drip. Furthermore in a simple drip arrangement with a Levin tube there is an accumulation of fluid in the dependent part of the tube with an intermittent discharge into the stomach of a large quantity followed by a period with no flow.

### THE APPARATUS

The apparatus (Fig. 1) consists of an elevated bottle of water with a tube outlet and a simple clamp allowing water to drip into a lower bottle, which in turn is attached to a siphon system filled with a large supply of diluted (about 1%) aluminum hydroxide suspension. The filled siphon system, the outflow of which is a Levin tube may be tested before hand. It is readily seen that the water drip inflow releases the

Fig. 2

Case 1. L. S., 34 years, male, laborer. A. Gastric ulcer on the lesser curvature at the beginning of treatment. (4 plates). Also typical fluoroscopically. B. Seven days later: Ulcer deformity entirely gone. (Four other plates of the stomach taken at this time, at all angles, showed no deformity).

Fig. 3

Case 3. C. J. S., 38 years, male, school teacher. A. Ulcer at the outlet of the stomach or first part of the duodenum at the beginning of treatment. (3 plates). B. Seven days later: The crater of the ulcer is no longer demonstrable. (Four other plates taken at this time, at all angles, did not show the crater of the ulcer).

siphon system outflow at precisely the same rate, that is drop by drop. When the Levin nasal tube is in the patient's stomach, the outlet being at a somewhat lower level than the supply bottle, there is a continuous drip of the aluminum hydroxide suspension fully controlled by the water drip. The system is automatic, simply requiring to be kept air tight and replenished with water and aluminum hydroxide suspension each morning.

#### METHOD OF PROCEDURE

A small Levin tube, size 12, is passed through the patient's nostril into his stomach. A specimen of gastric content is withdrawn for analysis and also to show that the tip of the tube is in the stomach. About 200 c.c. of 7% colloidal aluminum hydroxide is added to 600 c.c. of distilled water and stirred until well mixed. The 800 c.c. of the diluted aluminum hydroxide is poured into bottle (C). The gravity flask (A) is filled with water while the clamp is closed. Allow the aluminum hydroxide to siphon from bottle (C) into a pan until it ceases. At this time there is a negative pressure created in bottle (B) and above the fluid level in bottle (C). Now connect the tube to the Levin tube and adjust the clamp beneath flask (A) so that the water will drip from flask (A) into bottle (B) at the rate of 5 or 6 drops per minute. Each drop creates that much positive pressure in bottle (B) and causes a drop to drip from the end of the Levin tube into the stomach. As the fluid level rises in bottle (B) it will cause the fluid level to fall proportionately

in bottle (C) and at the rate of 5 or 6 drops per minute it will take 24 hours to be completely empty. The entire system must be air tight.

#### RESULTS

In a small group of cases, prompt relief from pain especially night pain was one of the striking results. A constant achlorhydria was produced as proved by frequent sampling during the day and before the morning feeding. One recent case had persistent pain after four weeks in bed on a Sippy routine and was referred for surgery. This case was pain-free within one week on the above treatment. There is very little discomfort with the nasal tube, warmed before insertion, lubricated if necessary with plain mineral oil and attached with adhesive to the face. Cases with definite X-ray deformities were selected and a number of films in several directions taken at the end of one week. The rapidity of change was very striking. Gastric ulcer of course lends itself better to the demonstration of the structural change. Duodenal ulcer may heal and leave a deformed cap, but in the case below a definite ulcer crater later disappeared in one week's time. Dr. R. J. May, roentgenologist of St. Luke's Hospital made a special effort to demonstrate these lesions after the special treatment (Figs. 2, 3).

#### SUMMARY

We believe this method of continuous twenty-four hour adsorption of gastric acidity by aluminum hydro-

xide has promise of definite usefulness in the treatment of the acute stage of peptic ulcer. If reliance is placed on ant-acid treatment, there is every reason to carry it out in the most thorough and continuous manner. The aluminum hydroxide drip is free from the danger of alkalosis and of secondary acid secretion. The method is entirely compatible with any type of dietetic or sedative treatment. Because of continuous

neutralization the diet can be suited more definitely to the nutritional needs of the patient rather than crowded in frequent feedings to control acidity. Functional rest of both the secretory and motor function of the stomach may be allowed in larger measure. Especially for the intractable case, before surgery is resorted to, this method represents an additional refinement of technique in medical management.

## Therapy of Peptic Ulcer: Conservative Versus Radical\*

By

ERNEST H. GAITHER, M.D.  
BALTIMORE, MARYLAND

IN all fields of endeavor in which worthwhile progress has been achieved, frequent, earnest and at times acrimonious controversial arguments have been rife. Medicine is no exception to the rule; and during the past few years, the proponents and opponents of various types of therapy relating to peptic ulcer have been extremely active in publishing views extolling or decrying this or that new remedy, and defending or attacking what may be termed the "older" types of therapy. The opportunity for comparison afforded by bringing together for calm consideration sharply differing views, cannot but be conducive to continued progress.

Of late years, myriads of new therapeutic agencies for the treatment of peptic ulcer have been brought forward; many of these are parenteral methods; each remedy has been presented by some author as the only true *sine qua non* for the alleviation or cure of peptic ulcer. To present only a part of this array, one may mention the following remedies: Non-specific proteins, aolan, histidine, mucin, vitamin-C; diathermy of the cervical, sympathetic and parasympathetic ganglia by short waves; local application of radioactive substances; colloid aluminum hydroxide; injectable extract of pituitary lobe; specific vaccine; injections of parathyroid extract; amino-acids; insulin; intravenous injections of sodium benzoate. Various theories as to why these remedies should prove efficacious have been advanced.

Martin thinks it likely that ulcer in man may be the result of a reaction of sensitized cells to a specific antigen; the ulcer is simply an allergic phenomenon, and the aid brought about by the parenteral injection of milk protein may be due to a non-specific desensitization of the sensitized cells. He cites German authorities who are of the opinion that the intravenous injection of a foreign protein brings about a "shock" and the results are due to the ensuing reaction.

Martin's results in 95 patients observed over a period of 4½ years are as follows: 78 per cent had been greatly improved or clinically cured; a greater percentage of those whose symptoms had existed for only a few months were clinically cured or improved, that is, 86.4 per cent. One to four years after treatment, 60 per cent of the 60 cases who reported were clinically cured or improved. Of those whose symptoms had existed less than one year prior to treatment, 77.9 per cent were improved or clinically cured.

It is to be noted that Martin invariably states that the patients were "clinically cured or improved," and fails to state that the percentages given are indicative of unqualified healing and a complete relief of the condition. In this connection it is interesting to quote him as to the roentgen-ray proof of healing. He states: "Films taken from 2 to 18 months after the end of treatment frequently did, however, show definitely less spasm. Occasionally a smaller defect was seen; but in most cases no change was noted."

Schiff states that protein therapy results in either increased antibody formation or increased mobilization of pre-formed antibodies, and, further, that increase in agglutinins has been demonstrated to follow injection of albumose and nuclein, and milk protein. Protein injections may also act as non-specific desensitizing agents; and there is increasing evidence that the process of desensitization is not strictly specific. His investigations were made on a series comprising 27 cases of duodenal ulcer, the patients being given 10 c.c. of "aolan" intragluteally twice weekly for an average of 10 injections; 20 of the cases were allowed to continue their work and no diet or drugs were prescribed. Marked improvement or practically complete symptomatic relief occurred in 18, or 66.7 per cent; and less marked though definite improvement in 5, or 18.5 per cent, making a total of 85.2 per cent deriving benefit. No constant change in the degree of acidity or volume of gastric juice was noted. Comparative X-ray studies showed that the deformity persisted in all the cases in the series.

\*From the Digestive Clinic of Johns Hopkins Hospital, Baltimore, Maryland.  
Submitted October 25, 1935.

Eads presents a preliminary report after carefully studying a series of 35 cases of peptic ulcer, of which 30 were duodenal and 5 gastric in type. In most instances no special diet or medication was followed. This author made use of "histidine," a 4 per cent solution of the hydrochloride being used; it was given in daily injections of 5 c.c., the intramuscular route being preferred. The best results were obtained when the average course of treatment extended over a 21 to 24 day period. At the outset, he remarks that although orthodox medical and surgical treatment both fail at times to achieve the desired result, the final analysis of cures effected compares favorably thus far with the newer modes of therapy, and only a few of the latter have had sufficiently long periods of observation for any accurate estimation of their real value. He believes that the actual mechanism of the action of this amino-acid in the healing of these ulcers is by no means clear, and comments on the fact that the number of cases observed by him is not large, but compares favorably with the series reported recently by other authors. Bulmer reports on 52 cases, Borgendorfer on 30 cases, Hessel on 22, Weiss, Aron and Lenormand on several small series, Volini and McLaughlin on a series of 21 patients. The reports are for the most part concerned with immediate results, the follow-up of the cases being quite insufficient. However, for the most part, these authors report favorably on the histidine method, and assert that gastric ulcer responded better than duodenal ulcer, as a rule. Bulmer reported 58 per cent symptomatic cures with disappearance of abnormal X-ray findings, 19 per cent clinical improvement with no radiological changes, and 23 per cent failures in his series, of which a large number were gastric ulcers.

Various notations as to changes brought about by this treatment are presented by Eads, but I shall be able to give only a few of these: the acid gastric curve remained generally unaffected except in 5 cases; the improvement symptomatically consisted in relief of discomfort, a gain in appetite and weight, and a tolerance for a more normal dietary; the improvement usually appeared after the fifth treatment. Those presenting an obstructive lesion showed no response to treatment. The X-ray findings were variable: six showed disappearance, eight an improvement, and the remaining 21 no change. Eads' immediate results were as follows: 6 cases (17.1 per cent), showed clinical and X-ray evidence of immediate healing; 8 cases (22.8 per cent), showed evidence of clinical and X-ray improvement; 9 cases (25.7 per cent), showed amelioration of symptoms but no X-ray change; 12 cases (34.3 per cent), were unimproved at the completion of the course of treatment. He expressed the opinion that these immediate results are not so favorable as other authors have reported.

Engel presents the results of his treatment of a group of 70 cases by protein therapy of gastric ulcer in which an ulcer had been demonstrated by roentgenoscopy, gastroscopy or clinical examination. The injections were made intravenously at intervals of 3 to 4 days, from 4 to 12 injections being given. Complete cure was effected in 19 per cent of the cases; great improvement, this is, complete freedom from symptoms, was observed in an additional 39 per cent of the cases; slight improvement was noted in 30 per cent, and in only 12 per cent was the protein therapy

a complete failure. This author considers that these results compare favorably with those of other therapeutic methods, and that ulcers which do not yield to dietetic treatment should be subjected to protein therapy before surgical treatment is applied.

Smithies writes in regard to parenteral therapy: "General impression: helpful, even if not curative, in uncomplicated cases, in approximately 70 per cent; rather a dangerous procedure to place in the hands of general practitioners who may not select cases, or recognize the presence of complications. In addition to the parenteral therapy, the patients were on a smooth diet, with small doses of antispasmodics and sedatives at times. 'Shock-reaction,' twice very severe, was noted in 7 cases."

A personal letter from Arthur Hurst of London, in regard to the non-specific protein method of treatment, tells of his experiences with many patients treated under that method by a German authority and dismissed as "cured"; but Hurst later observed at operation that the ulcers were as large as before, showing that while the protein "shock" treatment had relieved pain, it had not helped the ulcer, and in fact, had achieved no results that dieting and rest could not have secured.

Eusterman had a similar experience while working in prominent Clinics abroad; patients who had been supposedly cured by protein therapy were found at operation to display no trace of healing. He thinks that very probably none of the other preparations are any more efficacious.

D. M. Rosenberg informs me in a personal communication that he took particular pains to question physicians afflicted with peptic ulcer, who had undergone parenteral treatment, and was told by the majority that they were greatly disappointed with the results. This investigator is thoroughly convinced that peptic ulcer is a chronic disease which in many instances presents spontaneous remission, and that the parenteral method is in no wise superior to orthodox therapy.

Garbat, in a personal letter, states that he has observed in both private and ward practice, the application of duodenal intubation, mucin, "aolan," insulin, "larostidin," etc.; and without criticism of those who advocate these methods, he has concluded that basically, diet is the essential treatment, all other agencies to be used as adjuvants only. He considers it a poor principle for physicians to depend on parenteral methods without diet, because the ultimate care of the ulcer and associated gastritis and the prevention of recurrence, can only be accomplished by dietetic and medicinal methods carried over a period of years. He emphasizes the fact that it takes 6 months to 2 years or more to cure an ulcer and its associated gastritis, if the process is curable; and he rarely speaks of a real cure in ulcer.

Regarding the results in peptic ulcer following specific therapy with alleged improvement or cure of the disease, T. R. Brown directs attention to two very significant but sadly neglected facts: first, that uncomplicated ulcer is a self-limited disease, and only the most pernicious form of therapy will prevent it from healing in its self-appointed time; second, we do not know the cause of ulcer, and until we know the primary cause, if such there be, prevention is difficult and treatment often unsatisfactory and symptomatic.

Aaron, of Buffalo, writes me: "As to the parenteral therapy for ulcer, we are not using it at all. We believe its claims are unwarranted and we have had a sufficient number of cases on the hospital Service who have had this treatment. They still have roentgen evidences of ulcer and the symptoms have still persisted. It seems to me that the orthodox method is still the best we have at hand."

A newer method which during the past few years has gained considerable recognition is gastric mucin therapy in the treatment of peptic ulcer. This form of treatment has been particularly lauded by Fogelson, on a basis of Lim and Ivy's work, and in a late article he presents statistics based on questionnaires submitted to clinicians throughout the country, concerning 494 patients with peptic ulcer treated by gastric mucin. The results showed that all symptoms were controlled in 70.5 per cent; partial relief was obtained in 23 per cent, and failure to afford relief in 6.5 per cent. "In 217 patients with intractable ulcer, unable to obtain relief of symptoms by medical management, 69 having had previous surgical procedures, gastric mucin brought about absolute relief in 63.1 per cent, partial relief in 29.4 per cent, and no relief in 7.5 per cent. Because of the limited time for observation, the permanence of the results was not considered."

Ralph C. Brown, Chicago, in a recent letter, says: "I have carried on a very considerable piece of work with animal mucin and have discarded it as a rational method of treatment because of its tremendous secretagogue effect. The acid curve resulting from its administration (following a brief period of acid-neutralization) is exactly superimposable to that obtained by the administration of histamin. I am too profound a believer in the influence of free HCl as a causative agent in the chronicity of ulcer to believe that mucin is the answer to the problem. To sum the matter up, I am old-fashioned and orthodox to a degree in my viewpoint. I know quite well that there are very few peptic ulcers either of the stomach or duodenum which will not heal if the surface of the ulcer can be freed throughout the day and night from the proteolytic action of gastric juice containing definite concentrations of free HCl. The evidence here is overwhelming, especially that obtained by a series of films of large, deeply penetrating gastric ulcers. I could show you hundreds of such cases where we have films made at ten-day intervals showing rapid and progressive disappearance of the lesion. When one can obtain such results by the intelligent and skillful application of such a proven principle, why should he countenance the use of methods which have no scientific background, or at least a questionable scientific background?"

Smithies, after a very thorough clinical study, concluded that mucin was unsatisfactory; administration was difficult with or without food; the dosage was too arbitrary, and the effects not good enough to justify the high cost and the confidence placed in the remedy by over-optimistic patients. Moreover, some cases displayed disquieting toxic symptoms after its application.

Eusterman, also Henning and Norpoth, have observed favorable response in a number of cases treated by this method. However, it has never appealed to me, and after reading unfavorable reports and being

personally informed by responsible and capable investigators of their disappointment in its results, I have never become sufficiently interested to adopt it as a therapeutic measure in peptic ulcer.

### AUTHOR'S ULCER REGIME

The *orthodox or conservative method* in peptic ulcer therapy, of which I continue to be an advocate, I shall outline in brief; however, it is to be thoroughly understood that individualization in each case is practised as regards hygiene, both physical and mental; in diet, and in medication; indeed, very few cases are treated in an identical manner.

The procedure in this method, reduced to essentials, is as follows: *Hygiene*: rest, physical and mental; physical rest includes both general bodily rest, and rest of the digestive tract; it must be realized, however, that a definite number of individuals respond far more satisfactorily when allowed to be up and about, attending to their daily duties, than when confined to bed, since the latter may be conducive of worry, irritation and apprehension about household or business duties. Recently there has been accorded a rightful recognition of the effect of mental states in these cases; therefore, appropriate gestures in this domain must receive due consideration; in short, the patient must be studied as an economic, as well as a physiologic, entity. *Local heat or cold* must always be considered. The *elimination of all foci of infection* should be a routine matter; thorough investigation of every organ, group of organs, and the tissues, is involved in this.

*Diet* begins with small amounts of bland liquids, not too frequently applied; various views exist as to the efficacy of milk and cream, or watery carbohydrates, this latter method being termed by Smithies "the physiological rest" method. I have found a combination of both most effectual. We should individualize in our therapy, and if an individual has a true idiosyncrasy toward certain articles of diet, these should be eliminated; otherwise the greater the variety of foods available, the more satisfactory the course for the patient and the doctor. According to the response of the patient, a gradual increase in amount, consistency and variety of food is carried out. The computation of the caloric value of the daily food and vitamin balance, should never be neglected. One of the most costly mistakes the average physician makes, is failing to insist upon the most careful dietetic regime being continued for at least 12 months; it takes moral courage, but it should be done; he should also insist that the patient bear always in mind that the digestive tract is the weak link, and will necessitate continual caution in regard to food and the details of daily life.

The *medicinal phase* of the treatment should be as simple as possible. I do not approve of the hourly application of drugs, preferring in the usual case, intervals of two or three hours, from early morning until bedtime; here again individualization is urged. We have always had, and continue to have, much faith in belladonna or atropine. But alas, now comes Bastedo, stating in a recent paper, that our views as to the efficacy of these remedies are quite erroneous, and that the dosage used is ineffectual; that to produce the results we desire, it would be necessary to give an amount which would be poisonous and very dangerous! It does seem that our troubles never will cease!

Various combinations of the alkalis: sodium bicarbonate, calcium carbonate, magnesia, have, in our hands, in sufficiently large dosage, proved most efficacious; in patients with obstructive and kidney complications, the possibility of alkalosis must receive consideration; but we have never encountered such a complication. In obstinate cases, duodenal feeding is used by some authorities, also nightly aspiration of the gastric contents.

The so called neutral salts marketed as "Triophos," "Tri-Calsate," "Alucol," have been highly recommended; frankly, however, I have never been convinced that they possess worthwhile superiority over the homely alkalis which I have enumerated.

The mild, stimulating type of laxative indicated,—magnesia, mineral oil, liquid agar, cascara and enemata,—are the most satisfactory and effectual.

The *upbuilding phase of therapy* is best accomplished by the use of nourishing food, well-balanced dietary, as regards vitamins and caloric value; fresh air, sunshine, rest, recreation, vacation, relaxation both mental and physical. Massage; physiotherapy, light therapy, are often most valuable if applied by experts; hematinic agents, iron, liver, arsenic per os or hypo. In short, common-sense therapy based upon physiologic facts so far as we know them.

In 1925, Smithies presented a very detailed report showing the result of the "physiologic rest method" in peptic ulcer. It will be possible to enumerate only a few of his results, which were obtained by a very thorough clinical investigation. He emphasized the too frequently overlooked fact that peptic ulcer is often, viscerally, a self-limited ailment of peculiar "periodicity," whose "natural" remissions are too generally regarded as dependent on special modes of management. In this attitude I heartily concur.

The material analyzed in his study comprised 470 patients with ulcers as follows: 128 wholly gastric; 36 pyloroduodenal; 306 duodenal; all were observed for a period of 10 years; he makes the very significant statement that when a clinician follows any type of therapeutic management for any particular form of ailment in a considerable group of patients over a number of years, he is in better position to secure the desired results than are those to whom the procedure is new, or who manage only an occasional patient. In his series, the average hospitalization was 28 days; bed confinement averaged less than 9 days; in 40 per cent all pain had disappeared within 48 hours of beginning the treatment; an added 33 per cent experienced pain relief within 48 hours; 8 per cent required 72 hours; 15 per cent almost 96 hours; in approximately 4 per cent it was necessary to relieve pain by opiates, this last group comprising those with complication. A total of 81 per cent were subjectively comfortable in 3 days or less. Of 41 per cent of the cases exhibiting positive occult blood tests when treatment was begun, at the end of 5 days, 92 per cent of the stools were bloodfree. 7 of the cases (1.5 per cent) went into actual perforation. In 66 patients who came to laparotomy for numerous intra-abdominal lesions, following institution of his ulcer management, completely healed scars were demonstrated in 54, or approximately 82 per cent. Roentgen-ray proof of healing was shown in 94 cases by disappearance of local ulcer, tender areas on palpation during fluoroscopy, or by absence of inferential motor phenomena

characteristic of active ulceration. For the whole series, recurrences were noted in 14 per cent (66 cases); the recurrences were of an ailment like the primary one, and roentgen-ray proof was available showing that the visceral upset was at the site of the initial lesion. After a very thorough study of the 470 cases, Smithies was convinced of the cessation of the ulcer process in 361, or 77 per cent.

In a recent personal communication, Smithies calls attention to an important fact often ignored,—that the roentgen deformity following the healing of an ulcer is at times greater than it was before the healing, due to accumulation of protective scar tissue; and in this connection, marked or complete obstruction of the stomach or duodenum may be brought about; also that malformation of the stomach may result from vigorous scar response in an attempt at healing; in such changes, the ulcer may heal; but the resulting deformity is so marked that corrective surgery becomes imperative; thus we see that the healing of a peptic ulcer does not always mean a stomach or duodenum of perfect or normal contour.

As a further proof of the efficacy of the conservative, orthodox rest-method, I desire to present the results of a thorough, most painstaking and convincing piece of investigative work by Sara Jordan and Lyman Boynton; they state that the rate of healing could be, and was, estimated by the diminution in size, and disappearance of, the X-ray defect on 41 ulcers of the media or lesser curvature, and in 6 prepyloric lesions. In 13 cases complete healing of the ulcer had occurred before the patients left the hospital, *i.e.*, within 21 to 28 days after the beginning of treatment, while 19 showed by diminution in size of the defect, satisfactory evidence of healing before leaving the hospital, and in 4 to 10 weeks after discharge showed complete disappearance of the niche. Of the 6 prepyloric lesions, 3 were originally diagnosed as ulcer, but were operated upon because of persistent X-ray defect and suspicion of malignancy; 2 were completely healed by X-ray evidence, within 7 weeks of the first observation; one was apparently healed and could not be controlled for further observation until 9 months later, when he returned with a carcinoma involving the ulcer, and it was a question as to the origin of the malignancy in the stomach or the pancreas. As to the therapy, Jordan and Boynton say: "We use the Sippy treatment or some modification of it, but we do not always use alkalis in these stomach cases; sometimes rest in bed, careful diet, freedom from worry, are adequate, the rest particularly." Thus we observe a series of perfectly controlled cases, 47 in number, in which it was proven that healing of the ulcer occurred in 35, approximately 75 per cent, within 10 weeks after the institution of conservative rest type of treatment.

I challenge any of the proponents of the various parenteral methods of therapy to present indisputable evidence which could equal these splendid and definitely proved achievements.

A recent and most comprehensive clinical study has been presented by Emery and Monroe; in which they call attention to the continued unsatisfactory management of peptic ulcer, due largely, they believe, to our ignorance regarding its etiology; in this regard, they quote Brooks in his statement that we should not speak of the *cure* of peptic ulcer, but rather of mitigation of certain of its signs and symptoms, until the cause of

peptic ulcer has been definitely demonstrated. These authors lay great emphasis on the fact that symptoms fluctuate with spontaneous remissions and relapses, the intervals ranging from weeks to many years; in 500 patients who were particularly questioned, the remissions seemed definitely spontaneous in 131.

It seems pertinent to inquire as to the dependability of dogmatic statements regarding the efficacy of this or that type of treatment when so large a number show spontaneous remissions; and it is interesting as well as enlightening to note that these authors have long since ceased to entertain the notion that one form of therapy is far superior to all others, and that they call attention to the need of individualization in the supervision of each case. It is very significant, albeit discouraging, to note their belief that the longer one follows patients with peptic ulcer, the fewer are medical cures he can claim. They are convinced that peptic ulcer is primarily a medical problem, and that a strict Sippy regime is the best medical solution; they have used and discarded mucin because of the unsatisfactory results; further, they feel that while surgery is at times indispensable, even life-saving, it does not cure the disease or alter its tendency to persist. They note that if patients are allowed to revert to their usual habits, they will relapse as frequently after a Sippy regime as any other, and that none of the present medical or surgical gestures do more than assist in bringing about remissions. Their results of medical treatment, after 3 to 6 years observations of 1,085 cases show: No symptoms, 13.7 per cent; very few symptoms, 36.5 per cent; definite improvement, 30.8 per cent; improvement, 6.3 per cent; no improvement, 12.5 per cent. However, the cases reported by Emery and Monroe did not represent their own personal experiences in management; the majority of the cases were taken from hospital records. The patients had been treated by numerous physicians and, doubtless, by several regimens of therapy.

I was interested in their admonition that one must treat the whole patient, and not the ulcer alone. In a final summary of a group of 1,258 patients receiving medical and surgical care, they consider that 81 per cent were successfully treated.

### SUMMARY

I have no hesitancy whatsoever in stating that to date my experience in the use of parenteral therapy has been overwhelmingly unsuccessful and disappointing; so far as I am able to see, its only virtue is its antispasmodic effect, and this seems to me no more striking than that obtained by rest of body, mind, and digestive tract, as already outlined in the orthodox rest method. Be that as it may, I still maintain an open mind and watchful attitude, and shall continue

to follow with intense interest the work which others are now carrying on with this radical method; if at a later date I am convinced of its superiority over the conservative therapy which I now support and use, I shall hasten to modify my present views.

It is in matters of moment such as this question of therapy of peptic ulcer, that criticism is most valuable; for from the collision of adverse opinion there flashes the spark of truth which, fed by eager devotion for knowledge, becomes a revealing flame.

I am not reactionary, for I whole-heartedly realize the need of the pioneering spirit, above all in the field of medicine; and inquisitive and independent thought is to be encouraged in order that we may be freed from the shackles of traditional assumptions; every idea has a right to existence, and intolerance and bigotry should be banished to the limbo of forgotten evils, but it is quite possible for progress to be made in a rational manner with the establishment of a mutual understanding of our problems, if we consider it a bounden duty to listen to both sides of every question with thoughtful attention.

However, as the medical profession has been only too prone to accept uncritically and to place a benediction upon, the attractive and the spectacular, every theory and procedure should henceforth be required to present properly conducted and adequately supervised laboratory and clinical research in substantiation of its claim.

I wish to place myself in that group of observers who look upon peptic ulcer as a chronic disease, the etiologic factor or factors of which have so far not been discovered; a disease which is characterized by spontaneous remissions, and thereby deprives us of the right to state unequivocally that it is cured. No matter what remedies have been applied, a large number of cases will always give favorable results; the statistics thus far published to support the claim that parenteral therapy has established its superiority over that of physiological rest, or orthodox method, do not bear out this claim, since they are inadequate in number, and the period of time over which the cases have been observed has not been sufficiently prolonged to prove permanent results.

Finally, the whole question of therapy really becomes more and more of a problem, and one wonders just how much is really accomplished by our efforts along the lines of hygiene, diet and medication. I am by no means a therapeutic nihilist, but after much experience over many years, I am moved to inquire of myself if there may not be a germ of truth in the witticism: "Medicine is the art or science of amusing a sick man with frivolous speculations about his disorder, and temporizing ingeniously until nature either kills or cures him."

## SECTION VII—Surgery of the Lower Colon and Rectum

### Lymphopathia Venerea: A Clinical Survey

By

COLLIER F. MARTIN, M.D., F.A.C.S.  
PHILADELPHIA, PENNSYLVANIA

**T**HIRTY years ago I began working in the Rectal Clinic of our good friend, the late Lewis T. Adler, Jr. Since that time I have served with the Philadelphia Polyclinic Hospital and the Medical Department of Temple University, and in 1918 returned to the Polyclinic, then known as the Graduate Hospital of the Medical Department of the University of Pennsylvania. During all of these years many cases of rectal stricture were encountered which in early days were ascribed to syphilis, gonorrhea, colitis and those of unknown etiology. It was noted that the majority of these cases of stricture occurred in the female and that the negress seemed particularly susceptible. In 1932 my attention was called to the fact that many of these strictures, with their curious sequelae, might be due to the disease at that time called Lymphogranuloma Inguinalis, now called *lymphopathia venerea*.

It is my purpose in this short paper simply to review the work and some of its problems which we met in the routine treatment of these cases, leaving out much of the historical detail.

During the past three years many articles upon this subject have appeared in American literature, although hundreds of articles have been published abroad previous to this date. Just at present the medical profession of the United States seems to be becoming lymphopathia minded, so that we may expect a flood of literature during the next few months or years.

The term "*lymphogranuloma inguinalis*" given to the disease recognized by Nicholas and Favre in 1913 is so frequently confused with "*granuloma inguinalis*" that in 1932 Wolf and Sulzberger substituted the term "*lymphopathia venerea*," believing that this term more fully described the pathology concerned.

The disease itself is believed to be produced by a filterable virus and is manifested in the male by the presence of a suppurative or non-suppurative adenitis. Various inflammatory conditions of the rectum and anus, frequently evidenced as multiple ano-rectal fistulae, recto-vaginal fistulae, and the formation of stricture of the rectum, more frequently encountered in the female. Such conditions as genito-rectal elephantiasis and esthiomone are of frequent occurrence both in the male and female. In 1925 Frei developed a skin test which was, and is, believed to be specific.

The antigen he employed was made from pus secured from an inguinal bubo. While we have used Frei's technique in preparing this test, and even have made use of pathologic tissue taken from a positive case, we have always felt that there was no way to standardize this substance for its activity.

While the disease is not confined to the Negro race, the Negro probably shows more variations in pathology than the white. Whether this be due to the co-existence of other venereal infections or to racial differences described by Rosser as the "fibro-plastic diathesis" would be hard to prove. Rosser probably had in mind a tendency toward keloidal changes in the skin of the Negro and the tendency to rather massive granulomatous changes along the lines of the lymphatics in the deeper tissues. In 1924 the writer used the term "Negromata" to describe these peculiar granulomatous tumors.

In Philadelphia we have a very large Negro population, practically 11%, in other words, nearly 220,000. New York City has but 4.4%, and in Chicago practically 6% are blacks. While Philadelphia is the third city in population, and also is third in the total number of blacks, it stands first in saturation. In our rectal clinic, situated almost in the center of the Negro district, there is ample opportunity to meet many of these pathologic cases. In other countries, such as in Europe or Asia, more cases may be found among the white, probably due to the fact that there the colored race is not so much in evidence.

Stricture of the rectum is more frequently encountered in the female, therefore this sex predominates in our clinic, while in the male the primary penile sore associated with inguinal adenitis is more frequently seen. Due to the mode of transmission, it is unusual to find a patient without some other associated venereal disease. This is true among the blacks and the lower class of white prostitutes. In spite of the fact that the pus employed to make antigens has been taken from patients with one or more additional venereal diseases, apparently their presence did not influence the specificity of the Frei reaction. So far we have obtained positive reactions in 96.7% of the cases.

Since inguinal adenitis was seen rarely in the female it was found necessary to obtain the cooperation of the Departments of Dermatology and Urology to procure pus for the production of our antigens. In the male the primary lesion was met with as a penile sore, herpetiform or vesicular in type, resembling

somewhat the so-called "hard chancre." The primary infection was quickly followed by suppurative of the inguinal glands, either unilateral or bilateral. These glands would break down, discharge, heal, break down, discharge, and heal, *ad infinitum*. The longer this condition progressed, the more the induration of the overlying tissues became apparent and the later scars became contracted, probably due to the fusing of the layers of underlying tissues. Following excision of these glands, or following simple palliative treatment, it was not unusual to notice marked thickening, hypertrophy or even elephantiasis of the genital organs.

The female obtaining her infection from the male develops the primary sore in the fourchette, the posterior vaginal wall, or the posterior lip of the cervix. As the primary sore is non-painful and is not accompanied by any marked discharge, it is not to be wondered at, that it is overlooked in this sex. Instead of the infection traveling to the inguinal glands, it is transferred to the para- or perirectal lymphatics, affecting the massive groups of lymphatics traveling to the anal nodes of Gerota. This peri- or pararectal lymphangitis is characterized by a rather marked infiltration of round cells or inflammatory cells which later become organized into dense fibrous tissue. In these areas of infected tissues, frequently are to be noted miliary abscesses and it is these multiple foci that probably account for the repeated and multiple points of massive induration and suppuration. Because of this inflammatory deposit, stricture formation occurs rather early, and with this stricture formation and with this interference in the blood supply and in nutrition, necrosis of the lining of the rectal wall occurs rather early. When the stricture stage is reached, there seems to be no deformity or complication which may not be present—abscesses, fistulas, hypertrophies of the anal and urogenital tissues, and even elephantiasis. Many cases show marked deformities of the genito-anal areas, frequently described as *lupus excedens* or *esthiomone*. Many writers have blamed the elephantiasis and deformities upon the destruction of the lymphatics following operative interference, but it may be just as true that the disease itself having caused obliteration of these vessels would produced the same effect.

During the past two years we have on our records about 155 cases of *lymphopathia venerea*. Some of these cases were observed by members of our Proctologic Staff also connected with other hospitals, notably W. O. Hermance, at the Woman's College Hospital, J. C. Werner, at Mt. Sinai, J. D. Schofield, at Hahnenmann, and Harry E. Bacon, at St. Luke's Hospital. Also, Bacon has studied some cases at the Temple University Hospital, in the service of Dr. H. Z. Hibshman.

With this cooperation from outside and with the close contacts within our School, it has been possible to gain some idea of the prevalence of this disease. As the majority of patients with rectal pathology from *lymphopathia venerea* occur in women, this sex must predominate in a rectal clinic. Also, as inguinal adenitis is comparatively rare in the female, we are forced to obtain the pus for antigens from the Urologic Service. Frei and others have insisted that the pus for

this antigen must be obtained from a patient free from syphilis, gonorrhea, soft chancre, tuberculosis, and other diseases which may produce specific or non-specific allergic skin reactions. This would seem like looking for virtue in Sodom and Gomorrah, as we have been thoroughly impressed with the fact that the individuals of the Negro race carry about every variety of infection known to Venus and her gentlemen friends.

We have been rather in doubt as to the standardization of, and the specificity of, our Frei antigens, since during the past few months we have simply sterilized them and not preserved them with any antiseptic, feeling that even the addition of carbolic acid might produce a local skin reaction. Formerly we made a control antigen from macerated inguinal glands obtained from an apparently normal individual. As the control antigen never showed a positive reaction, this method was abandoned. While the reaction obtained from the antigen as prepared by our laboratories was apparently satisfactory, yet the possibility of contamination, or the delayed growth of bacteria already present in the antigen was felt to raise some doubt as to our readings. However, Bacon reports that 264 cutaneous tests with these antigens were 100% negative in cases where *lymphopathia venerea* was unsuspected. Homer I. Silvers reports that 100 injections made upon clinic patients in the Atlantic City Hospital, not suspected to have this disease, were negative. In the Urologic Clinics 200 tests were made and 19 gave a positive reaction, 18 occurring in the Negro race. All of these cases had ano-rectal symptomatology and gross pathology. This would apparently indicate that our antigens were not contaminated. At present we are trying to standardize our Frei antigen.

Our clinics are fairly well filled with Negro patients in all stages of the disease. We are greatly impressed with the fact that, like the poor, they are always with us. One case, Roberta M., has been operated upon once, twice, or more times, per year, for the past thirty years. She has been treated for everything from alopecia to syphilis and gives a very positive reaction of the Frei antigen. I may add that tissue removed from her vulva was macerated and made into an antigen which apparently was extremely active.

Our cases seem to have every possible complication, such as inguinal adenitis, elephantiasis, esthiomone, rhagades, and almost every deformity known to woman and occasionally transferred to man. The diseased tissue is not moth-eaten, but rat-bitten in appearance, showing multiple sinuses of the vulva, perineum, perirectal tissue, and even, in many cases, recto-vaginal fistulae.

The rectal strictures found in most of these patients tend rather to be extensive in their encroachment upon the rectal and perirectal tissues. Vaginal examination to the palpating finger may reveal the dense inflammatory mass, feeling much like a piece of garden hose, which replaces the normal rectum. The entire pelvis below the reflection of the pelvic peritoneum is filled with a dense deposit of this peculiar granulomatous tissue. Local examination in many cases shows a patulous anal orifice, anal rhagades, and a papillomatous proliferative change of the anal and lower rectal tissues. The stricture, if present, usually is above the

ano-rectal line, extending from one to ten centimeters upward, of a calibre which may admit the index finger, but which usually will not admit the passage of an ordinary lead pencil. The mucous membrane frequently is absent in the greater portion of the rectum. The tissue is unyielding, undilatable, and does not give the impression of a massive infiltration of new tissue such as found in cases affected with malignancy. To use a homely comparison, I would say that the malignant stricture rather "jumps at you," while the lymphopathic stricture will not let you pass.

The question of treatment may not be considered in this paper because of time. Suffice it to say that, so far, nothing has been discovered that has given any relief of the obstruction from a therapeutic standpoint. The mechanical relief of obstruction is best obtained by colostomy, which may or may not be followed by extirpation of the total mass. All other operations have been found ineffective. I believe that the removal of a rectum infiltrated with this granulomatous mass presents a far greater mechanical problem than in a case suffering from carcinoma. I cannot avoid feeling that *lymphopathia venerea* is not simply a local disease, but that it is a very generalized infection associated with massive local pathology and deformities at the point of primary spread. There seems to be no picture which uniformly represents the changes encountered, and there seems to be no limit to the variety of gross tissue changes and no end to the many complications met. To me, other venereal diseases, even syphilis, would seem rather easy to describe, compared with the multiplicity of complications met with in *lymphopathia venerea*. Every form of medical treatment has been tried—injections of tartar emetic, "Fouadin," non-specific proteins, and intravenous, cutaneous and subcutaneous injections of the Frei antigen, and even intravenous injections of hydrochloric acid, 1 to 1500. So far, little or no improvement has been noted. Locally, surgical measures such as dilatation, proctotomy, carbon dioxide snow, and the Jelks' operation, have given poor results. A permanent colostomy apparently is our best procedure. Should the case present a good surgical risk, both locally and symptomatically, the colostomy may be followed by a complete extirpation. It must not be overlooked that these patients suffer with multiple rectal and perirectal infections, a somewhat lowered vitality, and frequently they have a rather pronounced anemia. At present the mortality will probably exceed that following extirpation for carcinoma.

Undoubtedly, our patients belong to the lower stratum of society and at the present time are unemployed, and if encouraged, will remain so. It is easily to be seen that the problem presents a very important study in cost to a community. Practically all of these cases are admitted to our wards, with no hope of the hospital receiving one cent of remuneration, and they are treated in our clinics for exactly the same fee. Once the diagnoses are made, we know that these patients will probably be visitors to the clinic and inmates of the hospital as long as they live. They

certainly are not welcome in our private offices and they take up an immense amount of our time in the free clinic. In Philadelphia, New York, and other large cities which have a large Negro population, the cost to the community must be excessive.

While there are very stringent rules for the examination of help employed in restaurants and hotels, *lymphopathia venerea* has been unrecognized and undiagnosed. As it seems to be a contact disease, it is a grave question as to how easily it may be transmitted by other means than by sexual intercourse. Undoubtedly, some cases have been reported of mouth infection. The inference is that abnormal practices may be blamed, but who knows? This probably is a more or less generalized, world-wide disease.

In Europe, particularly in Sweden, Germany, France and Roumania, the rapid increase of cases appearing in their hospitals has occasioned much alarm. As the patients nearly all belong to the lower stratum of society, are not self-supporting, and are dependent upon the dole, the problem is an important one. Hospitals in Europe, and I may say in America, are certainly in need of money, and any extra burden placed upon them certainly must be considered. Sweden is seriously considering including *lymphopathia venerea* among the venereal diseases to be reported under their extremely drastic law, and has requested cooperation from Germany, France and Roumania. In this country, undoubtedly cases are increasing, the largest number being found in the colored race because of their rather promiscuous living conditions and lack of intelligent cooperation with medical authorities.

During the World War while prophylactic stations were established in about every third house in the towns frequented by soldiers, the mere fact that after voluntarily accepting this proper treatment the soldier's name was reported to his commander and recorded on his permanent record, soon resulted in no reports being turned in and a tremendous increase in the spread of venereal disease. Many of our colored patients belong to the class working in kitchens and are more or less directly concerned in handling food. Should they be reported they would lose their jobs. The result is obvious. They certainly will never appear for examination as long as they are fit to work.

Apparently we are confronted with a disease, which is wide-spread, of extreme chronicity and devastating in its effects and eventually fatal in termination. Very shortly we will agree with the European medical authorities that we are confronted with an incurable disease far worse than syphilis and ranking very close to malignancy in its operability. Apparently the only efficient means of control of this disease lies in preventive medicine. The fact that the male rarely reports early and the female never, would place them in the class of incurability. Very early treatment might be effective. The passage of more legal restrictions might or might not be useful. Should these be enforced as laxly as the present ones on other venereal diseases, little may be expected.

# Recto-Urethral Fistula: An Operation For Its Cure\*

By

CECIL D. GASTON, M.D., F.A.C.S.

and

A. B. LEE, M.D.

BIRMINGHAM, ALABAMA

IN 1913 Young and Stone (1) presented an operation for the radical cure of post-operative recto-urethral fistula with a report of three cases. In a second publication (2) four years later, these authors added eight additional cases, making a total of eleven, all but one of which were successful. Later, Davis (3) reported three successful results by this method. Briefly, the Young-Stone operation is a radical ano-rectal dissection, the prime feature of which compares with an extensive Whitehead hemorrhoidal operation, where a cuff of the rectum is mobilized and drawn down far enough to be amputated above the fistulous opening. Other essential features are suprapubic drainage, urethral closure, and the bringing together

lithotomy. As a sequel to suprapubic prostatectomy, Bayer (4) reports one case, Stark (5) reports one case, Young and Davis (6) report two cases and Graves (7) reports one case. The subject under consideration records an additional or sixth case following suprapubic prostatectomy.

The diagnosis is easily made. Passage of gas per urethram and urine per rectum is the characteristic feature. With the history of a previous operation, little doubt exists as to the condition. Rectal examination reveals an opening in the mid-anterior rectal wall, within one or two centimeters above the sphincter ani, communicating directly with either the membranous or the prostatic urethra, usually the former.

Fig. 1. The position for patient. A modified Sims' retractor is placed into the angle of the posterior proctotomy.

of the fascia and levator fibers in the midline as an additional barrier between urethra and rectum.

In the attempt to cure this tragically surgical complication or sequel, a review of the literature discloses eloquent proof of the difficulties and failures encountered. The primary purpose of this paper is to describe a simplified operative technique with adequate field exposure and to relate the result of its clinical application. An exhaustive consideration of the lesion itself will not be attempted. It is to be emphasized that the type of case under consideration does not include those fistulae of tuberculous or malignant origin, but only those occurring as a result of surgical trauma.

The majority of recto-urethral fistulae are unfortunate results of perineal prostatectomy or perineal

In many cases, a communicating perineal fistula presents.

## CASE REPORT

The operation under discussion was performed upon a white male of sixty years. The history of this fistula dates back to a suprapubic prostatectomy that was performed September 15, 1933. While straining at stool eleven days later, the tip of the urethral catheter presented through the anus. Following this accident, the urethral catheter was removed and a suprapubic tube was reinserted. Gas and feces passed with the urine through the suprapubic tube. Similarly, urine passed per rectum and fecal products, chiefly gas, passed per urethram. Rectal examination showed an opening into the membranous urethra large enough to admit the tip of the little finger. The margin of the opening was well defined and densely infiltrated. Suprapubic drainage was continued for eleven weeks, when the operation for closure of the fistula was performed under spinal anesthesia.

\*Read before American Proctologic Society, 35th Annual Meeting, Atlantic City, New Jersey, June 10-11, 1935.  
Submitted November 8, 1935.

Fig. 2. This shows the field exposure with fistulous opening. Anal incision is completed. Dashes show the approximate line of amputation. Dots show the uppermost line of undercutting.

**Operation:** A clear concept of the technique of dissection and repair is best gained by a study of the illustrations. The patient was placed in the ventral-prone posture, hips were elevated 15 centimeters, the body plane was lowered 30 degrees, the thighs and legs were lowered to a plane just below the horizontal (8) (Fig. 1). A complete posterior proctotomy was first performed. A Pennington forceps was placed at the right and left anal points. Posterior retraction was gained with a modified Sims' retractor, the blade being inserted into the depths of the posterior incision. Complete exposure of a bloodless field was thus obtained. Between the Pennington forceps, an incision was made anteriorly, a few millimeters proximal to the anal verge (Fig. 2). From this incision, anal integument and rectal mucosa were dissected upward to

Fig. 3. Amputation of flap. Fistula is closed with interrupted catgut sutures following excision of fistulous margin. Levator fibers with coverings are to be apposed over this closure.

Fig. 4. The flap has been mobilized, drawn into apposition with incised anal skin and is partially approximated with sutures of interrupted catgut. Black space at left angle represents the small redundant fold of mobilized flap.

form an apron of tissue. Following exposure of the sphincter ani, this muscle was retracted forward with an Allis forceps, the mucosa was grasped deeply and the planes of cleavage were followed upward. Sharp dissection was found to be necessary about the fistulous tract. The apron of tissue was mobilized upward to a midline point approximately 2.5 centimeters above the fistulous opening, the upper border of the flap representing a sharp upward curve. The flap was then amputated just proximal to the fistulous opening, the line of amputation passing from the left angle to the right angle of wound. The margin of urethral opening was excised and closure was accurately accomplished over a retention catheter with interrupted sutures of No. 0 chromic catgut (Fig. 3). Several interrupted sutures of No. 1 chromic catgut were then placed deeply and laterally to bring into apposition

Fig. 5. This shows the appearance of field upon conclusion of operation. Note the absence of packing to prevent incontinence.

the levator ani elements as an additional barrier. Following complete hemostasis the margin of the anterior mobilized flap was sutured, without tension, to the skin margin with interrupted sutures of No. 0 chromic catgut. These sutures were inserted in such a fashion as to leave a slight redundancy of the flap at each outer angle of the wound to provide drainage (Fig. 4). Figure 5 shows the appearance of the field upon completion of operation. Several strips of rubber tissue were placed through the anal canal to aid in the maintenance of rectal decompression. Throughout the operation the acetone-alcoholic preparation of mercurochrome was generously used.

**Post-operative course:** Adequate post-operative care is imperative. In this case dressings were performed three times daily. An effort was made to approach a dry post-operative field. Mineral oil was administered nightly, beginning the night following the operation. On the fourth post-operative day a spontaneous bowel movement occurred. The urethral catheter was removed on the sixth post-operative day. Three days later much of the urine was passed per urethram. On the fifteenth post-operative day, the suprapubic tube was removed and six days later the suprapubic opening closed. Healing continued without tissue break-down. The patient was discharged on the twenty-third post-operative day.

Six months later, the patient was readmitted to the hospital for correction of a moderate anterior mucosal eversion. The following day, under caudal anesthesia, the rectal mucosa lining anterior anal canal was dissected away. The wound was left open to heal by granulation and epithelialization. An examination, July 21, 1934, demonstrated a complete anatomic and functional recovery.

There was neither complaint nor evidence of anal incontinence. A No. 16 F., urethral sound was passed without difficulty. This patient now holds a responsible position without an indication of former physical difficulty.

In this paper our purpose is to present the following data:

1. A brief discussion of traumatic recto-urethral fistula.
2. To urge the employment of an operative posture that presents a complete and bloodless field exposure.
3. To suggest that the usual wound break-down following repair of these cases comes from the rectal rather than the urethral phase. The mass of literature on this subject reveals that an attempt to cure the lesion usually has been and is considered a general surgical or genito-urinary problem. Apparently slight attention is directed to the rectal side of the case. Of prime importance in the prevention of wound break-down is the maintenance of rectal decompression. This is best obtained through employment of a posterior proctotomy with a follow-up attempt to encourage effortless bowel movements.
4. To submit evidence that this type of case justifies the cooperative efforts of the genito-urinary and proctologic surgeon.
5. To present a simplified technique for the cure of a select type of recto-urethral fistula.
6. To record a sixth case of recto-urethral fistula following suprapubic prostatectomy.

## Annual Abstracts of Protologic Literature

(May, 1934-May, 1935) By CLEMENT L. MARTIN, M.D., Chicago, Illinois

The complete bibliography from which these Abstracts were made will be published in full in the Transactions of the American Proctologic Society, 1935.

#### AMEBIASIS

The occurrence of the disease in Chicago in 1933 caused chiefly perhaps by contaminated hotel water supply, resulting from leaky valves or cross-connections in old plumbing, served to fix the attention of the profession throughout the country on this disease. It is now rather generally taken into account when diarrhea is a symptom. Many atypical cases and a number of very acute infestations are reported. (See Brown, Simpson, and others).

Fresh stool examinations in clinical laboratories are becoming more reliable due to better training of the personnel in parasitology. Stool cultures are being used more in Chicago. Some authorities think no suspected stool should be considered ameba-free without a negative culture. The complement fixation tests have not had a wide acceptance as yet. Water transmission of the disease was again demonstrated by a number of infestations following the Stock Yards fire in Chicago in 1934, during which the water supply became contaminated.

Spector, Kaplan, et al, conclude from their work that contamination by carriers of *Entamoeba histolytica* under the ordinary conditions of food handling occur, if at all, quite rarely.

Arnold cites authorities for the belief that there are lumen dwelling *Entamoeba histolytica* which may invade the mucosa only when the susceptibility of the host changes. His own work demonstrated that the permeability of intestinal mucosa was affected by unfavorable changes in animal environment. Hot weather may be a factor in causing active infestation when amebiasis is present in the bowel.

It has long been known that diet has an influence in the disease, especially a restricted diet with relatively high carbohydrate ingestion. Faust and Kagg have shown experimentally that raw liver, liver extract, and cod liver oil caused recovery or improvement; dessicated hog stomach and canned salmon caused rapid and severe aggravation of the disease.

The articles of the speakers at the A.M.A. symposium on Amebiasis at Cleveland: Craig, Simon, Magath, Reed, Melaney, K. Lynch, and McCoy and Chesley, cannot be summarized. They present in excellent form current knowledge of the subject and repay reading. This is equally true of Craig's paper in the first issue of the American Journal of Digestive Diseases and Nutrition.

Diagnosis (See 1933 "Review").

The advantage of proctoscopic examination and of obtaining material from rectal ulcers is becoming better known and appreciated. *Soper* has emphasized this repeatedly. Several authors direct attention to this in the last year. *Melcney's* description of the colon lesions is what we ordinarily see, however, the diffuse granular appearance of the mucosa is not common, in my experience.

*Magath* relies on the direct smear for determining the presence of *Entamoeba histolytica*, stained with iodine or eosin in some cases for amoeba identification; 3 fresh stools are examined, ordinarily.

Therapy (See 1933 "Review").

Emetine retains its place for the control of the diarrhea and acute phase of the disease, and for hepatitis; the organic arsenicals or oxyquinoline derivatives are the effective amebicides, the latter especially are given with many variations of detail.

*Craig* advocates emetine hydrochloride and chiniofon (anayodin, yatren), 3 or 4, 0.25 G pills of the latter are given 3 times a day for 8 to 10 days. He treats the case with severe diarrhea by subcutaneous injections of 0.065 (1 gr.) of emetine hydrochloride daily for a period not to exceed 12 days. *Anderson* and *Reed* have used carbarsone rectally to control the severe diarrhea in acute cases. *P.*

*W. Brown* continues to obtain good results with emetine 3 to 4 grains for 2 days, giving at the same time treparsol 0.25 Gm.t.i.d., but continuing for a total period of 4 to 5 days. Intravenous arsphenamine is regarded by many as an inconvenient, expensive, and uncertain measure.

*Reed* advocates emetine hydrochloride, 1 gr. daily hypodermically (never intravenously) for 6 days. At the most these six doses may be followed by six of ½ gr. each. The total must never exceed 10 mg. per kilogram of body weight, or (0.65 Gm.) 10 grains for a man of average weight. Other forms of emetine and especially ipecac are not advised. He recommends carbarsone and vioform: carbarsone 0.25 Gm. in gelatine capsules, 2 or 3 times a day to a total of 20 doses or vioform in gelatine capsules 0.5 Gm. twice daily for 10 days. Ten day to two week intervals between the first and second course are usual.

Having been thus definite, *Smithies'* warning on the danger of standardizing treatment in this disease is worthy of comment. One can no more safely follow fixed dosage in this than in any other disorder. Kidney and liver function must be watched when using arsenicals, emetine's effect on heart muscle should be borne in mind.

*Reed's* subdivision of these cases into groups, makes his article on treatment particularly worth while.

## SECTION VIII—Editorial

NOTE: The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Gastroenterological Association is in no way responsible for editorial expressions.

### THE JOURNAL'S SECOND BIRTHDAY

THE Editors and the Council have enjoyed watching the substantial growth of this Journal during the two years since its inception.

An ideal toward which effort now is being exerted is greater brevity in the articles which we shall publish. We seek the cooperation of contributors. Eventually, the need for brevity must become appreciated by our profession, otherwise, medical literature is destined to become forbiddingly prolix and its substance attenuated. Genuinely new material is rare; it is best exhibited and understood when not lost in language.

Beginning with Volume 3 (March, 1936), there will be but a few minor changes in the Journal's format. Such will conform with certain suggestions sent to the Supervising Editor by interested readers.

One outstanding explanation for the Journal's unusual progress lies in the remarkable interest shown by its audience throughout the United States, Canada, and Europe. Many readers have manifested an actual, individual concern with several aspects of this magazine, a feature as unusual as it is pleasing.

From our advertisers, we are gratified to learn that their use of our pages actually has brought results, in even these days of economic uncertainty. No doubt the main reason for this happy circumstance, rests upon the plain fact that the readers of this periodical constitute a select and understanding professional group; they are "key-men" whose opinions and purchases influence others.

It is our hope that readers will continue to consider this Journal as their's, in a very real sense and to a large degree. Suggestions for its improvement not only are welcomed but urgently are solicited.

It is with keen appreciation of the *entente cordiale* which exists between readers and Editorial Staff that the Journal will present Volume three.

Beaumont S. Cornell, Supervising Editor.

### REGARDING THE "HOUSE" PAGE AND CERTAIN EDITORIAL PROBLEMS

PRACTICALLY all publications set apart a page to give information about themselves and better to guide prospective contributors.

These "House," "business" or "literary" pages often are unread, partly because custom may place them in obscure sections of magazines but, more especially because readers or contributors feel that "House" pages have no scientific value, hence are none of their concern. Such attitude is unwarranted.

This Journal's "House" page always has been—and still is—at the front of the magazine and behind the first non-cover advertisement page. It is recommended that readers, contributors and business people read the "House" page, at least once; it carries much information with regards the policies and the administration of this Journal. Let us emphasize certain facts.

When we print that this magazine is "The Only Monthly Periodical in Its Special Field on the Western Hemisphere," we are not boasting; neither are we attempting to rival or to cover so much territory as does the *Chicago Tribune*, with its inclusive slogan, "The World's Greatest Newspaper!" We state the envied position of the Journal because it is a fact and because that fact emphasizes the international opportunity open to contributors. That this Journal eagerly is looked for in countries of the Western Hemisphere,

other than the United States, is evidenced by the abundant correspondence, requests for reprints, books, abstracts and the like which reach both its business and its editorial offices. That the advertiser finds this Western Hemisphere coverage of significance is proved by the number of direct enquiries which reach him, particularly from Latin America. One South American technical magazine on two occasions has sought permission to re-print, *in toto*, articles which the Journal has carried.

"The Only Monthly Periodical in Its Special Field on the Western Hemisphere" is not a boastful slogan; it is a *fact*. Such being so, Editors and Publishers alike recognize that this unique status imposes upon them a large measure of responsibility. On them, it is incumbent, that this Journal carry to its readers only such material as represents the most reliable and advanced investigative and clinical effort. Further, that this periodical bend every energy towards *promptly* printing data in a form which is easy to read and which is supplemented by the most skilled exhibition of tables, charts and photographs. In these respects, while the goal set not yet has been reached, voluntarily many readers have stated that the close collaboration existing between the Supervising Editor, Dr. Cornell, and the printers, has resulted in the production of one of the most technically attractive medical magazines extant.

The issuance, monthly, of any journal throws a tremendous routine burden upon those who work to a time-schedule. "Heavy" cerebral action not necessarily is demanded—even though it may be welcomed). The purely physical maneuvers required are a real task for the small group entrusted with the duties of "pushing things through." It is in respect these routine duties that perusal of the "House" page vastly would lighten the task of the "Office"—of men who work earnestly and willingly without thought of financial reward. We list a few of the ways by which the "Office" could be helped if readers, contributors or business fold carefully would scrutinize the "House" page.

(a) Dozens of letters asking about subscription or single copy rates would not demand the time and the expense of answering.

(b) Manuscripts would be prepared, *before submission*, in a fashion which greatly would facilitate their being read; more quickly then, would Authors learn of acceptances, revisions, rejections.

Graphs, charts, tables, photographs properly would be designated and made understandable without lengthy correspondence and thus not lost with regards "tops," "bottoms," "legends," "right" or "left," or even with regards manuscripts to which they belong. A weary, perplexed Editor but proves he is human when he casts a stoney eye on a sloppily-typed, miserably organized manuscript or spends half an evening endeavoring to hitch a group of blurry pictures, arm-long tables or monotonous, wordy "case histories" to a lot of typed sheets which are not even numbered!

(c) "References" in keeping with the subject matter of a manuscript are desirable. All too often, Authors submit "bibliographies" of encyclopoedic length, with incorrectly spelled names of workers or journals, errors as to subject, volume, pages, etc. Oft, indeed, it is evident at a glance, that such bibliographies are not germane to the text, are not known inti-

mately to the essayists and appear only for the purpose of impressing the general reader—which, of course, they don't, inasmuch as only readers interested in the topic being discussed give attention to bibliographies. When such special readers do so, very quickly doubt is cast upon the subject presented, when it is noted that the reference lists palpably are inaccurate or not specifically called for. Being generous with his bibliography not always is an indication of a writer's language-knowledge, broad understanding, reading or of general erudition. Not uncommonly, a vast bibliography is a tail which wags a feeble scientific dog. Besides, it's a costly affair to "set up" such an eye-laming punishment to Editors and proof-readers.

(d) Authors who speculate respecting what has become of their manuscripts would do well to recall whether or not the contributions were sent to the *Editor* or to the *Business Office*; whether they travelled at *first class* rates, and in *sealed* containers which carried Authors' return *addresses*; whether return postage was enclosed; whether illustrations were protected against the quite good-natured, tho destructive activities of the mail-handlers.

(e) Good sportsmanship is an outstanding American characteristic. Occasionally poor sportsmanship crops up, even among physicians and scientists. Its most common evidence lies in failing to give credit to men who have done original or meritorious work on subjects being discussed; in quoting *partial* paragraphs which do not carry the entire sense of another's observations; in casting doubt upon men or institutions and their efforts, should those men be not "Olympians" or their work-shops be rivals; in making excerpts from important papers and then *forgetting*. (!) properly to include those small, but all-important, quotation marks; in appropriating whole blocks of references or—this, we are happy to admit is rare—wilfully plagiarizing entire articles (even to the degree of not crediting illustrations!) which previously have been published, perhaps in journals (often foreign) or Transactions not readily accessible to the average reader. There is nothing more reprehensible or contemptible than the theft of another's brain-children! Manuscripts sent to this Journal are assumed to be *original* efforts, not rehashes, slickly disguised summaries or outright stealings. While, in such circumstances, Editors may be deceived, readers are not. Within a few days following the printing of these spurious essays, critical and condemning communications pour into the Journal's office.

Means whereby these imposters, who chance to have degrees in medicine, could be disciplined—even to their expulsion from reputable organizations of physicians—imperatively would seem to be called for. Their crimes are not just thoughtlessness or carelessness. Preparation of medical essays requires too much time and effort to credit such excuses. Those "Authors" deliberately steal men's brain work and present the results for personal advertising purposes. When commercial organizations throughout the land punish and ostracize dishonest advertisers, it is high time that the medical clan purge itself of "research" fakers and copyists. At any rate, it might curb these glib arm-chair and library "investigators"—clinical or laboratory—to know that in any Editorial Office deserving that name, they are recognized and listed.

(f) Orders for reprints are purely business transactions. They should be sent to the *Publication Office* when Authors return corrected proofs to the publishers. Reprint orders sent to the Editor mean only delay, increased expense of operating that office or in the orders' being mislaid or lost. The manufacture of Authors' reprints represents a courtesy to contributors. Rarely do publishers "break even" on reprints. If they do not, then the expense wholly is borne by the publishers. It is but fair that Authors recognize this fact and promptly pay for their reprints. In these days of economic stress, few publishers can afford to pay for the reprints of others' articles—i.e.—actually to pay for the privilege of printing Authors' essays and, also for their publicity-programs—for, often that is just the use to which huge numbers of reprints are put.

(g) Books for purposes of review are an Editorial responsibility; the Business Office has no concern with such matters. Publishers and Editors find it expensive to ship the many weighty volumes of medical-today hither and thither, in order that they may reach their proper destinations. This Journal's reviews are made by competent men whether they be or be not members of its Editorial Council. Further, it is our policy to have reviewers actually read the new books and thus then to see to it that their comments sufficiently are inclusive to give readers bases upon which they may determine whether or not the books will prove valued additions to professional libraries. That the Journal's reviews are appreciated is evidenced by the many congratulatory letters received from publishers. Occasionally, a subscriber takes time off and expresses his approval of a recently printed, particularly brilliant review. Finally, reviews are printed without censorship by the Business Office.

(h) As this Journal approaches the issuance of "Volume 3," it is not inappropriate again to mention that its policy does not permit the whole-sale piratical plundering of its pages by the lay or the medical-business-man publisher of those "sent free," bound collections of advertisements which call themselves "magazines." Contributors should appreciate the en-

deavors put forth by this Journal that they be protected from these shameless parasites who, at times, hiding behind the names of publicity seeking physician—"editors," publish scrambled, often ridiculous and misleading "abstracts" of articles which have appeared in reputable periodicals. This Journal's entire contents are copy-righted. Contributors are protected from "scissors-editors" and "immature publicist" wise-crackers' by our constant, monthly survey of the "gratis" magazines. We believe that the really earnest clinicians and investigators appreciate our efforts. It is of interest to observe that the contributor who occasionally sends a note stating that he has given permission to the publishers of the "*Current Economist*," and its like, to abstract his essay already printed in this Journal is one of those who has failed to read our "House" page; if he has read it and still wishes to split his modicum of sciences or medicine with the "ad" sheets dressed up to represent a magazine, then it is not difficult to judge why he publishes. Needless to say, his next contribution finds no space available in the Journal.

(i) Not being sufficiently clever to enjoy cards, we have but scant knowledge of the various possible combinations which may make a game, and less, perhaps, of the lingo of the card-player. However, we believe that out of the latter there has come the word "Kibitzer." Our understanding of this hybrid word is that it signifies one who does not play but who ever is ready to look over others' "hands" and offer advice. This Journal seems greatly to have stimulated the growth of the "Kibitzer" clan. For a periodical to be talked about is considered in some quarters, a half-won battle. During the coming year we hope to translate many "Kibitzers" into "Subscribers." If those who now faithfully remit annually will be rather selfish of their Journals and not pass them out freely to the "Kibitzers" our task will be an easy one. We are so hardened that we venture to hope that, in respect the "Kibitzers" and *your* Journal, you will make "Old Scrooge" look like a philanthropist.

Frank Smithies, M.D., Editor-in-Chief.

## SECTION IX—Book Reviews

(This section is open to contributions from any medical reader, whether or not a member of the Editorial Council).

*Aids in Diminishing Operative Risk. Preparation. Anesthesia. Post-operative Course. Transfusions. Infections (Pour Diminuer Le Risque Operatoire. Preparation. Anesthésie. Suites. Transfusions. Infections),* by Depuy de Frenelle. 91 plates, with an alphabetic index of Authors, an index of the subject matters by chapter, and a table of plates. (2nd Edition) Librairie Maloine, Paris, France.

THE work is divided into five parts. The first explains clearly the investigation for determining the resistance of the patient to operation (the ability of the patient to withstand operation), which is established after an examination of the urine, of renal function, of the blood, and after determination of the blood pressure, both arterial and venous.

The second part deals with the preparation of the patient for operation; pre-operative diet is mentioned with details for the different types of disease, uremia, diabetes, hypotension, etc.

In the third part the Author considers the preventive treatment of post-operative complications.

*Infection.* Preparation of an infected patient for operation. Prophylaxis and treatment of the infection by vaccine and antiviral therapy. Serotherapy, irrigation and drainage, and chemo-therapy.

*Pulmonary complications.* Phlebitis and embolism. The ideal preventive for the last two named would be, according to the Author, rest in bed with active movements and operative gymnastics.

Prophylaxis of occlusion, of tetanus.

In the fourth part, the Author, with the collaboration of Luquet and Moons (of Anvers), gives a detailed description of the different methods of anesthesia. "Anesthesia is that stage of the operative act which still remains the furthest from perfection. It is the weak point of surgery."

The different modes of anesthesia, by inhalation, are reviewed and details of their technique given. The advantages and the inconveniences of each one are specified. Spinal anesthesia, epidural and para-vertebral anesthesia, transabdominal anaesthesia of the splanchnics, regional anaesthesia, local anaesthesia with novocaine, and anaesthesia by injection are all dealt with.

In the fifth part, the Author studies the methods to be taken for diminishing the risk of operative shock and hemorrhage, the use of different serums, their indication, their value, and the technique employed in their use.

Blood transfusion is studied at length. Transfusion of whole blood, of blood treated with glucose, of citrated blood, with or without the addition of either salt or glucose are all considered. The indications for transfusion, the different techniques, and the dangers and accidents are clearly explained.

The study of this volume is highly recommended to all surgeons who are anxious to diminish operative risks by employing to this end all of the means, pre and post-operative, at their disposal. The reading is agreeable and easy, the text clear and precise, the rules and essential remarks are well underlined.

Pierre Smith and Thomas Farmer, Montreal.

*Dietetics for the Clinician: Second Edition.* By Milton Arlander Bridges. Published by Lea & Febiger, Philadelphia, Pennsylvania, 1935, 970 pages.

THE general plan of the second edition of Bridge's book, "Dietetics for the Clinician," has not been changed from that of the first edition. The principal changes that bring the book up to date are: Revision

of the sections on Physiology and Chemistry of Digestion, Vitamin Factors in Diet, Selection and Preparation of Foods, Allergic Diseases, Dentistry, Tuberculosis, and Pediatrics. These subjects have been rewritten and amplified in approval of the more recent investigative work.

In the *Part I*, the Author discusses briefly but clearly the Mechanics, Physiology and Chemistry of Digestion. Only the practical essentials of the metabolism of food have been explained. A section is devoted to the Selection and Preparation of Foods and to various recipes.

*Part II* discusses the Dietetic Management of Disease of Adults, and *Part III* is devoted to Pediatrics. Diseases and their Diets are discussed from the physiological and pathological needs of the patient suffering from the disease. Many sample menus for the various diets are presented and detailed lists of those foods to be used in limited amounts, or omitted entirely from the diets, are given. Throughout the book there are many practical medical and culinary suggestions of value.

The section devoted to miscellaneous subjects on dietetics, Food Adjuncts, Special Methods of Feeding and Practical recipes, is a very useful portion of the book.

Other features that enhance the value of this work are, The Food Table, in the appendix, and the Definitions, of, and a modern table analyzing the various alcoholic beverages.

This book offers to the physician, dietitian, and nurse a useful and authoratative presentation of the subject of Diet and Nutrition in a non-technical style, practical and physiologically sound.

Clifford J. Barborka, Chicago.

## SECTION X—After "Hours"

JOHANN GREGOR MENDEL\*

By

J. DUFFY HANCOCK, B.S., M.D., F.A.C.S.  
LOUISVILLE, KENTUCKY

### INTRODUCTION

MANY men achieve desired and lasting prominence while they are still alive to enjoy it; others, less deserving, may have that same pleasure if they are fortunate enough to die at the right time before the shallowness of their pretensions is realized; some few leave accomplishments that are gradually appreciated

as time "separates the wheat from the chaff"; but rarely does a man die in obscurity and yet, in the very next generation, have his name elevated among the immortals and his fame constantly increased. Such a man was Johann Gregor Mendel, promulgator of the Mendelian Law of Inheritance and Abbott of the Augustinian Monastery of St. Thomas at Brunn.

My school-day interest in this man was revived and intensified by reading Hugo Iltis' "Life of Mendel" to

\*Read before the Innominate Society, Louisville, Kentucky, November 13, 1934.  
Submitted October 23, 1935.

which I am indebted for much of the biographical data that follows.

### THE YOUTH AND STUDENT

A hundred years bring many changes—especially in the map of Europe. One reads that Mendel was born in Heinzendorf bei Odrau in Austrian Silesia. To find his birthplace now one must look in the north-eastern corner of Moravia in that part of Czechoslovakia at whose border the boundaries of Germany and Poland meet.

On July 20, 1822, when Johann Mendel was born, the villagers little realized the contribution their new neighbor would make to that age of scientific progress guided by Asa Gray in America, Pasteur in France, Lister in Scotland, Darwin in England, Helmholtz and Kach in Germany and Mendel in Austria—a partial list of the outstanding lights of a new scientific age.

Mendel was the second of three children; the two others were girls. He was christened simply "Johann"—the additional name of "Gregor" being taken when he became a member of the Augustinian order. His parents were "free-men" but peasants, his father being required to work three days of each week for the neighboring Noble. From early childhood, both on the farm and at school, he was interested in natural science and improved methods of cultivation.

After preliminary education in the local village school, Mendel matriculated, at the age of 11, into a higher school at Leipnik and later was admitted to the Tropeau High School. There the headmaster was Pater Ferdinand Schaumann, an Augustinian monk from the monastery at Altbrunn. Due to lack of finances it was with great difficulty that Mendel was able to complete the course. He had to work his way through school and knew what it was to be hungry.

His eagerness for more knowledge led him to apply, unsuccessfully, for a position as private tutor in Olmutz where he hoped to attend the Philosophical Institute. That he was finally able to enter was due to the fact that his father, now ailing, deeded the farm to a son-in-law with a proviso that some contribution was to be made towards Mendel's maintenance while a student. Even that was insufficient, and worry over the situation resulted in a protracted sick spell for Mendel. At this time his younger sister, Theresia, came to his aid by renouncing her share of the family estate and thus enabled him to resume and complete his studies at the Philosophical Institute.

Shortly after graduation, he had an opportunity to enter the Augustinian order. While monastic life had a definite appeal, his private circumstances (financial) evidently played some part in his choice of professions. At any rate, on October 9, 1843, he was admitted as a novice at the Koninginkloster.

### THE TEACHER AND PRIEST

Fortunately for Mendel, the Monastery of St. Thomas (Koninginkloster) at Brunn (Altbrunn) was one of the chief centers of the spiritual and intellectual life of the country. Almost immediately Mendel began to devote his spare time to the study of the small botanical and mineralogical collection at the monastery. At the end of his novitiate, he began the four year theological course embracing ecclesiastical history, archeology, and law, dogmatics, moral theology, pastoral divinity, methodology of elementary school education, Hebrew, Greek, Syriac, and Arabic

languages, agriculture, and other subjects. His work, diligence and behavior always were excellent and by special dispensation he was ordained a priest at the age of 25—before he was quite through with his studies. This dispensation was granted since there was an unusual shortage of priests at the monastery at that time.

For a few months after his graduation Mendel was an assistant parish priest. This work, however, was distasteful to him because of his timid, sensitive nature, which made visits to those ill and in pain an ordeal which seemed to upset him nervously. For that reason he welcomed an appointment to teach in the high school at Znaim. Since he had not attended a university or passed a teacher's examination, his position was that of a deputy or "supply" teacher. In 1850, without benefit of university training, he failed the examination in Vienna for a teacher's license. In 1851 he substituted for a few months at the Brunn Technical School. Upon his release from this position he attended the Vienna University from 1851 to 1853, studying physics, chemistry, botany, zoology, mathematics, and the practical use of the microscope. While a university student, he tried his luck in a lottery but the calculus of probabilities failed him.

In 1854 Mendel was appointed "supply" teacher at the Brunn Modern School and taught there for the fourteen years until he was elected abbot. As a teacher of zoology, botany, and physics he was not only competent but also gentle, kind and cordial. He seldom allowed a student to fail—coaching those who needed it without asking any special fee. He was fond of all animals except snakes, which he feared. Among his pets were a fox, hedgehog, birds and mice. In speaking of his breeding experiments, he used plain terms to describe matters of sex and when once some of the pupils tittered said, "Don't be stupid! These are natural things"—a rather liberal attitude at that time. In 1856, again he tried the teacher's examination at Vienna. Whether he failed or retired from the examination, he was, at any rate, unsuccessful and continued from then on as a "supply" teacher although all his colleagues were fully accredited.

While there are no hints that he was ever insubordinate, dissatisfied or negligent in his religious duties, he was not prominent as a priest. His chief interests, evidently, were scientific. He enjoyed teaching and, during those happy days, worked out his contribution to the scientific world. However, much of his success was probably made easier by the freedom from financial worry and the time for contemplation afforded by his monastic life.

### THE SCIENTIST AND DISCOVERER

From early childhood Mendel had been interested in gardening. Later, as priest and teacher, he began some haphazard work in hybridization and had even for a while bred mice in his room. His main interests, however, were always botanical rather than zoological, and if he kept any records of his experiments with mice they have been lost.

Although he cared nothing for fiction, Mendel read extensively in many fields of science; in the monastery library there are still many of his books with notations and comments in his handwriting. It is foolish to say that Mendel had no fore-runners, for he did, as have nearly all discoverers. Although their ground

work was based on insecure foundations, probably they influenced and certainly inspired him in his research. References in his writings show both knowledge and acknowledgement of the work of others but it conclusively can be demonstrated that he was the first to carry out the definitely planned experiments and to deduce scientifically those facts which are basis of his law.

For several years before 1856, Mendel had made rather extensive observations on hybrids of flowers as well as of the common, edible, garden pea; it was probably chance discoveries which, in that year (when he was but 34), led him to begin his careful experimentation. This continued for about seven years; two years after that, in February, 1865, his history-making paper, "Experiments in Plant-Hybridization," was presented before the Brunn Society for the Study of Natural Science.

In his attempt to study the law of hybrids, Mendel's methods differed from those of his predecessors in several ways. Instead of selecting species or varieties that differed in many qualities he chose those differing only in respect to one or a few characters. In addition to observing only the various characters presented by the hybrids, as others had done, he paid especial attention to the numerical ratios presented by the hybrids. This inclusion of *mathematics* with botany was an entirely new departure. His other original experimental procedure was the individualization of plants and their seeds. He regulated the planting and fertilization of each plant and studied each generation of hybrids separately rather than considering the whole of the offspring as a great chaos.

After careful consideration of the pea, Mendel decided to ignore characters that were rather quantitative in nature and to concentrate on those which were qualitative and paired. The seven contrasting pairs of characters selected were: 1, the shape of the pea (round or wrinkled); 2, the difference in the color of the cotyledons (yellow or green); 3, the tint of the seed coat (white or else gray, grayish brown, or buff with violet spots); 4, the difference in the shape of the ripe pods (simply curved or deeply constricted between the seeds); 5, the difference in tint of the unripe pods (green or yellow); 6, the difference in the position of the flowers (axial or terminal); and 7, the difference in the stature of the plants (tall or dwarf). Consideration of these factors by use of the methods just described gave Mendel the information upon which his deductions were based. An eighth character, the blooming season, later was studied and fairly well elaborated, but this was after the publication of his important monograph. It must be remembered, too, that these pairs of divergent qualities may be intermingled; for example, to use a very elementary illustration, tall or dwarf plants may have green or yellow pods, etc.

A detailed description of Mendel's experiments probably would be boresome to the reader—a complete analysis and explanation difficult for me. Therefore, let us consider only a few simple findings. If a tall race of peas is crossed with a short race, all the progeny in the *first* filial generation are tall. This is because tallness is "dominant" to shortness which is "recessive." When these tall hybrids are self-fertilized, as is normal with the pea, their offspring, the *second* filial generation, will be partly tall and partly short, in

the proportion of three tall and one short. The quality of shortness, it is apparent then, was not lost or blended but was only suppressed for the time being and the offspring of this short plant, self-fertilized, will all be short. The offspring of the tall plants will, however, vary. One tall plant will breed true as did the short one and all its offspring will be tall. The offspring of the other two tall plants will be partly tall and partly short in the proportion of three tall to one short. This illustrates Mendel's first fundamental, that *segregation* rather than *blending* occurs when hybrids are formed.

The other law, that there is an independent assortment of different pairs of qualities, can be shown in its simplest form when individuals with two pairs of contrasted characters, each exhibiting complete "dominance," are crossed, all types will be produced in the *second* filial generation. These represent the original distribution of the characters and the two possible recombinations between them. Since each type, considered separately, will appear in a 3:1 ratio in this *second* filial generation, the four will be brought together in a combination of two such ratios: that is, 9:3:3:1. Of these sixteen types, nine will contain one member of each dominant pair, three will be without one dominant type, and three without the other, while one will have all its factors "recessive"; and further, of these sixteen plants, one-fourth (composed of one member of each of the four types) will breed true. Contrasting this dihybrid with the previously mentioned monohybrid (tall and short only), we find of the sixteen combinations only nine distinct forms as compared with four combinations with three forms. Mendel showed that, in more complicated hybrids, the number of combinations would always be evidenced in a smaller number of forms which could be expressed as 3 to the *n*th power, *n* being the number of contrasting characters. We shall not consider these further than to say that Mendel, with infinite patience, was able by repeated crossings to produce all the possible combinations of the seven paired and contrasted characters previously mentioned.

$$\begin{array}{rcl}
 9 (4AaBb + 2AaB + 2ABb + AB) & = & 4AB \\
 3 (2AaB + Ab) & = & 2A \\
 3 (2ABb + aB) & = & 2B \\
 1 (ab) & = & 1ab \\
 & & 9 \\
 3 (A + 2Aa) & = & 2A \\
 3 (A + 2Aa) & = & 1a \\
 & & 3
 \end{array}$$

The "Mendelian Law" is, therefore, based upon *two fundamentals*. These are *first*, the *segregation* of contrasted unit-characters when pure-bred individuals are crossed, and *secondly*, the *independent assortment* that occurs when two or more pairs of contrasted characters are brought into the "cross." Since Mendel worked before the development of cytology, of course, he did not realize that the nucleus was the responsible part of the cell and that these unit-characters were present in the chromosomes. This latter amplification has somewhat modified the second fundamental (that of independent assortment) and furnishes the additional factor of *linkage* which, showing the numerous characters that must often be present in a single chromosome, explains apparent discrepancies that occur in some instances of "crossing" when multiple contrasted characters are present. Sex-linkage, cross-

ing-over, and mutation are other additional factors that have been incorporated in the Mendelian Law to make it more generally applicable.

The only other plant that Mendel wrote much about was the hawkweed. Experiments with this were done at the request of Nageli, a prominent German botanist. Only in their correspondence do we find references to numerous other plants studied by Mendel. A partial list includes columbine, snapdragon, plum, pear, bean, flax and nasturtium.

Before dismissing the scientific work of Mendel, mention should be made of his efforts as gardener, bee-keeper and meteorologist. As a gardener, his principal interests were with fruits and wild flowers. He secured seeds from many, widely separated parts of Europe and, today, in the monastery garden are Florentine grape vines and many fine fruit trees marked with a leaden seal bearing the initials "G.M." The old gardener there, who died a few years ago, is authority for the statement that Mendel affected five to six hundred crossings of fruit trees, raised their seedlings and grafted some of them on older trees.

Mendel's bee-hives are still intact, as are his original sketches for their construction. His experiments here were not limited to hybridization but included study for determinization of the best type of food, protection of the hives from mildew and control of disease among the bees. The only account I could find of any display of humor on Mendel's part was in connection with his observations on bees. The incident is so quaintly expressed by the victim, Pater Clemens, that I shall quote him verbatim: "One day towards the end of winter (it was in early March, and the ground was still under snow, but the sun was shining already with the warmth of early spring) we came to the bee-hives and watched the bees which the sun was already attracting forth from the hives. With a roughish smile, Prelate Mendel told me, then a youthful priest, to lay my black biretta on the white snow in front of the hives. He looked on with a grin when all the bees promptly settled on this attractive black patch, which very soon was yellow instead of black, for the bees used it as a site on which to void that which, for reasons of cleanliness, they had refrained from voiding in the hives during the winter."

One would think that these varied interests would have been sufficient for even so many-sided a man as was Mendel. However, he had time for meteorological studies. He was collaborator at Brunn for the Central and, later, for the Vienna Meteorological Institute. The barometer, maximum-and-minimum thermometer and rain gauge which he used were located each at a different part of the monastery grounds and, until less than a month before his death, he made thrice daily observations of each instrument. In addition to these regular tasks he made a study of sun-spots, of the level of the subsoil water and of the tornado which struck Brunn in 1870. These meteorological observations were the principal scientific attainments of his later years.

In the versatility of his interests, Mendel shows a trait so common to many men of eminence. The same is true in regard to the immense volume of work he managed to accomplish. Indeed, he well exemplified

the truth of the old adage that if one has a task to be done he should ask a busy man to do it.

### THE ABBOTT AND BISHOP

As an ordinary monk, Mendel had access to a very little garden on which to conduct epoch-making observations. He had hoped, however, when he was elected abbot, that, with the entire gardens, at his disposal he could do much more work than ever before. Unfortunately for science, the responsibilities of his new position kept pace with its honor and authority. After his election in 1868, experimentation became an increasingly unimportant part of his life—not that his interest lagged but his time was occupied by other duties. His selection as abbot, or more strictly speaking, prelate, of his local religious community was not a complete surprise to him as we find mention of its possibility in a letter to his brother-in-law several days before it occurred. While he may have regretted his promotion later when he realized that it meant virtually the end of his experimental work, Mendel appreciated at the time the honor of his new position. This position was more than that of an ordinary abbot in that the prelate of the Koninginkloster was mitred—that is he carried the rank and actual office of a bishop. It was indeed an achievement to bring satisfaction to the peasant-born youth. Some of his satisfaction is evident in a letter to the great Nageli who had sometimes been rather condescending in his scientific correspondence to the "supply" teacher. Mendel's elevated position, however, did not make him forget his early friends. Out of his own funds he educated the three sons of his sister Theresia who had sacrificed her dowry for him. Then, too, he financed the establishment of a much-needed fire brigade at his native Heinzendorf in recognition of which he was made an honorary member.

He travelled some, entertained as his position required, was a patron of music, became curator of the Moravian Institute for Deaf Mutes, served as chairman of the Moravian Mortgage Bank, took an active interest in numerous scientific societies, was made commander of the Order of Francis Joseph and was active politically as a member of the German-Liberal Constitutional Party. When we realize that most of the religious opposed him in this affiliation, it seems most distressing that this very party was responsible for the passage of the bill which caused him so much strife and bitterness.

This bill was one that required regular religious communities to pay special taxes to a religious fund which was used to aid Catholic worship and to pay parish priests. Mendel's fight was not against the Church but against the State. He opposed this tax on several grounds: it was a discriminatory tax on a special group, the Catholic Church was not a state church and to him it appeared unconstitutional for the state to tax for the benefit of a private organization; further he claimed that his particular monastery had some years previously been exempt from such legislation. Other monasteries joined in the fight but the bill was declared constitutional and they gradually acceded. Mendel, though, regarded the issue as a "struggle for the right" and resisted the enforcement of the bill as long as he lived, in spite of threats, offers of bribes and sequestration of monastery income. Shortly after his death, the monastery accepted the law and was refunded monies drawn in excess during

the period of sequestration. The fight made Mendel was quite bitter and his friends gradually lost patience with his persistency, or obstinacy as one may choose to call it. With this separation from intimates, Mendel found relaxation in chess, not only playing the game well but inventing many problems in it.

With advancing years the family tendency towards obesity became more apparent. Several years before his death, Mendel developed chronic kidney disease and later organic heart disease and general dropsy. His pulse was frequently around 120 but he refused to reduce to any great extent the 20 mild cigars he usually smoked during the course of a day. He contemplated death stoically as a natural necessity but he feared premature burial. Possibly because of that, he exacted a pledge from his physician nephew that an autopsy would be done. The end, hastened by uremia, occurred on January 6, 1884.

Mendel's death was universally mourned in his immediate locality. Governmental officials, Protestants, Jews, neighbors, religious brothers and many of the poor whom he had helped so kindly, gathered to pay their last respects to Johann Gregor Mendel, the abbott. Mendel, the scientist, was eulogised twenty-five years later when a memorial to the investigator was erected at Brunn.

#### APPLICATION AND POSSIBILITIES OF THE MENDELIAN LAW

Mendel's records of his researches remained lost for about 35 years. This seems surprising for, although the Brunn Society for the Study of Natural Science was purely a local one and its "Proceedings" an obscure publication, nevertheless its publication was exchanged for those of numerous other societies on the continent and Mendel's studies should have been noticed earlier. The year 1900 marks the rediscovery of the essay. Within a few weeks of each other, de Vries, Correna and Tschermak independently published papers confirming by experiments the substance of Mendel's conclusions. A new era opened but it had taken science 35 years to learn what Mendel had already proved, years that could have been used in advancing knowledge rather than in trying to catch up with the advance which Mendel had made.

In considering the *application and possibilities* of the "Mendelian Law," both the theoretical and practical aspects must be reviewed. From a theoretical standpoint its possible place in explaining the theory of evolution is most interesting. To understand this, we must orientate ourselves in regard to this theory and not confuse "Darwinism" with "Evolution." Darwin simply tried to explain evolution as the result of natural selection—the weeding out of the *unfit* through survival and dominance of the *relatively fit*. The weak point to this is, obviously, the infinite time that must be required for minute changes to accomplish this. de Vries' "theory of mutation" (a *departure from type* suddenly developed in a *single generation*, explainable by change in habit, environment or nutrition) seems more plausible but still not so convincing as Mendel's theory and proof which permit hereditary changes and yet in no way involve the idea of chance or innate change. While Mendel became familiar with all Darwinian literature after he had

begun his own experiments it is unfortunate that Darwin never heard of Mendel's work. According to Bateson, "had Mendel's work come into the hands of Darwin it is not too much to say that the history of the development of evolutionary philosophy would have been very different from that which we have witnessed."

Viewed from a *practical standpoint* untold benefits may be reaped by the application of the Mendelian Law. For instance, susceptibility and immunity of wheat to rust have been demonstrated to be a pair of Mendelian characters, of which susceptibility is "dominant." By cross-breeding susceptible plants with otherwise desirable qualities and immune plants with some undesirable qualities, a pure strain of immune plants with other desirable qualities has been produced experimentally. Similarly horns, a "dominant" character, have been crossed out of sheep with characteristics otherwise entirely desirable. In considering horses that are naturally pacers or trotters, it has been found that pacers are "recessive" to trotters. Numerous other instances might be noted and will undoubtedly be developed.

The most important of all fields applicable to the Mendelian Law is, of course, the human race. Students of eugenics and genetics barely have scratched the surface here. While much must be learned regarding unit characters as well as linkage it is likely that Mendelism is as certain as in the other instances quoted but, as has been said, it will be of little use so long as wisdom lags behind personal liberty. Claw-hand, color blindness, presenile cataract and mental deficiency are said to be unit characters. The great obstacle to the study of the human race is the slow reproduction of successive generations. Speculation of what the future will show offers a fascinating diversion.

#### CONCLUSIONS

In concluding this rather rambling consideration of Father Mendel and his work, it might be well to summarize our impressions of him as a man.

He was from sturdy farmer stock. Poverty was his lot from early boyhood. While he was endowed with an excellent intellect, he worked energetically all his life to develop it to the utmost. In his scientific investigations he was characterized by attention to the most minute details, his insistence upon facts, his simplicity of method and his separation of the scientific from religious factors. Absolute integrity is apparent in all aspects of his life—mental, moral, religious and scientific. Although of a most serious and rather bashful nature and, in his later years, rather embittered because of controversy with civil authorities over what he considered a matter of principle, Mendel was thoroughly human. His affection for his family, his gratitude to his sister who sacrificed her dowry for his education, his hopefulness with the lottery ticket, his belief in his own abilities, his satisfaction in his accomplishments, his liberal generosity and his personal interest in friends and kindred workers all were marks, not of an eccentric or cold recluse, but rather of a normal human being, the kind of a man who would be an inspiring teacher and delightful acquaintance.

As an organizer and executive Mendel would be a most welcome addition to any scientific or lay society today. Finally, he not only drafted the modest announcement of his death but also proved his ability as a prophet in regard to the resurrection of his works by his statement to his friend Niessl, "*Meine Zeit wird schon kommen.*" His time did soon come. In a niche beside Darwin, Mendel's renown is so secure that the

future can only enhance it, but through that fame will shine the man mourned by Pater Clemens as  
 "Gentle, free-handed, kindly to one and all,  
 Both brother and father to us brethern was he.  
 Flowers he loved, and as a defender of the law  
 he held out against injustice,  
 Whereby at length, worn out, he died from a  
 wound of the heart."

## SECTION XI—Societies, Programs and Proceedings

### ANNUAL SESSION OF THE AMERICAN COLLEGE OF PHYSICIANS

**T**HE Twentieth Annual Session of the American College of Physicians will be held in Detroit with headquarters at the Book-Cadillac Hotel, March 2-6, 1936.

Dr. James Alex. Miller, of New York City, is President of the College, and has arranged a program of general scientific sessions of great interest to those engaged in the practice of Internal Medicine and associated specialties. Dr. Charles G. Jennings\*, of Detroit, is the General Chairman of the Session, and is in charge of the program of clinics and demonstrations in the hospitals, medical schools and other Detroit institutions.

Dr. James D. Bruce, Vice President, in Charge of University Relations, University of Michigan, is Vice

\*Sad to announce that Dr. Jennings has recently died.

Chairman of the Committee on Arrangements, and has in charge the preparation of an all-day program to be conducted at the University of Michigan on Wednesday, March 4.

Dr. Walter B. Cannon, Professor of Physiology at Harvard University Medical School, will deliver the annual Convocation Oration on "The Role of Emotion in Disease." Dr. Miller's presidential address will be on "The Changing Order in Medicine." About fifty eminent authorities will present papers at the general scientific sessions, while clinics and demonstrations will be conducted at the Harper, Receiving, Ford, Grace, Herman Kiefer and Children's Hospitals of Detroit.

E. R. Loveland, Executive Secretary.  
 Philadelphia, Pa.

## ABSTRACTS

ZINNINGER, M. M., M.D., AND MCCANDLESS, H. G., M.D.

*Drainage of the Common Bile Duct for Gall Stones.*  
 S. G. O., Vol. 59, No. 5, pp. 781-786, Nov., 1934.

This article is a review of the technique used at the Cincinnati General Hospital for drainage of the common bile duct and is based on a series of forty-two cases where drainage was instituted through the stump of the cystic duct and a series of twelve cases where drainage of the common duct was instituted through the duct itself.

In the forty-two cases where drainage of the common bile duct was instituted through the stump of the cystic duct, there was a post-operative mortality of 9.3%. The hospital morbidity averaged twenty-eight days. The tube was kept in place an average time of eleven days. It was felt that the total bile loss was less than where drainage was instituted through the common duct itself and that

there was less leakage of bile around the tube when placed through the stump of the cystic duct.

In twelve cases where drainage was instituted through the common duct itself, the mortality was 25%. The average hospital morbidity was forty-two days.

Because in this small series of cases the hospital morbidity was less, the operative mortality was lower and the total amount of bile drainage was less in the group of patients drained through the stump of the cystic duct, the Authors feel that this should be the method of choice for drainage. For adequate exploration of the common duct, a separate incision through the duct itself is usually necessary, but this should be closed primarily. The fact that it is necessary to remove the gall bladder before drainage can be instituted through the stump of the cystic duct, the Authors do not feel is a serious contraindication.

N. W. Swinton, Boston.

## SECTION XII—"The Clinic"

### Spontaneous Gastro-Colic Fistula

By

MILTON R. LOURIA, M.D.

and

EMIL ROTHSTEIN, M.D.\*

BROOKLYN, NEW YORK

**S**PONTANEOUS gastro-colic fistulae are seen as infrequent complications of primary neoplasms of the stomach or colon. Clinically, they are quite similar to gastro-jejuno-colic fistulae occurring as a complication of gastro-jejunostomy, and the two conditions usually are described in the literature under the single head of "gastro-colic fistula."

Gastro-colic fistula was first reported in 1755, by Haller (1). In 1900, Zweig (2) collected 70 cases from the literature; of these 11 had been diagnosed ante-mortem. Brinton (3) in a study of 505 cases of carcinoma of the stomach found that perforation was an infrequent occurrence, it being found in 17 patients (3.4%). Of these, 11, or 2% of the total, presented gastro-colic fistulae. White (4) states that 4% of gastric carcinomas perforate, Smithies (5), 2½-6%, while Friedenwald and Feldman (6) found perforation in only 3 cases out of a series of 1000. Voerhoeve (7) collected from the literature 105 cases of gastro-colic fistula (1912) and calculated its occurrence as 3.75% of gastric carcinomas. Verbrugge (8) in 1924 collected 216 cases of gastro-colic fistulae and gastro-jejuno-colic fistulae from the literature. Of these 95 followed posterior gastro-enterostomy and 121 were due to primary gastric or colonic malignancy. However the 70 cases prior to 1903 were all due to malignancy, while of those after that year only 30% were secondary to carcinoma. The reason for this is two-fold: increasing surgery is lessening the number of gastric and colonic tumors neglected to the point of rupture, and similarly, increasing surgery is adding to the number of gastro-enterostomies. Of Verbrugge's 21 cases from the Mayo Clinic,

2 were due to carcinoma of the colon, and the remaining 19 were secondary to posterior gastro-enterostomies. Balfour and Down (9) analyzed two groups of gastro-enterostomy cases, totalling 1244; 3% presented gastro-jejunal ulceration. The percentage of perforation (not stated) was high. Anterior gastro-enterostomies with jejunal ulcerations perforated into the anterior abdominal wall, usually with abscess formation. Posterior gastro-enterostomies tend to perforate into the mesocolon or into the colon.

#### CASE REPORT

A. L., Negro male, 55, laborer. Admitted to K. C. H. 3/15/35. Claimed perfect health until 1/15/35, when he developed severe pain in the lumbar region. This pain persisted intermittently for two weeks and then disappeared. It was associated with chills and chilly sensations. About six weeks prior to his admission to the hospital severe epigastric pain appeared. This symptom lasted until the time of his death. It was intermittent and cramp-like; it was intensified by food and partially relieved by vomiting. During this period, he became progressively weaker and lost from forty to fifty pounds. Vomiting occurred about one month before his admission to the hospital. It persisted intermittently throughout the course of his ailment. It was most marked after eating. The vomitus was described as foodstuff, and occasionally "foul brown matter." There was no gross blood noticed. During the entire illness, the patient was moderately constipated.

Upon examination, the patient was weak and emaciated, with marked *feet ex ora*. The essential findings were in the abdomen. There was marked epigastric tenderness extending into the left hypochondrium; slight bulging could be seen and felt to the left of the epigastrium but due to marked tenderness and rigidity accurate palpation was impossible. Nevertheless the presence of a mass was definitely diagnosed in this region. At this time the clinical diagnosis was carcinoma of the stomach. A few days after

the admission note, a specimen of the vomitus was secured and examined. The following note was made: "The patient vomited profusely yesterday. The vomitus is apparently pure fecal matter. In the absence of signs of advanced intestinal obstruction this finding is pathognomonic of gastro-colic fistula, probably due to a ruptured carcinoma of the stomach." A few days later an attempt was made to confirm this impression by the dye test. The patient was given two capsules of methylene blue by mouth. Enemata given one and three hours afterwards, however, revealed no discoloration of the stools.

Laboratory data revealed the following: Urine—Neg. Stool—Positive for occult blood. Blood—Wassermann neg. Red count—3,000,000; Hbg. 65%; White count—11,000; Polys 81%. X-ray studies—Chest negative. Roentgen study: Fluoroscopy could not be performed due to the weakened condition of the patient. Similarly, in order to spare him several trips to the X-ray department (and before the clinical diagnosis of gastro-colic fistula was entertained) barium was given to him in bed and then in the X-ray department six hours later. Thus the presence of barium in the colon did not necessarily indicate any communication between the colon and the stomach. There was a constant filling defect in the pyloric portion of the stomach. The stomach plates, reviewed post-mortem, showed a large out-bulging deformity in the region of the greater curvature which corresponds with the ulcer and fistula found at necropsy. The clinical course was rapidly downhill with *exitus* two weeks after admission.

The autopsy protocol revealed: 1. Adenocarcinoma of the stomach with gastro-colic fistula. 2. Acute generalized purulent peritonitis. 3. Chronic adhesive pericarditis. 4. Chronic adhesive pleurisy. 5. Old healed fibrotic pulmonary tuberculosis. "There is an acute purulent peritonitis present involving all loops and surfaces of the visceral and parietal peritoneum. A large mass is found in the epigastrium, consisting of the stomach, transverse colon, and the right half of the pancreas. This mass is densely adherent to the gall bladder and the mesen-

\*Associate Attending Physician and Junior Visiting Physician, respectively; from the Service of Dr. Chas. E. Hamilton, Department of Medicine, Kings County Hospital, Brooklyn, N. Y.

Submitted October 10, 1935.

A—Constant deformity, indicative of carcinoma. B—Large niche, found at necropsy to correspond to the ulcer of the carcinoma, and to be continuous with the fistula.

tery. The stomach shows a large necrotic ulcerated mass in the pyloric region. On section the edges of the ulcer are undermined and the mass is seen to be composed of firm pearly white tissue. Situated on the greater curvature, 2½ inches proximal to the pylorus, is a fistulous opening into the adherent transverse colon, of about ¾ inch diameter. There is also a small perforation (3 mm.) on the anterior surface of the stomach, accounting for the general peritonitis." Microscopically the tumor was composed of typical adenocarcinomatous tissue.

**Discussion:** The clinical picture of gastro-colic fistula secondary to carcinoma is fairly characteristic in most cases. The clinical course at first is that of the malignancy. Perforation rarely occurs until the growth is well advanced. There is then usually a rapid progression of the picture with a downhill course. Quick weight loss is associated with moderate to severe pain. A fecal odor is noticed to the breath, especially

associated with eructations. Nausea and vomiting follow. The vomiting occasionally is fecal in character. This symptom is practically pathognomonic of gastro-colic fistula, as it occurs only in this condition, with the exceptions of far advanced low intestinal obstruction, jejuno-colic fistula and duodeno-colic fistula. Another important and characteristic symptom is the sudden onset of diarrhea, as a change from the constipation commonly associated with advanced gastric malignancy. Examination of the stool usually reveals the presence of undigested food. Diarrhea is unrelated to the hydrochloric acid content of the gastric juice, as it occurs in cases with achlorhydria as well as those presenting only a decrease in the acid content. The diarrhea is therefore in all probability due to the introduction of food directly in to the colon, and not to the irritating effect of the acid upon the colonic mucosa.

It is commonly found within one-half hour of the ingestion of food. It is present in most reported cases, although absent in our's. Examination of the patient, in addition to general cachexia, usually reveals the presence of a mass in the abdomen, associated with tenderness and rigidity. Depending upon the size and location of the tumor there may be evidence of distension of the stomach. Similarly if there is sufficient invasion of the colon there may also be evidence of distension of the proximal half of this viscus, as well. Fever is a common observation.

*Laboratory findings:* Examination of gastric contents, vomitus, and stool are often of the greatest significance, allowing a clinical diagnosis to be made. The stool in the typical case is foul and diarrrheal and contains blood and food particles. If the latter can be identified and the time of their ingestion is known, the discovery of a complete passage through the alimentary canal in two-three hours is of the greatest importance. The gastric contents, in addition to the findings of an advanced malignancy, often show the presence of gross fecal matter. Of all laboratory procedures, however, the X-ray examinations are of the greatest value. These studies reveal the presence of a large gastric neoplasm, at least partially affecting the greater curvature. In most cases, the fistula can be visualized with the fluoroscopy or the stomach plate. In others the colon is seen to contain the barium a few minutes after it has been given by mouth, with no sign of it in the small bowel. In a certain number of cases the fistula either is intermittently closed or, due to a valve-like action, is patent only from below. Such cases will show barium enema is given. The portion of the colon involved is often irregular, with a filling defect. Due to temporary blockage of the fistula, when small, by food, feces or fragments of tumor tissue, the connection may not be visualized by roentgen study.

**Pathology:** The cause for the development of a gastro-colic fistula is the slow perforation of a gastric carcinoma, with walling off rather than acute spreading. The greater curvature is practically always involved and the colon in its splenic flexure or distal half of the transverse portion. Although the fistula is usually short and direct it may be long and tortuous. Its diameter

varies from a few mm. to several cm.

**Diagnosis and Differential Diagnosis:** Fecal vomiting or the sudden appearance of diarrhea, associated with food particles in stool, in a known case of gastric malignancy is practically pathognomonic. Many cases have been misdiagnosed at first, either as non-perforated carcinoma, or as non-malignant disease of the gastro-intestinal tract (typhoid, dysentery, ulcerative colitis, etc.) Apart from careful X-ray study, the use of colored dye substances is of value. Charcoal, methylene blue and carmine red may be given by mouth and searched for in

the stools (if diarrheal) or in the enema washings, one, two and three hours afterward; if this is unsuccessful the same substances may be given by enema and looked for in the gastric washings.

**Treatment:** Gastro-colic fistula, when secondary to tumor, usually is inoperable, but the surgeon must decide this in relation to the individual patient.

**Summary:** Spontaneous gastro-colic fistulae result from perforation of gastric tumors into the colon, or from perforation of colonic tumors into the stomach. A case of the former is presented; it was diagnosed clinically. In arriving at a

diagnosis, diarrhea, fecal vomiting, and sudden downhill course are of extreme value. Roentgenographic studies are usually pathognomonic. Treatment is usually palliative.

# Urogenital Symptoms Referable to Intra-Abdominal Disease\*

By

CHAS. GORDON HEYD, B.A., M.D., F.A.C.S.  
NEW YORK, NEW YORK

THE urogenital system is placed behind a broad curtain of peritoneum. It is not surprising that disabilities and infections of this system should invoke symptoms that are referable to disease of the intra-abdominal organs. In like measure and perhaps more frequently pathological changes in the intra-abdominal organs may initiate symptoms that are referred to the urogenital system.

The most common cause of acute abdominal pain is appendicitis and thereafter in the order of frequency occur cholecystitis, perforated gastroduodenal ulcer, acute pelvic conditions — ruptured extra-uterine pregnancy, twisted ovarian cystoma, salpingitis; acute hematogenous infection of the kidney, acute diverticulitis and mesenteric vascular occlusion.

The microscopic presence of blood in the urine may be part of any pathological process of the genito-urinary apparatus but the presence of any acute abdominal inflammation in proximity to the kidney, ureter or bladder may also occasion microscopic blood.

The last paper written by Maurice Richardson of Boston was entitled

"The Error of Overlooking Ureteral Stone Under a Diagnosis of Appendicitis," and Connell records two cases with a mass in the pelvis and a distended bladder filled with bloody urine. Laparotomy in both instances disclosed a gangrenous appendix in contact with the fundus of the bladder.

A few years ago one of the most celebrated malpractice suits brought into court in this State hinged upon this dual mechanism of symptomatology. The surgeon had made a tentative diagnosis of suppurative appendicitis or "an infection in and about the kidney." A laparotomy for an appendectomy revealed no adequate pathology to explain the symptoms. The surgeon thereupon exposed the right kidney and drained an infected renal cyst. The claim for malpractice was based upon an alleged error in diagnosis together with assault against the person of the patient.

When there is symptomatic interrelationship between abdominal and urogenital pathology the diagnostic problem is a difficult one. Many years ago Riedel described a jaundice due to right-sided nephropotosis and the designation of Riedel's lobe gave a medical eponym that has persisted in abdominal symptomatology.

Pathological conditions of the right side of the abdomen and more particularly the right upper quadrant would many times simulate renal pathology and more frequently diseases of the urogenital system may suggest clinical entities of the gall bladder, gastro-duodenal segment, appendix and affections of the large intestine. The urgency of the surgical indication in many of the affections of the right side of the abdomen is such that time does not permit of a thorough investigation of the various organs concerned in the symptomatology of this region of the abdomen and while it is granted that extended study would differentiate most affections of the gall bladder, stomach, pancreas, duodenum, appendix and kidney, yet the very acuteness of the manifestations of these affections is such that they present a confusing diagnostic picture.

The symptomatic evolution of acute appendicitis is precise, definite and sequential. There occurs a certain number of cases of acute appendicitis wherein the urogenital symptoms are prominent. A reasonable proportion of the appendices lie retroperitoneally and occasionally are placed with a covering of peritoneum in close proximity to the lower pole of the kidney. A perforation of such

\*Read before the Joint Session of the Surgical and Genito-Urinary Sections of the New York Academy of Medicine, New York. Submitted November 22, 1935.

a retroperitoneally placed appendix will invoke all the mechanisms of a perinephritic abscess. In the presence of urinary symptoms rigidity of the right leg due to spasm of the iliopsoas muscle is a physical finding that while infrequent is by no means rare. If a silver dollar were laid one inch to the right and an inch and a half above the navel, it would roughly cover an area of great pathological incidence. The periphery of the silver dollar would embrace the pyloroduodenal area, enclose the fundus of the gall bladder and overlie the superior pole and the upper portion of the pelvis of the right kidney. In addition, it would cover the head of the pancreas and the junction of the common and pancreatic ducts. On its inner periphery it would overlie the vena cava, the superior mesenteric artery and vein, together with the loose retroperitoneal tissue and the retroperitoneal lymph glands. Below the lower border of this imaginary dollar would be the ileocecal angle, rich in its lymphatic glands, and also the lymphatics between the posterior surface of the cecum and the pelvis of the right kidney.

The mechanism of biliary colic due to calculus and that of ureteral colic due to calculus is fundamentally the same. There is the sudden arrest of a passage of fluid from a superior to a lower level. The secretion continues behind the obstruction and there is invoked a remarkable degree of hyperperistalsis and hydrostatic pressure in the attempt to dislodge the obstructing calculus. The onset of symptoms is sudden, dramatic and intense. The history, sex and anatomical distribution of pain usually allow of diagnostic differentiation but occasionally even the X-ray interpretation is dubious.

Another clinical picture that deserves consideration is the similarity of symptoms between the stone in the common duct without jaundice and a calculus of the right kidney. The attacks may be similar, the X-ray examination may expose a shadow and yet the pain may be definitely referable to the area of the upper pole of the right kidney. The transverse localization of upper abdominal pain in disease of the pancreas is not without its possible implication of kidney disease. Moreover, an obstructive condition at the outlet of the pelvis of the kidney may produce such an intense visceral reaction as to simulate in detail an

acute intestinal obstruction. A clinical picture of intestinal obstruction occurring in a virginal or nonoperative abdomen should always require careful diagnostic scrutiny as to the possibility of kidney disease. An infection arising from infected uterine contents may spread through the parametrial lymphatics and produce a retroperitoneal lymphangitis which will simulate to a remarkable degree a hematogenous infection of the kidney.

#### CASE REPORTS

Case No. 1. A young woman, twenty-eight years of age, entered the hospital, with a temperature of 103°, pulse 120, anxious, worried facies, vomiting, with moderate generalized abdominal distention and pain in the left hypogastrium. The blood culture was negative, the white differential count revealed 21,000 leucocytes, 19% polymorphonuclear. The routine urinary examination was negative. The patient had never been operated upon. A clinical diagnosis was made of a pneumococcal peritonitis, largely upon the absence of any—at that time known—etiological factor. Gynecological examination by two different consultants recorded the pelvis negative. Under expectant treatment the patient slowly improved and after five days complained of intense pain in the region of the left kidney and was exquisitely sensitive on mass percussion over the left renal region. Cystoscopic examinations were made and after careful diagnostic scrutiny, the possibility of either kidney as the site of disability was ruled out. After protracted convalescence the patient made a satisfactory recovery and it was then revealed that some five days before admission to the hospital there had been a forceful emptying of the uterus for a supposed six weeks' pregnancy. It seemed evident in retrospect that the atrium of infection was by the lymphatic system of the parametrium and that a retroperitoneal lymphangitis was responsible for the urogenital symptoms.

Acute mesenteric vascular occlusion may well simulate the characteristic symptoms of Dietl's crisis and the surgical record of acute hematogenous infection of the kidney—Brewer's septic infarct of the kidney—indicates the atmosphere of doubt that may surround this condition in view of the fact that in Brewer's original thirteen cases laparotomy was performed three times and in

Cobb's eight cases laparotomy was done in three instances.

One of the most confusing clinical pictures is the development of a subphrenic abscess secondary to a laparotomy for some infected condition within the abdomen. The continuation of temperature, the varying degree of dehydration and the almost uniform absence of pain tend to make localization of a subphrenic abscess one of extreme clinical difficulty. The degree with which an intraperitoneal but subdiaphragmatic abscess may simulate a perinephritic abscess is a factor of recorded experience.

The perforation of a neoplasm at the hepatic or splenic flexure will simulate a primary neoplasm of the kidney. There will be fixation of the colonic mass to the perirenal tissues, as well as frequency of urination and the presence of red blood cells. The precision of X-ray diagnosis and the almost absolute precision of urogenital diagnostic measures make it possible to allocate the anatomical identity of the neoplasm. Of much greater diagnostic difficulty is the patient with a known pyuria and an intra-abdominal affection. It is well to recall that statistically the right-sided bacilluria is more frequent than the left and according to Bishop is in proportion of ten right to one left. The lymphatic route from the cecum to the pelvis of the right kidney is short and direct. Pathological conditions involving the terminal ileum, the cecum or the appendix, are factors that contribute to the development of right-sided urogenital symptoms.

Case No. 2. A child five years of age, male, entered the hospital with a temperature of 105°, with marked frequency of urination, moderately severe diarrhea and a mass in the right loin. There was a history of the child crying out suddenly, being unable to pass urine, but after twelve hours beginning to dribble urine. The child was treated at home and was brought to the hospital, when the temperature rose rapidly and the child complained of abdominal pain. Aside from the mass the most obvious symptom was the urinary dribble. This was due to seepage from over-tension of the bladder, which was obvious on catheterization. In addition to palpation, a flat X-ray revealed a mass overlying the right ureter and bladder. At laparotomy

# Avoiding Gall Stone Precipitation

IT has been authoritatively stated that if a patient is being treated for Gall Stones, in which case temperature is of long duration and the patient is refusing food, he should be given, three times a day, BILE SALTS.

For nearly a quarter of a century the one bile salts that has been generally accepted because of its efficacy is

## TAUROCOL BILE SALTS TABLETS

TAUROCOL is a combination of bile salts, extracts of cascara sagrada, phenolphthalein and aromatics and is an agent recognized by the medical profession and widely prescribed for about a quarter of a century.

### TAUROCOL COMPOUND TABLETS

In combination with digestive ferments (pepsin, pancreatin, extract nux vomica) are especially indicated for intestinal indigestion and auto-intoxication.

Insufficient gastric and intestinal digestion is frequently associated with biliary sluggishness. In such conditions addition of digestive ferments is of advantage.

an appendiceal abscess was revealed.

The presence of a palpable mass to one side or the other of the median line and arising from either the pancreas as a pancreatic cyst, or from the retroperitoneal lymph glands as a retroperitoneal sarcoma or Hodgkins disease, invites consideration of kidney disease.

Endometrioma is apparently not as infrequent as is generally supposed. The name is applied to various tumors containing endometrium and which have the property of growth outside of the uterus and on almost any of the intra-abdominal viscera. They have a predilection for multiple endometrial transplants on the sigmoid, in the cul-de-sac and on the wall of the bladder. Masson recently has drawn attention to vesical irritability, increased frequency of urination and hematuria, and with occasional dysuria and macroscopic hematuria.

It is a matter of clinical observation that neoplasms of the right side of the colon generally develop few obstructive symptoms, whereas neoplasms of the left colon in the course of their growth do develop obstructive symptoms. The addition of spasm to a neoplasm of the sigmoid may produce such a similitude of symptoms as to suggest a left-sided renal calculus. Acute perforating diverticulitis or, as it is sometimes called "left-sided appendicitis," not infrequently is associated with manifest urogenital symptoms. Since this condition usually occurs in the more mature or elderly male patients, they very frequently have prostatic and bladder symptoms by reason of intrinsic changes in the bladder and prostate. However, approximately ten per cent of those patients consult a physician for their urinary symptoms. Anatomically, the perforation will occur extraperitoneally as frequently as it will within the peritoneal cavity and the presence of an infective material in the retroperitoneal space below the sigmoid and impinging upon the ureter and bladder produces an associated ureteritis and cystitis with vesical symptoms.

The presence of jaundice may produce a nephrosis and the nitrogenous retention primarily due to the pathological factors producing the jaundice is very apt to be construed as due to renal damage.

Elsewhere we have described an infrequent complication in gall bladder surgery characterized by a

*Dear Doctor:*

Routine, pre-operative cleansing of the bowels is a recognized procedure. Enemas have had the preference in most cases because cathartics may not evacuate completely, and may cause distressing symptoms and pre-operative fatigue.

May we suggest that you try TAXOL a few days before the operation; one, two, or more b.i.d., or t.i.d., according to need, because the dosage varies. You will find that TAXOL achieves the desired results without untoward symptoms.

X-ray studies testify to the completeness of the evacuation with TAXOL. Why not try it? Even enemas have their inconveniences.

*Very respectfully yours,*

M. D.

D. D. 2-36

gradual cessation of urinary secretion, a rise in the urea-nitrogen in the blood and a fatal termination. These patients may have associated with their terminal complication acute abdominal pain, distention, severe vomiting and fever. Clinical examination of the blood shows a normal icteric index and an ascending scale of urea-nitrogen. The death certificate is usually signed "uremia." It is our opinion that uremia does not occur in the manner herewith described as nitrogen retention, per se, does not necessarily

indicate an insufficient kidney function. A dehydration equal to a fluid loss in relation to total body weight of five per cent will occasion a pathological rise in the non-protein nitrogen of the blood similar to that found in many cases of chronic nephritis. It can be explained on the basis of the concentration of the blood due to the loss of water by dehydration, as well as an increased protein catabolism. Increasing study has shown that the hepatic complications may mimicry uremia with striking fidelity.

## ABSTRACTS

WANGENSTEEN, O. H.

*Repair of Recurrent and Difficult Hernias and Other Large Defects of the Abdominal Wall Employing the Iliotibial Tract of Fascia Lata as a Pedicle Flap.* S. G. and O., Vol. LIX, No. 5, pp. 766-780, Nov., 1934.

The operative procedure which the Author presents is a new application of the principle of transplantation of tissue with nerve and blood supply intact—the pedicle transplant. The transplanted tissue is the iliotibial tract and fascia rotated on the Tensor Fascia Lata Muscle as the pedicle from which the nerve and blood supply are transmitted.

Pre-operatively the skin is prepared by washing with soap and water, followed by the application of alcohol, benzine, ether, and finally, tincture of iodine applied in two coats. The iodine is later removed by Richardson's solution. In patients having large hernias, the Author inserts a Levine tube with multiple perforations into the stomach the night before operation, and applies suction to it post-operatively.

A vertical incision tapering laterally is made on the antero-lateral surface of the thigh, and the desired area of fascia lata exposed by undercutting the skin. This area of fascia is incised anteriorly, posteriorly and inferiorly, after which it is dissected away from the muscles and the intermuscular septum from below upwards leaving it suspended from the muscle *tensor fascia lata*. The deep surface of this fascia is smooth, while the superficial surface is covered by a variable amount of fat. In the repair of defects of the abdominal wall this flap is pulled up beneath Poupart's ligament with the fatty side down, and fixed in place with sutures of chromicised catgut. In the repair of hernias the flap is best slung over Poupart's ligament. In incisional hernias the flap is used as a patch over the site of suture, while in inguinal and femoral hernias the flap is intimately incorporated with the adjacent tissues in the closure. In certain instances of femoral hernia the Author has split the flap using part of it beneath Poupart's ligament, and part above.

Meticulous care is observed to obtain absolute haemostasis in both wounds; dead spaces are effectually obliterated. A subcutaneous drain is left in place for 24 to 48 hours in larger hernias. No attempt is made to close the fascial defect in the thigh. No functional disability in the thigh or leg is complained

## IN FECAL PUTREFACTION

# • KARICIN •

In the treatment of intestinal toxemia, putrefaction, mucous colitis, Karicin helps to

Detoxify the toxins of intestinal flora

Check fermentation

Reduce flatus

Soothe irritated mucosa

**DOSAGE:** The average dose of Karicin is a tablespoonful three times daily, taken in water or milk, at least one hour before or one hour after meals.

**SIZE:** Karicin is available in 10 oz. wide-mouthed bottles.

MATHEWS, ROBERT W., AND SCHNABEL, TRUMAN, G.

*Primary Esophageal Carcinoma, With Especial Reference to a Non-stenosing Variety.* J. A. M. A., 105:1591, Nov. 16, 1935.

In a group of 108 patients with carcinoma of the esophagus that came to autopsy, twenty-two exhibited a non-stenosing variety of lesion. The usual symptoms of dysphagia, pain, regurgitation of food and vomiting were not prominent in this nonstenosing group. The outstanding complaints were weight loss, pains in the chest, vomiting, cough, hoarseness and weakness. Dysphagia was relatively infrequent. The clinical course of the nonstenosing group was one-third as long as that of the stenosing group.

Roentgen examination should be followed by esophagoscopy and tissue obtained for biopsy in suspected cases. The fact that esophageal carcinoma may not produce stenosis must not be overlooked.

Francis D. Murphy, Milwaukee.

ZOLLINGER, R.

*Uretero-Intestinal Anastomoses. The Use of Mechanical Anastomosing Apparatus.* S. G. and O., Vol. LIX, No. 5, pp. 796-805, Nov., 1934.

The Author presents a technic of uretero-intestinal anastomosis in which a modification of the ordinary snap dress button is used. A free flow of urine postoperatively is allowed, and the ureter is protected from infection ascending by its lumen, or its lymphatics.

The male portion of the button is placed in the previously cleansed rectum, and held in place by means of a dressing forcep. After the abdomen has been opened and the mucosa prepared, the button is grasped by the thumb and the fore-finger, and the clamp in the rectum is released by the unsterile assistant. The sterile portion of the button, with a small catheter attached and sutures passed through the top of the button for anchorage of the ureter, is then pressed into position. One should attempt to allow just enough room for the mucosa to be pinched tightly, but not cut off at the time of anastomosis. The buttons are not entirely satisfactory in that respect: a screw button for that purpose should be constructed. About six inches of a No. 7 whistle tip catheter is used on the sterile portion of the button. After the button is pressed to-

gether, sterile saline should be injected into the catheter to make sure that a free communication to the outside exists. The short catheter is then threaded into the ureter, and the end of the ureter is fastened to the sterile portion of the button by the sutures previously put in place. The ends of the ureter projecting beyond the button are sutured to the mucosa of the bowel thereby insuring the presence of viable ureter beyond the small opening made when the button is removed. Immediately, and for a week after the operation, the animals were given 500 to 1000 cubic centimeters of saline intravenously to insure a continuous flow of urine.

By this technic the Author has obtained excellent results in dogs. The factors which contributed to the failures encountered could be readily controlled in the human, and even better results expected there.

A discussion of the methods previously used to accomplish uretero-intestinal anastomoses is given.

Twenty-one figures accompany the article.

*Action of Oil of Peppermint on the Secretion and Motility of the Stomach in Man.* Arc. Int. Med., Vol. 56, No. 1, p. 88, July, 1935.

Oil of peppermint, when given by itself or with a secretory stimulant, depresses the secretion of acid by the stomach. The mechanism of this action, the Authors state, is unexplainable.

In dogs the action seems to be local, on the mucosa.

In patients suffering from peptic ulcer, the secretion of acid of the stomach at rest is depressed or inhibited by Oil of peppermint. When this secretion was abundant, as after the administration of alcohol or histamine it was diminished or completely abolished by the Oil of peppermint.

The dose administered was from one to two c.c.

FITTS, JOHN B.

*Motor and Secretory Dysfunction of the Gastro-Intestinal Tract and the Vitamin B. Factor: A Clinical Study.* South. Med. Jour., 28:920-923, Oct., 1935.

The triad, "gas, belching, and fullness after meals," heard by the surgeon as well as the internist is ascribed, in the absence of an organic pyloric cause, to delayed emptying time resulting from atonic gastric musculature. Other symptoms accompanying these include constipation, nausea, regurgitation and headache. A physical sign of importance is a successive gastric splash with which there is frequently found a pal-

## NO NEED NOW FOR USING TOXIC ALKALI

**I**N the treatment of peptic ulcer and other conditions where the neutralization of gastric HCL is desirable the alkalies can be satisfactorily replaced.

**Y**OU can guard against the toxic effects of sodium bicarbonate, magnesium oxide, calcium carbonate and the like by depending upon TRI-CALSATE, the buffered neutral antacid.

**N**ON-TOXIC and non-irritating, TRI-CALSATE may be safely prescribed even in cases which are complicated with a bowel or kidney irritation.

**T**RY TRI-CALSATE. You will find that it gives you all of the advantages of the alkaline antacids without any of their disadvantages.

You can avoid the vicious circle of alkali neutralization when you prescribe

# For the Food Finicky Patient

THE sickly and undernourished are often finicky about their food, particularly children, during the winter "shut-in" period. They need something to tempt the appetite, something that will be easily digested and will be highly nutritious.

Ovaltine helps you to answer this problem very effectively. Children and adults delight in its enticing flavor, and Ovaltine actually adds important food elements to plain milk or, as a physician once aptly said, "It makes milk a square meal."

Ovaltine provides maximum nutritional value with minimum functional strain. It provides a good additional source of the essential mineral elements, notably calcium, iron and phosphorus, and of the Vitamins A, B, G and D, all of vital importance in the promotion and maintenance of robust health.

Ovaltine is invaluable for its building-up properties during convalescence, in wasting diseases, for the undernourished and therefore frequently nervous child, and wherever hyperalimentation is desired.

#### Fill in the Coupon for Professional Sample

Why not let us send you a trial supply of Ovaltine? If you are a physician, dentist, nurse or dietitian, you are entitled to a regular package. Send coupon together with your card, letterhead or other indication of your professional standing.

pable cecum and iliac colon. X-ray and laboratory examination reveal evidence of ptosis, hypo and achlorhydria, aplastic colon with stasis, subnutritional states and mild hypothyroidism. Chronicity and resistance to treatment is typical. Accompanying gall bladder disease is quite rare.

It is believed that these cases are the result of a deficiency of the B antineuritic factor of vitamin B. This deficiency is attributed to the downward trend in the use of meat and cereal with the corresponding increase in the use of sugar. Most cereals now used are de-

germinated and white bread is of questionable vitamin B content. A series of 75 cases constituted the clinical study of this report. In commenting on the fact that 50 per cent of the patients had had appendectomy performed, attention was directed to the effect of vitamin B deficiency on the integrity of lymphoid tissue.

Excellent results followed the administration of vitamin B. However, since sufficient bulky foods could not be consumed because of limited digestive capacity, it was necessary to administer vitamin B in a concentrated form of

wheat germ either the English product "bemax" or the American preparation "embo" being found satisfactory.

J. Duffy Hancock, Louisville.

STROMBERGER, L.

*La Colibacillose. Etude clinique et thérapeutique. Masson et Cie, Paris.*

This monograph of 248 pages presents a clinical and therapeutic study of the problem. It sets forth the pathologic manifestations of the common colon bacillus. The Author states that this organism produces three groups of symptoms (1) those concerning the urinary tract with definite pathology, (2) those concerning visceral localization, (3) and those in which other pathology exists, aggravated by the presence of the colon bacillus.

He discusses portal of entry and etiology from the standpoint of lesions of the upper and lower urinary tract and predisposing causes of the receptivity of the organism to this bacterium.

He deals with general, digestive, nervous, endocrine, blood, joint, and skin symptoms.

Colon bacilluria may result in septicemia, pulmonary lesions, hematuria, and other visceral manifestations.

The treatment has many ramifications. It concerns prophylactic measures. Diet is of great importance. Pyelitis and pyelonephritis must be considered. Intestinal manifestations are significant. Urinary antiseptics and mineral waters are used. Finally, vaccine and serum therapy may be indicated.

This treatise should be interesting and instructive reading for both the gastro-enterologist as well as the urologist.

J. Arnold Bargen, Rochester, Minn.

MACGUIRE, D. P.

*Carcinoma of the Colon. S. G. and O., Vol. LIX, No. 5, pp. 762-765, Nov., 1934.*

The Author presents a surgical procedure for carcinoma of the colon in which the growth is excised without cutting or clamping the bowel intraperitoneally. The patient is prepared by a preliminary cecostomy, blood transfusions and the administration of fluids. An indwelling catheter is put in place. A median or left rectus incision is made, and the mesentery is resected from a point above the growth down through the peritoneal reflection. The abdomen is temporarily closed, and the patient placed in the lithotomy position. The perineal incision is made with a cautery, and is continued until sufficient rectum extrudes so that a rubber glove can completely cover the lower bowel. Having dissected up to the peritoneal reflection the abdomen is re-entered, the peritoneal reflection dissected, and the entire segment of bowel

**JOHN WYETH & BROTHER, INCORPORATED**  
PHILADELPHIA, PA. • WALKERVILLE, ONT.

carried out of the abdomen through a left sided colostomy incision. The peritoneal reflection is closed, and the incision in the abdomen is also closed in the usual manner. The perineal wound is packed and sutured. The end of the bowel containing the tumor is cut between clamps. By these manipulations there is very little chance of infection and peritonitis.

In those cases of tumor of the left colon the Author prefers a modified Mikulicz and Paul operation after preliminary cecostomy. More colon may be

drawn out of the abdomen if the phrenico-colic ligament is cut fairly high up.

When dealing with malignant tumors in the right half of the colon the Author uses the Paul-Mikulicz type of operation, the terminal ileum being used as one barrel and the hepatic flexure of the colon as the other. In no case is the bowel sutured to the parietal peritoneum.

The Author believes that no operation in which the large bowel is clamped can properly be called aseptic since

many microbes are spilled into the peritoneal cavity every time clamps are applied across the lumen of the bowel.

Twelve figures accompany the article.

N. M. Percy, Chicago.

SANDERS, L. C.

*"The Colon—A Consideration of Its Important Diseases and Disordered Functions."* *South. Med. Jour.*, 28:848-851, Sept., 1935.

Differentiation of the disorders of the colon is simplified by considering them under the following classification: first, organic disease of the colon, including new growths, parasitic diseases, infections, and anomalies, and secondly, functional disorders of the colon including neurogenic, allergic, dietetic, and reflex factors. The large number of apparently border line conditions can usually be placed in one of these groups after sufficient study and observation. An excellent concise symptomatology is given for each group. The Author recognizes the difficulty involved in treating the functional disorders as calling upon the art as well as the science of medicine.

J. Duffy Hancock, Louisville.

BROWN, B. W.

*Results and Dangers in the Treatment of Amebiasis: A Summary of Fifteen Years' Clinical Experience at the Mayo Clinic.* *J. A. M. A.*, 105:1319, Oct. 26, 1935.

The Author reviews the treatment of amebiasis in 834 cases. In 523 of these cases information as to the results of treatment was secured later. Emetine hydrochloride seems to be a standby throughout the entire period. With the introduction of treparsol and acetarsone, the use of emetine hydrochloride decreased somewhat. At the clinic emetine hydrochloride has been administered subcutaneously. The distressing complications of emetine therapy are peripheral neuritis or palsy and cardiovascular disturbances. At the clinic emetine is used to control acute manifestations of the disease. Reactions are very few. If the use of the dose of ten grains of emetine hydrochloride subcutaneously in a month's time is not exceeded, the danger of reaction is less than one per cent. Of the organic arsenicals arsphenamine, acetarsone and treparsol have been used at the clinic. Acetarsone has been thoroughly tried and there have been no deaths in 232 cases. There were two cases of neuritis and thirteen cases of toxic erythema. Treparsol was given to 301 patients. There were eight cases of toxic erythema, and there were no cases of neuritis. One patient had nausea and vomiting after taking one gram.

Chiniofon, also known as yatren or anayodin, has been regarded favorably at the clinic. Increase in diarrhea is rather frequent with the usual dosage of three grams daily. The drug was

## TILDEN Has Kept Faith With Physicians

# FIROLYPTOL (TILDEN)

A FREQUENT prescription in *Strumous Diatheses* for many generations has been the Firolyptol made by The Tilden Company. The composition of the product has been imparted only to physicians and consists essentially of the Bromides, Phosphates, Iodides, Eucalyptol, Ol. Gossypii Sem. Purificat. combined in a manner exclusive with Tilden. The quantities are sufficient and have full therapeutic effect when taken in dosages and in a manner indicated in the condition. There is ready subsidence of the symptoms of Pain, Discomfort, Nervousness and Metabolic Disturbance often observed in this branch of treatment.

The continued use of Firolyptol (Tilden) for generations and its increasing value as an ethical prescription specialty have been appreciated by the medical profession as its increased use indicates.

The public sees no Tilden advertising since an appeal for consideration of these ethical products is made only direct to the medical profession and through no other source than the best medical journals. All Tilden products are labeled only with the name and composition as required by the federal law and do not bear any therapeutic claims except in the rare cases where these are necessary for the information of the physician and in this case they are written in language not intelligible to the laity.

The Tilden Company has always been honored to receive requests from physicians who are sincerely interested in making clinical trial of these medical specialties with the view to prescribing or dispensing them.

## RUBIPHEN

*Rubiphen is a childrens' prescription recommended by physicians in Common Colds as an effective sedative and expectorant. It contains Phenobarbital, Sodium Citrate, Ammonium Chloride, and Tincture of Ipecac essentially.*

## When Acidosis Complicates Disease

Supporting the alkali reserve has become a routine measure in diseases characterized by acidosis. For this purpose, Alka-Zane is extensively used because it supplies the four bases of which the reserve is essentially composed: sodium, potassium, calcium, magnesium. These are made available to the organism in the form of carbonates, citrates and phosphates. Alka-Zane contains no tartrates, lactates, or sulphates, and no sodium chloride. It is a convenient and efficient way to prescribe alkalizing medication that is palatable and easy to take.

*Alka-Zane is supplied in 1½, 4 and 8 ounce bottles. Trial supply sent on request.*

# ALKA-ZANE

---

WILLIAM R. WARNER & CO., 113 West 18th Street, New York City

---

only employed in thirty-seven cases. Conclusions cannot therefore be drawn.

Vioform has been tried in only eighteen cases. There were no difficulties with its use.

The result of the treatment with the drugs is as follows: Emetine failed as a curvatures agent in 45 per cent of the cases. Too few results are available in the use of the other drugs for any opinion.

The present method of handling amebiasis at the clinic is as follows:

The patient is given a grain of emetine hydrochloride subcutaneously twice daily for three days; after an interval of a week  $2/3$  grain of emetine is given twice daily for three more days. With the institution of the emetine, four grains of treparsol is administered orally with each meal for four days. If there is no intolerance to arsenic, two more such courses are prescribed with intervals of ten days between. The very ill patient is kept in bed for the first few days. The diet should be bland

and simple, but full and generous diet is begun very rapidly.

If stool tests are positive following this regime, chiniofon is prescribed. Three grams orally per day for a week, and repeated for two or more such courses with a week between courses. Failure after this is followed by one injection of arsphenamine weekly for six weeks and a dram of bismuth subnitrate from three to six times daily during the period.

Francis D. Murphy, Milwaukee.

BEER, EDWIN.

"*Diagnostic Study of Obscure Abdominal Complaints.*" S. G. and O., 61:549-550, Oct., 1935.

In a brief editorial, the Author reminds us of our obligation to give more study to obscure abdominal complaints in order that earlier diagnosis may be made instead of waiting for late obvious clinical signs or resorting to frequently useless exploratory operations. Especial emphasis is attached to the use of X-ray examinations. The three "tubular systems" within the abdomen are studied by a flat picture of the abdomen, an excretory urogram, a gall-bladder series, and a gastro-intestinal series including a barium enema. In those cases where the pathology is not located by these measures and there is an adequate suspicion that the abdominal pains may be referred a lipiodol subarachnoid injection is made for diagnosis and localization of possible spinal cord neoplasm.

J. Duffy Hancock, Louisville.

BLANCK, E. E.

*Peptic Ulcer. An Experimental Study.* S. G. and O., Vol. 61, No. 4, pp. 480-493, Oct., 1935.

The Author performed experiments designed to determine the importance of the presence of bile in inducing experimental peptic ulceration. The experiments were performed on healthy dogs. The first group, consisting of two normal dogs, was sacrificed to serve as control studies. The second group consisted of five dogs with complete external biliary fistulas. The bile as secreted by the liver was collected externally but not fed back to the animals. In the third group of three dogs the bile was fed back to the animals after being mixed with the laboratory stock diet. When the condition of any animal became poor it was sacrificed to insure fresh material for microscopic study.

From a careful study of those experiments, the Author concludes that the presence of bile in the diet of the animals prevents the development of gastritis, duodenitis, jejunitis and ulceration which developed in those dogs which received no bile.

Nine figures, a review of the literature and a large bibliography accompany the article.

Nelson M. Percy, Chicago.

# The Logical Treatment for Peptic Ulcer Creamalin

The Specially Prepared  
Colloidal Cream of  
Aluminum Hydroxide

## Because Creamalin

- Neutralizes larger volumes of hydrochloric acid
- Provides prompt relief of pain, nausea and pylorospasm (Usually within 24 to 36 hours)
- Produces no increase of hydrochloric acid secretion
- Avoids all danger of alkalosis
- Is an ideal demulcent and protective
- Is economical and simple to administer

CREAMALIN, therefore, constitutes logical therapy in gastric and duodenal ulcers, especially those that have been resistant to ordinary methods of treatment.

CREAMALIN represents the latest significant advance in the treatment of peptic ulcer and allied conditions. Its efficacy has been demonstrated by competent investigators in thousands of cases of peptic ulcer.

CREAMALIN is a pearly white, amphoteric, colloidal cream of aluminum hydroxide slightly astringent but not unpleasant to the taste. CREAMALIN combines with 14 times its own volume of hydrochloric acid in one hour. The colloid particles in CREAMALIN are dispersed by a special technique which accounts for its unique neutralizing properties.

The merits of CREAMALIN can best be evaluated by critical clinical study. We invite gastro-enterologists to test CREAMALIN in this way. Sufficient material for clinical trial will be sent upon application to

Cleveland Chemical Associates - - Cleveland, Ohio

Kindly send me a supply of Creamalin for clinical investigation.

# PROTECTING THE EXPECTANT MOTHER

**N**ORMAL PREGNANCY has its disturbances. During the first half of pregnancy the woman's metabolic rate is not changed. After the fourth month it gradually increases to 23% above her norm. Caloric increase in the diet is thus necessary after the fourth month.

But vomiting of pregnancy interferes! The condition is looked upon today as a disturbance in carbohydrate metabolism. Upon this assumption is based the present-day treatment by carbohydrate diet. The early introduction of small carbohydrate meals at 3 hour intervals helps prevent this disturbance. Karo added to foods and fluids prevents glycogen depletion and ketosis.

The enlarging of the uterus further produces reflex vomiting and unless carbohydrate is taken throughout the day to maintain the blood sugar at a high level, ketosis results. This aggravates the vomiting, frequently beyond control, because of the inability of the damaged liver in pregnancy to resist ketosis. Karo helps provide the expectant mother with readily assimilated sugars preventive of ketosis. Karo consists of dextrins, maltose and dextrose (with a small percentage of sucrose added for flavor), not readily fermentable, rapidly absorbed and effectively utilized.

Corn Products Consulting Service for Physicians is available for further clinical information regarding Karo. Please Address: Corn Products Sales Company, Dept. D-22, 17 Battery Place, New York City.

# A BRIEF REVIEW OF THE RESEARCH ON BRAN

THE Kellogg Company has aided, for some years, research in leading university laboratories. These studies indicate that bran is a wholesome food for normal people, and that the laxative effect of bran is not reduced by continued use. (1)

Laboratory measurements (2) have proved that bran is a good source of vitamin B, and (3) that it is rich in iron.

Independent research has proved that bran corrects constipation due to insufficient "bulk." (4) Further tests have shown that, with some individuals, the "bulk" in fruits and vegetables is largely broken down in the alimentary tract. So bran is often the more effective source of "bulk." (5)

Kellogg's ALL-BRAN is accepted by the American Medical Association Committee on Foods. It is usually more satisfactory for correcting atonic constipation than the continued use of medicines. A few individuals have diseased or highly sensitive intestines. In these cases, any form of "bulk" is inadvisable.

ALL-BRAN is sold by all grocers. Made by Kellogg in Battle Creek.

(1) *The Influence of Bran on the Alimentary Tract*, pages 133-156, *J. Am. Dietetic Assn.*, July, 1932.

## An Intestinal Antiseptic of Proved Performance

Whatever the causal agent of Ulcerative Colitis may be, we know that the intelligent use of Alpha

**ALPHA NAPHCO**  
in water or  
orange juice

Naphco has a remedial effect quite beyond expectations, except to those physicians who have given it an exhaustive trial.

### JELLY of ALPHA NAPHCO in Capsules

In Amoebic Dysentery and in Amoebiasis without frank diarrhea, the use of Alpha Naphco in liquid or

capsule form has a definite place in the armamentarium of the gastroenterologist,—it brings results as testified by a growing list of clinical investigators. These striking results may be due to the influence of the preparations upon the secondary invaders, whose importance is well recognized. In seasonal diarrheas, due to *B. dysenteriae*, or *B. welchii*, and in cases where the etiology cannot be readily discovered, Alpha Naphco therapy is winning a prominent place, both as an independent agent and as a most valuable adjunct to other forms of specific medication.

Exhaustive clinical and animal experiments have conclusively demonstrated the non-toxicity of the preparations... On receipt of your letter head or a page from your prescription book we shall be glad to send you supplies for clinical test and condensed reports.

**Carel Laboratories**  
Redondo Beach California

# HERE ARE THE 5 TYPES ★

THEY afford a range of laxative potency which will meet practically every requirement of successful bowel management. ● Petrolagar is a mechanical emulsion of pure liquid petrolatum (65% by volume) and agar-agar deliciously flavored and pleasant to take. ● It does not upset digestion, mixes easily with the intestinal content, acts as unabsorbable fluid and has less tendency to leakage.

# For bland diet therapy, especially ULCER cases—PABLUM

**F**AR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastro-intestinal disorders is a deficient diet. An analysis made by Troutt of ulcer diets used by 6 leading hospitals in different sections of the country showed them to be "well below the Sherman standard of 15 milligrams" in iron and low in the water-soluble vitamins.<sup>1</sup> "Vitamin B would appear to be represented at a maintenance level in most cases," writes Troutt, "but the possible relation of vitamin B to gastro-intestinal function and appetite should make one pause before accepting a low standard."

Although Pablum has a low fiber content it is 37 times richer than farina in iron and in calcium, 4 times richer in phosphorus, and  $4\frac{1}{2}$  times richer in copper.

## Low in Fiber—High in Iron

Pablum is the only food rich in a wide variety of the accessory food factors that can be fed over long periods of time without danger of gastro-intestinal irritation. Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than farina and is an excellent source (+ + +) of vitamins B and G, in which farina is deficient. Supplying  $8\frac{1}{2}$  mgms. iron per ounce, Pablum is 8 times richer than spinach in iron.

## Rich in Vitamin B

The high vitamin B content of Pablum assumes new importance in light of recent laboratory studies showing that avitaminosis B predisposes to certain gastro-intestinal disorders. Apropos of this, Cowgill says, "Gastric ulcer is another disorder which can conceivably be related to vitamin B deficiency. Insofar as the treatment of this condition usually involves a marked restriction of diet the occurrence of at least a moderate shortage of this vitamin is by no means unlikely."

Requiring no further cooking, Pablum is especially valuable during the healing stage of ulcer when the patient is back at work but still requires frequent meals. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Pablum has the added advantage that it can be prepared in many varied ways—in muffins, mush, puddings, junket, etc. Further, Pablum is so thoroughly cooked that its cereal-starch has been shown to be more quickly digested than that of farina, oatmeal, cornmeal, or whole wheat cooked four hours in a double boiler (studies *in vitro* by Ross and Burrill<sup>2</sup>). In addition to the above advantages, Pablum is the only base-form cereal (except Mead's Cereal which is the uncooked form of Pablum).

Pablum (Mead's Cereal thoroughly pre-cooked) consists of wheatmeal, oatmeal, cornmeal, wheat embryo, alfalfa, yeast, beef bone, iron salt and sodium chloride. <sup>1,2</sup> Bibliography on request.
